The analysis of the hydrologic budget includes an assessment of the influence of vegetation (through its control over the rate at which evapotranspiration occurs). Since actual measurements have not been made, results of pan evaporation studies and of calculations using a modified Blaney-Criddle formula (Soil Conservation Service, 1970) have been used as independent methods to calculate potential evaporation and evapotranspiration losses (see Technical Support Document, Section B.3).

This rate is normally expressed by the potential evapotranspiration, but with a plant cover, this value can be modified with a factor that varies with the type of plant, the stage of plant growth, the development of leaves, and the density of the plant cover. The factors were applied to the measured pan evaporation of 53 inches per year (Technical Support Document, Section B.3), suggesting that potential evapotranspiration from grassland in the Colstrip area is in the range of 36 to 45 inches per year (Dollhopf, 1980; Gray, 1970). Monthly values for these estimates are presented in Table II-8.

The results of the Blaney-Criddle analysis and the balance of monthly precipitation and evapotranspiration are presented in Table II-9. Both this method and the pan evaporation study illustrate that evapotranspiration is highly significant in the water balance of the area.

An additional, although less significant, role of vegetation is the interception of precipitation by vegetation and its subsequent loss by evaporation. No actual measurements of this mechanism exist; however, as part of the water budget analysis made by Western Energy in the Area C Permit Application (26.4.314), the interception of rainfall by grasses in the Colstrip area has been estimated using a relationship developed by Horton (1919). Unfortunately, this empirical relationship is appropriate only for individual storm events and is therefore difficult to apply on an average basis. Results of Western Energy's average monthly interception calculations are discussed in the Area C Permit Application (pages 349 through 351). The total yearly value for the interception of rainfall was estimated to be approximately 0.5 inch per year.

c. Evaporation from Surface Water Sources

Evaporation from surface water sources, such as ponds and reservoirs, can be estimated from Class A pan evaporation data. The results of various studies of pan evaporation data are discussed in the Technical Support Document, Section B.3. These studies indicate that surface water evaporation can range from 33 to 53 inches per year.

d. Infiltration

Infiltration rates for soils in Area C have been estimated from soil surveys conducted by Western Energy as part of the mine permit application (26.4.314, p. 356-358). Most soils in the proposed mining area have a fine loam texture. Infiltration rates for this group range from slow (0.06 inch per hour) to moderately rapid (6 inches per hour).

e. Soil Moisture Budget and Deep Percolation

A major consideration in the water budget of the Colstrip area is whether any of the surface moisture received from precipitation will reach the groundwater table.

An analysis of properties of the major soil groups in Area C indicates that little, if any, water is contributed to the groundwater from these soils (see Technical Document, Section B.3). The soils with the greatest potential for recharge under realistic field conditions appear to be the clinker residual soils (Technical Support Document, Section B.4). Also, in areas where water can accumulate (such as small depressions, ponds, and channel bottoms) sufficient moisture may be available to allow significant infiltration into the subsurface.

f. Groundwater Recharge

Water flow in ephemeral stream channels in the Colstrip area is characterized by the passage of well-defined peak flows, often of only a few hours duration in the summer season, separated by long periods without flow. As a consequence, groundwater recharge is relatively low, both in the channels and on the hillslopes. Infiltration (or transmission loss*) into the groundwater reservoir formed by the valley fill material is controlled by hydraulic gradient*, hydraulic conductivity of the aquifer, and hydraulic conductivity of the stream bed.

No direct observations of infiltration or transmission losses of streamflow are available in the Colstrip area. However, measurements in other semiarid areas indicate that the volumes lost to valley fill aquifers may be large. Keepel and Renard (1962), for example, observed that 50 percent of the maximum stream discharge was lost and total flow volume was reduced by 35 percent over a 10-mile stream reach. Turner et al. (1943) stated that infiltration losses of 75 percent in 15 to 25 miles were common. In perennial channels, a study of 57 flood events on 18 rivers in the Great Plains revealed an average loss of 40 percent on channel lengths of 50 miles, with as much as 75 percent of the flood volume being lost.

The relative importance of transmission losses is obviously related to the inflow volume, at least up to some level of discharge because of the characteristics of the channel cross section. Where the width/depth ratio of a channel is large (that is, where a small increase in flow depth will yield large increases in stream width), the consequent increase in surface area covered by water will also increase transmission loss. Many of the streams of the Colstrip area are similar to this, with an incised, active channel bordered by a shallow high-flow channel and floodplain. In these cases, there may be a sharp jump in the increased losses as flow spreads out onto the floodplain during high flows.

Ertec's estimate of recharge to the valley fill aquifer at a point approximately three miles north of Colstrip was made using a two-dimensional model of the system at steady state (Technical Support Document, Section B.1). Input considerations included rainfall, evapotranspiration, transmission losses, and tributary inflow. This analysis indicates that the amount of recharge to the valley fill aquifer is approximately 195 acre-feet per year.

g. Groundwater Discharge

Groundwater discharge to the East Fork Armells Creek drainage system (and specifically to its valley fill aquifer) takes the form of springs, seeps, and upward leakage from the Rosebud aquifer. A value was estimated by Ertec using a two-dimensional steady state computer model of the valley fill system (Technical Support Document, Section B.1). This model indicates that the total amount of groundwater discharge to the system is approximately 130 acre-feet per year.

h. Hydrologic Budget Analysis

The hydrologic budget of the water transmitted in the valley fill aquifer of East Fork Armells Creek is based on Ertec's two-dimensional steady state computer model (Technical Support Document, Section B.1). The inflow to the system consists of discharge from the Rosebud aquifer, seepage from the Montana Power Company's surge pond, recharge and tributary inflow. Outflow from the system includes downward leakage, evapotranspiration losses, and the amount of underflow through the valley fill material out of the system.

Considering these parameters, the hydrologic budget for a location on East Fork Armells Creek approximately three miles north of the Colstrip townsite is as follows:

Inflow	
Discharge from the Rosebud Aquifer:	130 acre-feet/year
Surge Pond Seepage:	175 acre-feet/year
Fly Ash Pond:	24 acre-feet/year
Recharge and Tributary Inflow:	195 acre-feet/year
	524 acre-feet/year

Outflow	
Downward Leakage and Evapotranspiration:	375 acre-feet/year
East Fork Armells Creek Underflow:	149 acre-feet/year
	524 acre-feet/year

Total inflow = Total outflow

No other data, whether measured or estimated as available for leakage (inflow) or outflow in the system (Hydrometrics, 1981). A similar water balance was conducted for Stocker Creek which indicated no impacts would occur (see Table III-3).

It is difficult to accurately quantify gains and losses from the Cow Creek Drainage. However on a sustained basis one can assume that most inflow occurs from groundwater discharge while most losses occur via evapotranspiration in those areas of Cow Creek alluvium which are assumed to be subirrigated.

The potential evapotranspration calculated for grassland in the study area was used to calculate the estimated losses in subirrigated areas. It is assumed that troughout the growing season a subirrigated area plant community has all of the available water it needs. That total loss (annually) would be 25.2 inches/year (see Table B3-27 TSD). The total present groundwater discharge to both North and South Fork Cow Creek is 15,681 cubic feet per day, or 5,723,565 cubic feet per year (131.4 acre-feet/yr). Potential losses due to subirrigation (all occurring along the North Fork of Cow Creek) total 319 acre-feet/year, or 13,895,640 cubic feet per year. Since this value obviously exceeds the amount of water contributed by groundwater discharge one or more of a number of factors are involved:

1. There are contributions such as infiltration from precipitation on alluvium which make a significant and unaccounted for contribution to alluvial groundwater.
2. The area identified as being subirrigated is, in fact, smaller than as mapped.
3. The actual uptake by plants is less than that calculated.

There is a constant difficulty with the use of synthetic water balances, particularly for the semi-arid west. Generally any water balance arrived at without direct meausrement is only a gross approximation of real conditions. In the semi-arid west a standard water balance usually results in zero net infiltration values. A water balance does not include the anomolous conditions which may allow for rapid infiltration, for example, without evapotranspiration losses.

HYDROLOGY GLOSSARY

Aggradation: The building up of the grade or slope of a stream by the deposition of sediment.

Alluvium (alluvial): A general term for clay, silt, sand, gravel or similar unconsolidated material deposited during comparatively recent geologic time by a stream or other body of running water.

Aquifer: Stratum or zone that contains sufficient saturated permeable material to produce water to a well or spring.

Base flow: The sustained runoff of a stream system, primarily composed of effluent groundwater; the natural flow of a stream unaffected by peaks due to storms, snowmelt, or the works of man.

Base Level: The lowest level to which erosion of the earth's surface constantly progresses; the level below which a stream cannot erode its bed; the level at which stream equilibrium exists.

Boundary: (As it refers to hydrology) Indicates or fixes a limit of lower permeability that affects the hydraulic characteristics of a system, i.e., faults, springs, creeks.

Clinker (Porcelanite) - Fused shales and clay that occur as a result of burned coal seams.

Colluvium (colluvial): A general term applied to loose and incoherent deposits, usually at the foot of a slope or cliff and moved chiefly by the force of gravity.

Confined: Refers to a groundwater aquifer under sufficient hydrostatic pressure to rise above the surface of the aquifer when penetrated by a well and bounded by an impervious stratum directly above or below the zone bearing water.

Crop out: To appear exposed and visible at the surface of the earth.

Dip: The angle that a bedding plane makes with the horizontal.

Discharge area: An area in which subsurface water, including both groundwater and vadose* water is discharged to the land surface, to bodies of surface water, or to the atmosphere.

Dissolved Solids: The quantity of dissolved material in a sample of water; the residue on evaporation or the sum of determined constituents; results are usually reported in milligrams per liter.

Electrical conductivity: A measure of the ability of a solution to conduct an electrical current, measured in millimhos. It is used on soil extracts as a measure of the soluble salts in soils.

Energy grade line: A line joining the elevations of the energy heads of a stream when referred to the stream bed.

Exhibit 3

Ephemeral stream: A stream or portion of a stream that flows only in response to precipitation. Its channel is at all times above the water table.

Erosion rates: The amount of soil loss per unit land area for a given time frame.

Evapotranspiration: Loss of water from a land area through the transpiration of plants and evaporation from the soil.

Flexure: A fold; a monocline formed by warping or other gentle deformation rather than by compression.

Gaining stream: A stream or reach of a stream that receives water from a zone of saturation and provides base flow; its channel lies below the water table.

Hardness of water: A physical-chemical characteristic that is commonly recognized by the increased quantity of soap required to produce a lather. It is mainly attributable to the presence of calcium and magnesium and is expressed as equivalent calcium carbonate ($CaCO_3$) in milligrams per liter.

Hummocky: Abounding in rounded or conical knolls, mounds, hillocks generally of equidimensional shape and not ridge-like.

Hydraulic conductivity: The rate of flow of water through a one square foot cross section under a unit hydraulic gradient, measured in feet per day (ft/day).

Hydraulic gradient: In a aquifer, the rate of change of pressure head per unit distance of flow; in a stream, the slope of the "energy grade line.*"

Hydrogen-ion concentration (pH): Indicates the degree of acidity or alkalinity of water and is expressed in terms of pH units. The pH value of a solution is the negative logarithm of the concentration of hydrogen ions, in moles per liter.

Interburden: At the Rosebud and Big Sky Mines, Montana, the consolidated material that separates the Rosebud and McKay coal beds.

Intermittent stream: A stream that does not flow continuously. Flow occurs in response to precipitation, snowmelt, and groundwater inflow.

Knickpoint: Points of abrupt change in the longitudinal profile* of stream valleys.

Longitudinal profile: The surface of a valley bottom or stream, drawn along its length from the source to the mouth of the stream.

Losing Stream: A stream or reach of a stream that contributes water to the zone of saturation; its channel lies above the water table.

Milligrams per liter (mg/l): A unit expressing the concentration of chemical constituents in solution. Milligrams per liter represents the weight of solute per unit volume of water.

Normal fault: A fault in which the hanging wall (or overlying side) appears to have moved downward relative to the footwall (or underlying side).

Outcrop: The exposure of bedrock or strata at the surface of the earth.

Overburden: Consolidated or unconsolidated material that overlies a coal bed.

Permeability: The capacity of porous rock, sediment, or soil for transmitting a fluid.

pH: See hydrogen-ion concentration.

Porosity: The percentage of bulk volume of rock or soil occupied by pores.

Potentiometric: Refers to an imaginary surface representing the static head of groundwater, defined by the level to which water will rise in a well.

Recharge area: An area in which water is absorbed that eventually reaches the zone of saturation in one or more aquifers.

Reverse fault: A fault in which the hanging wall (or overlying side) appears to have moved upward relative to the footwall (or underlying side).

Salinity: Qualitative term expressing the soluble salt content of a solution or material.

Salinity hazard: The impact of salt content in irrigation waters on crop growth. It depends on the dissolved solids in the irrigation water, soil condition, drainage, and management practice.

Sediment yield: The actual amount of eroded material delivered by a stream system to a given point in a drainage basin or subbasin.

Semi-confined: Refers to a regional groundwater aquifer that exhibits both confined and unconfined characteristics.

Sinuosity: ratio of the length of the channel to the down-valley air distance; streams with sinuosities of greater than 1.5 are called "meandering."

Specific conductance: A measure of the ability of water to conduct an electrical current, expressed in micromhos per centimeter at 25°C. Because the specific conductance is related to the number and type of ions in solution, it can be used for approximating the dissolved solids content in the water.

Spoils: At the Rosebud and Big Sky Mines, Montana, the reworked Rosebud coal overburden material, which has been replaced where the Rosebud coal has been mined out.

Storage coefficient: The volume of water an aquifer releases from or takes into storage, per unit surface area of the aquifer per unit change in head.

Subcrop: A buried outcrop.

Subirrigation: Supplying water to plants from underneath or from a semi-saturated or saturated zone where water is available for use by vegetation.

Terrace: Horizontal or gently inclined, relatively flat surfaces which are bounded by a steeper ascending slope on one side and by a steeper descending slope on the opposite side.

Transmission loss: The loss of stream flow to the alluvium (Syn: losing stream)

Transmissivity: Measure of the ability of an aquifer to transmit water through a unit width under a unit hydraulic gradient measured in gallons per day per foot (gpd/ft).

Unconfined: Refers to a groundwater aquifer that has a free water table, i.e., water not confined under pressure beneath relatively impermeable rocks.

Vadose water: Water in the zone of aeration.

Valley fill material: The unconsolidated colluvium and alluvium deposited by any agent so as to fill or partly fill a valley.

C. CLIMATE

Southeastern Montana, including the Colstrip area, has a continental climate. The majority of large-scale weather systems move from west to east, and being on the lee side of the Rocky Mountains, the Colstrip area is influenced by descending air masses characterized by the dissolution of clouds, and thus, clear-sky conditions and temperature extremes. In winter, inversions predominate; in summer radiation increases atmospheric turbulence (USGS, No date).

1. Temperature

Summers are characterized by warm days, but most nights, even during midsummer, cool down to 60 degrees F or less, so oppressive hot spells are not very common. Temperatures of 90 degrees F or more occur about 40 days each year and can occur in any month from May through October. The average temperature during the warmest month at Colstrip (July) is 71.5 degrees F. During July the average maximum temperature is 89.2 degrees F and the average minimum is 53.8 degrees F.

During winter, nights generally cool to less than 15 degrees F at night, but warm to 30 degrees F or better during the day. An occasional cold spell will generate sub-zero temperatures, but these spells seldom last more than two or three days. The average temperature during the coldest month (January) is 21.0 degrees F. During January the average maximum temperature is 34.4 degrees F and the average minimum is 7.7 degrees F.

The annual average temperature at Colstrip for the period 1941 to 1970 was 45.9 degrees F.

2. Humidity

The annual average relative humidity for the townsite of Colstrip was 55 percent in 1976 and 68 percent in 1977. The relative humidity has a wide diurnal variation related to similar variation in air temperature and a relatively constant amount of ambient moisture.

3. Precipitation

The annual average precipitation at the Colstrip National Weather Service station is 15.8 inches. Three-fourths falls during the April through September growing season. Winter precipitation is generally light with just over half an inch a month during the period November through February. Most of the precipitation during this time is in the form of snow. The average snowfall at Colstrip is 34.6 inches.

4. Severe Weather

Hailstorms are typically the most common and damaging form of severe weather in Montana and occur mainly in July and August. Floods may occur in spring and early summer as a result of the melting snowpack, but are more likely due to locally heavy thundershowers in late spring and summer.

5. Evaporation

The nearest National Weather Service station measuring evaporation rate is at Terry, Montana, about 90 miles northeast of Colstrip. Over a five- to ten-year period, the average total evaporation for May through September was 40 inches. Evaporation data are not obtainable from October through April because periods of below freezing weather frequently occur.

Evaporation rate is also measured at the Absaloka Mine by Westmoreland Resources, about 25 miles west of Colstrip. During 1979 (May 7 through September 17), total evaporation measured was 35.7 inches, or about 0.42 inches per day.

6. Dispersion Meteorology

Since the primary air pollutant emissions related to the proposed mining operations at Area C, Block I are particulates released from ground level or near-ground level sources, the meteorological parameters that affect air pollution potential the most are precipitation and/or soil moisture content, surface wind, and mixing height. Surface wind speed determines how fast the air pollutants are removed from the area, and in the case of fugitive emissions, the amount of air pollutants that are entrained into the atmosphere. The wind direction simply dictates where the air pollutants are transported. Therefore, atmospheric stability is important to the air pollution potential because if repeated or extended stable conditions occur, air pollutants will tend to accumulate in an area. Finally, mixing height is the height above the ground to which the air pollutants are carried or mixed. If mixing heights are low, air pollutants are contained in smaller volumes and concentrations are greater.

Surface wind speed and direction are monitored by Western Energy at the meteorological station located on a ten-meter tower inside the train loop in Area A (see Figure I-2). Figure II-17 summarizes the surface winds for 1980. Because of the predominance of southerly wind directions during several of the seasons, the annual windrose also shows a predominance of southerly winds. Strongest wind speeds were from the west-southwest, while slowest wind speeds were from the east. Calm conditions occurred 15 percent of the hours. Wind speeds in excess of 13 miles per hour occurred about ten percent of the hours, but wind speeds in excess of 25 miles per hour occurred less than one percent of the hours.

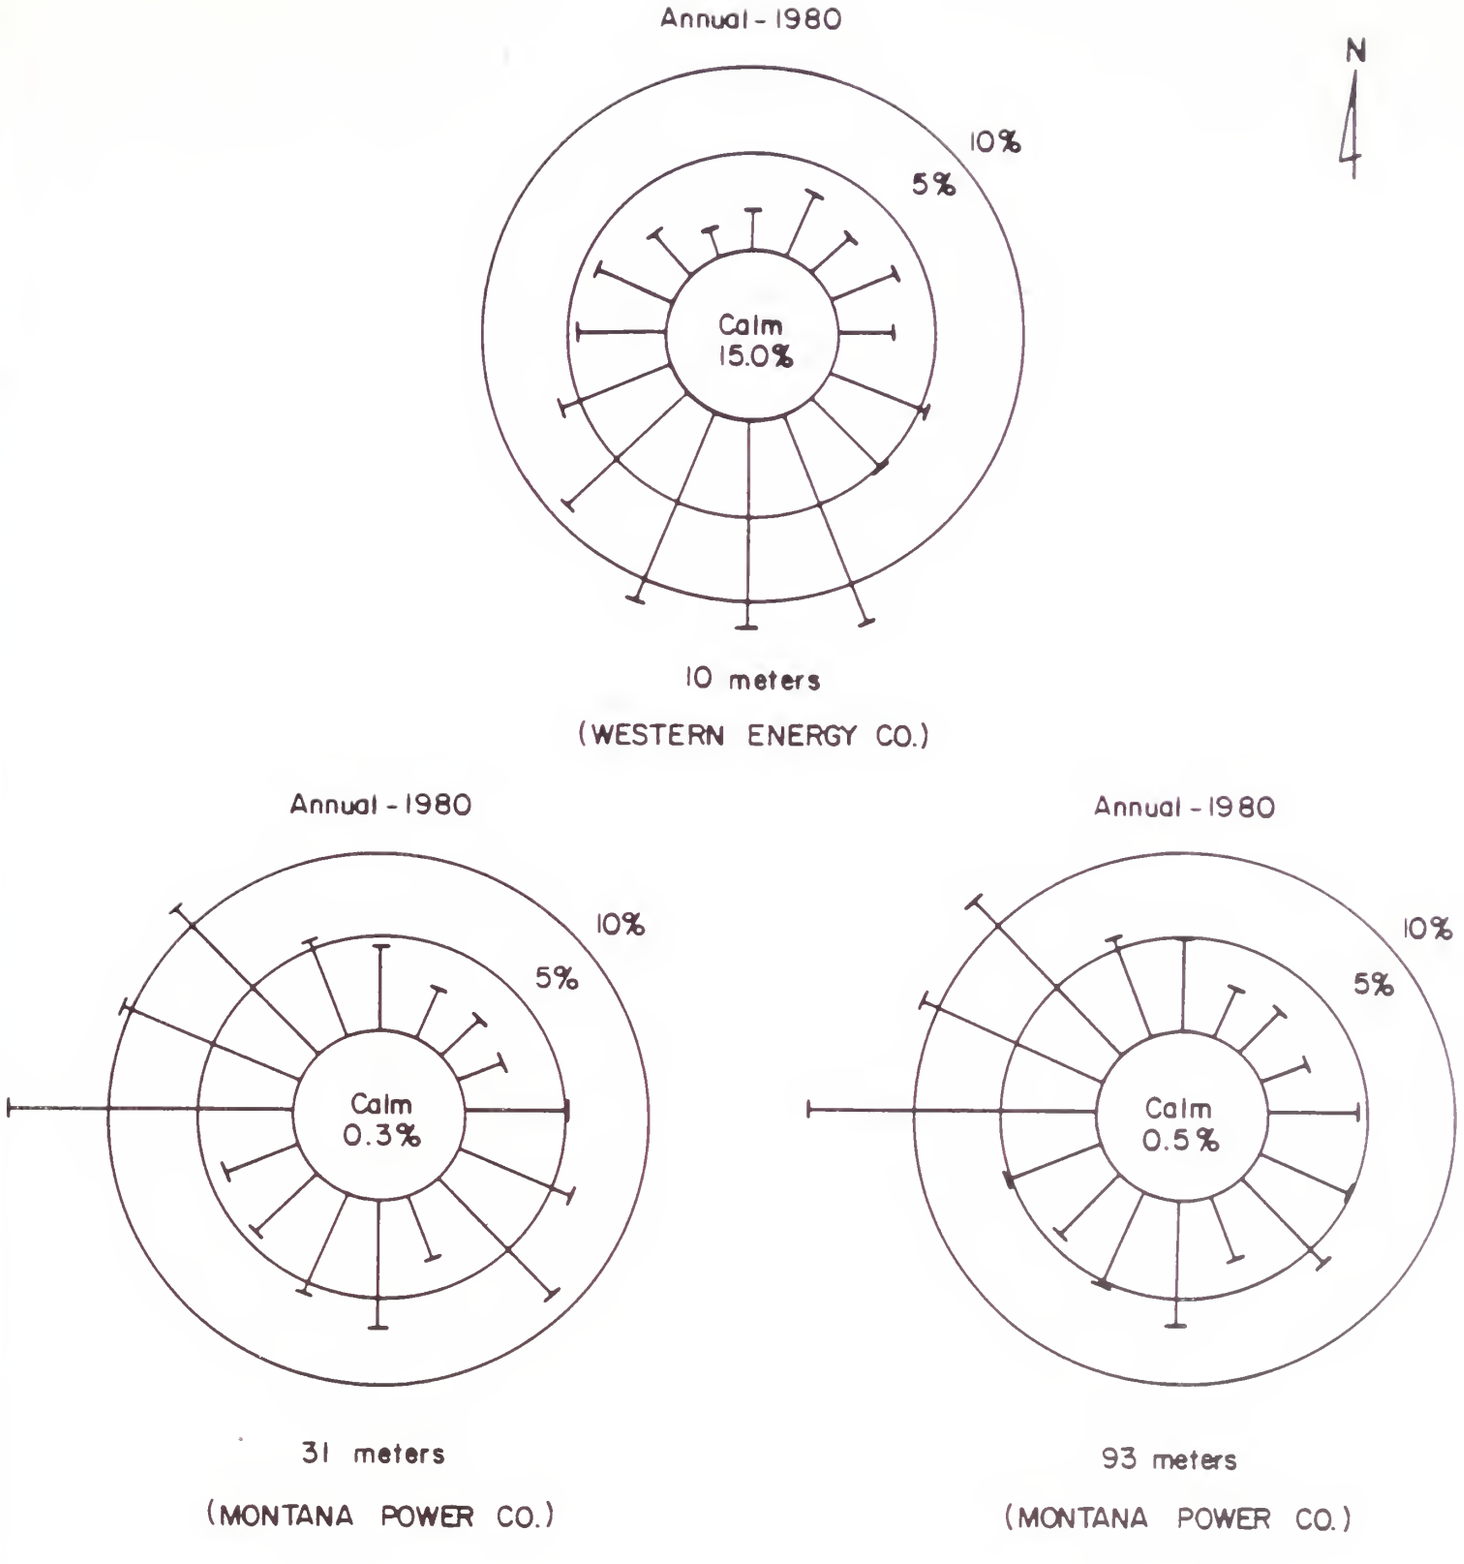

FIGURE II-17 COLSTRIP AREA ANNUAL WIND FREQUENCY DISTRIBUTIONS

Exhibit 3

Although a wind direction shift to a more westerly direction with increased elevation is predictable, the shift of some 90 degrees from the Western Energy ten-meter site to the MPC 31-meter level is more than expected. The MPC tower is located on top of a 30-meter hill, which can account for some difference. However, it appears likely that either local terrain influences or instrument problems account for the wind direction changes.

Mixing heights (or vertical temperature above 100 meters) have not been routinely measured in the Colstrip area. Montana State University (MSU) measured vertical temperature using aircraft in the Colstrip area during 1971-1972 (MSU, 1973). Results from the MSU measurements indicated Glasgow mixing heights were quite similar to Colstrip heights except during spring. Annually Colstrip and Glasgow mixing heights were very similar. Holzworth (1972) reported Glasgow mixing heights as shown below.

GLASGOW, MONTANA MIXING HEIGHTS*
(Values in meters)

Exhibit 3

D. AIR QUALITY

The following discussion is limited to particulate matter since the source of concern is a surface coal mine. Other, gaseous pollutants have been monitored in connection with MPC's generating Units 1 through 4, but the discussion only addresses those issues that are associated with the proposed mine operation.

1. Ambient Air Quality Standards

Air quality standards applicable to pollutant sources in the Colstrip area are those resulting from the Federal Clean Air Act and the Montana Clean Air Act. The Montana Ambient Air Quality Standards (MAAQS) and the National Ambient Air Quality Standards (NAAQS) are outlined in Table II-10. The NAAQS are expressed as both primary and secondary standards. Primary standards are those required, with an adequate margin of safety, to protect public health. Secondary standards are those necessary to protect the public welfare from any known or anticipated adverse effects associated with air pollutants.

Because of the high particulate matter levels, an area of 120 square miles centered on Colstrip has been designated as a non-attainment area for TSP. Part of the Area C, Block I mining operation is within this designation.

2. Total Suspended Particulates

Western Energy presently monitors TSP at ten sites around Colstrip; additionally, MPC monitors TSP at four locations. The location of these monitors is shown in Figure II-18.

Examination of the data from the existing Western Energy mining areas (Western Energy 3, 4, 6) reveals that current levels exceed both the NAAQS and the MAAQS. Short-term concentrations as high at 6,585 ug/m^3 have been recorded. The three samplers near or in Colstrip (Western Energy 1 just southwest of Colstrip, Western Energy 2 south of Colstrip; MPC 3 in the center of town) generally are near or exceed the 24-hour standards. The Montana annual arithmetic standard of 75 ug/m^3 has been exceeded at all three sites, although only MPC 3 exceeds the federal primary annual geometric standards of 75 ug/m^3. Western Energy has recently moved its monitoring station 2 to a new location where lower concentrations are being observed. According to a letter to the Montana Air Quality Bureau (MAQB) from Western Energy (August, 1980), Western Energy Company #2 was moved due to realignment of the county road. The sampler was moved to Area B (from Area A) in anticipation of monitoring emissions from Area B moving toward Colstrip. The relocation was approved by the MAQB.

The samplers located further from Colstrip and not in the mining areas generally reveal particulate concentrations below the NAAQS and MAAQS. Only the MPC samplers have measured short-term particulate concentrations near or above the standards. Annual particulate concentrations at these more distant sites are well below the ambient standards. It should be noted that NAAQS and MAAQS are considered to be violated if

TABLE II-10

Exhibit 3

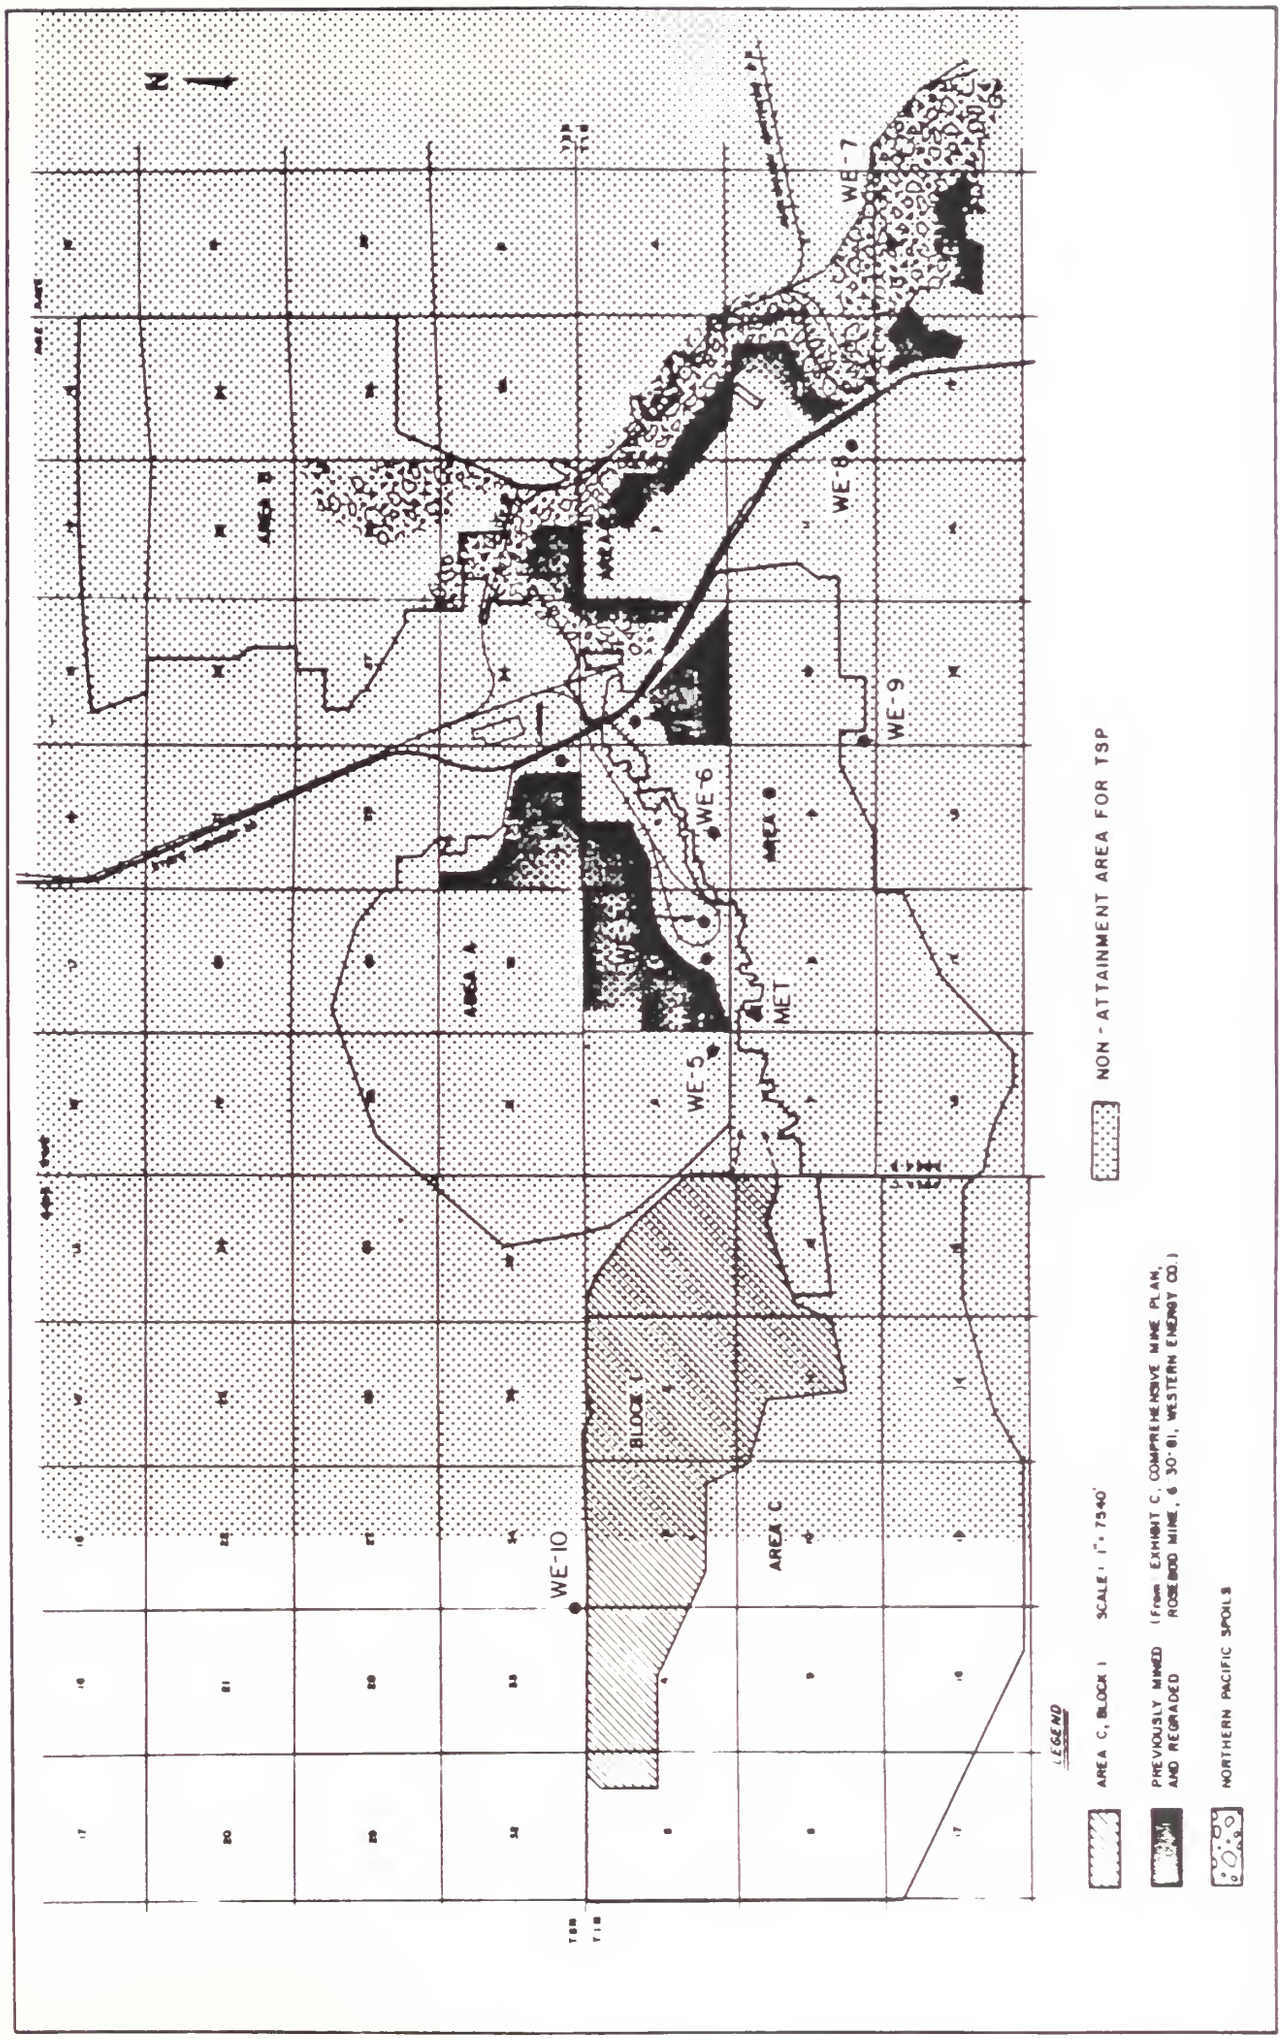

FIGURE II-18 HIGH VOL. & MET. STATIONS

Exhibit 3

values are obtained from samplers located in areas where the public would have access. Values greater than the standards at monitors located on company property are not considered violations of the standards.

Because of the high particulate matter levels, an area of 120 square miles centered on Colstrip has been designated as a non-attainment area for TSP. The U.S. Environmental Protection Agency (EPA) designated the attainment status of this area and various other areas in Montana on March 3, 1978 (43 FR 9009-9010). The state of Montana submitted a revision to the State Implementation Plan (SIP) on April 23, 1979 in which the state committed to bring the Colstrip area into compliance with both the annual and 24-hour NAAQS TSP standards by December 31, 1982. The Montana Department of Health and Environmental Sciences (MDHES) proposes to attain these standards through the enforcement of a revised airborne particulate rule by requiring existing mining operations to meet conditions of required operating permits. In the meantime, for any mine to expand in the non-attainment area, the mining company must demonstrate that it is decreasing nonfugitive particulate emissions in the area to a degree greater than will be generated by its proposed expansion. This is known as "offset" under the state and federal air regulations. The requirements hold true for any other major plant that might be sited in the non-attainment area.

The particulate situation in the Colstrip area is characteristic of fugitive dust impacts. Because the emission sources causing the problem (e.g., mining dust, construction dust, vehicular travel on paved and unpaved surfaces, and the coal handling around the power plant) produce particulates of a relatively large size (PEDCO, 1981; TRC, 1981), the dust settles out quickly and the impacts are very localized. Areas not close to any significant source generally experience low concentrations. Area C, Block I currently experiences very low particulate concentrations on the order of 25 ug/m^3 annual arithmetic mean based on Western Energy monitor numbers 10 and 11.

Fugitive dust problems of this type are relatively difficult to solve. Western Energy has in recent years undertaken a number of new dust control measures at their existing operations. A detailed discussion of these actions is provided in the EIS prepared for Area B (Montana DSL, 1980). The results have not significantly reduced TSP concentrations in Colstrip, partly because local sources in town, including construction sites, the coal handling facilities for Units 1 and 2, and unpaved roadways may be responsible for a sizable percentage of the impact, and because the amount of emissions reduction was small when compared to total emissions.

3. Settled Particulates

Settled particulate samplers or dustfall buckets are presently located at five of the Western Energy TSP sites. No federal ambient standard addresses dustfall. The Montana 30-day average standard of ten grams per square meter has been exceeded at Western Energy 3, 4, and 6, all in the train loop area. At Western Energy 7 (located in reclaimed portions of Area E) and 11 (located in Area C) dustfall amounts exceeded

the Montana standard during 1981. Dustfall levels exceeded the Montana standard in the past; however, sampling at Western Energy 5 (about one-quarter mile southwest of Area A) and 8 (two and one-half miles southeast of Colstrip) was discontinued in 1980. The settled particulate values follow the pattern of fugitive dust areas. The large-sized particles produced by fugitive dust sources settle readily and generally occur in large quantities.

4. Visibility

Ambient visibility has not been measured in the immediate Area C, Block 1 vicinity. However, an estimate of visual range (a measure of visibility) can be made using TSP measurements. In this way a value of 35 miles is derived for the existing visual range in the area. The Technical Support Document provides the details of this computation.

E. NOISE

Existing sound levels have not been measured in Area C, Block 1, but are believed to be very low. Summer sound levels are generally slightly higher than winter due to bird and insect noise. Noise related to man's activities is presently limited to occasional blasting from other nearby mining operations.

The 1979 Colstrip Project EIS (U.S.D.I, 1979) reported measurements taken some distance from the town. It was found that the tone radiating from the generating plant stack was distinctly audible, with a sound level of 37 dBA at a distance of 2.6 miles from the plant. At 3.8 miles from the plant, the tone was marginally audible at 32 dBA. It was assumed from these measurements that the background ambient sound level in the Colstrip area would be approximately 29 dBA if no noise source existed in the area. Thus the ambient sound levels in Area C, Block I are probably about 29 dBA.

Sound levels in the townsite of Colstrip have been documented more thoroughly. The 1979 Colstrip Project EIS discussed measurements at a variety of locations in and around the townsite. Due to the presence of generating Units 1 and 2, the sound levels observed (53 to 68 dBA) were more typical of an urban area than a small town. The measurements reported in the Colstrip EIS indicate that the L_{eq} (24) at two community locations was less than the 70 dBA level that might cause hearing loss, but greater than the 55 dBA that causes interference with outdoor speech and activities.

Neither Montana nor the townsite of Colstrip has specific ambient noise regulations. The Environmental Protection Agency, however, has published noise level guidelines in "Information on Levels of Environmental Noise Requisite to Protect Public Health and Welfare with an Adequate Margin of Safety" (EPA, 1974). Since the identified sound levels consider neither cost nor technical feasibility, EPA states that its guidelines are not to be interpreted as federal ambient noise standards, but rather as information for state and local government use in establishing their regulations. These levels are summarized in Table II-11.

TABLE II-11

SUMMARY OF NOISE LEVELS IDENTIFIED
AS REQUISITE TO PROTECT PUBLIC HEALTH
AND WELFARE WITH AN ADEQUATE MARGIN OF SAFETY

Effect	Level	Area
Hearing loss	$L_{eq} \leq 70$ dBA	All areas.
Outdoor activity	$L_{dn} \leq 55$ dBA	Outdoors in residential areas, farms, and other areas where people spend widely varying amounts of time and other places in which quiet is a basis for use.
	$L_{eq} \leq 55$ dBA	Outdoor areas where people spend limited amounts of time, such as school yards, playgrounds, etc.
Indoor activity intereference and annoyance	$L_{dn} \leq 45$ dBA	Indoor residential areas.
	$L_{eq} \leq 45$ dBA	Other indoor areas with human activities, such as schools, etc.

* In this table, L_{eq} refers to a 24-hour equivalent sound level; this is the constant sound level that has the same sound energy as a time-varying sound would over a 24-hour period. L_{dn} is a 24-hour equivalent sound level in which the nighttime (10:00 p.m. to 7:00 a.m.) sound levels are increased by 10 decibels to account for the added annoyance due to sleep interference.

Exhibit 3

F. SOILS

The soils of the Area C, Block I permit area are predominantly light-colored soils with weakly developed subsoils and thin, dark-colored surface layers (Aridisols). Other, less common soils in the area include poorly developed soils (Entisols) in which very little alteration from the underlying material has occurred (Soil Survey Staff, 1975).

Eighteen soil series have been recognized within the permit area in detailed mapping and sampling (Western Energy Permit Application, Area C, Block I). These can be grouped into four major soil types by similarities in parent material, texture, and landscape position. The four soil groups include:

- Sandy Residual Soils
- Alluvial Loamy and Clayey Soils
- Clinker Soils
- Unbaked Shale and Siltstone Soils

Each group represents several soil mapping units recognized in detailed soil mapping as occupying similar landscape positions and having similar physical characteristics. Table II-12 shows the characteristics of these groups, and detailed supporting summaries are included in Appendix F. Figure II-18 shows the general distribution of these soil types within Block I. Detailed large-scale maps of the Block I permit area and descriptions of each soil series and mapping unit can be found in the Area C, Block I permit application prepared by Western Energy.

The proposed disturbed area includes the crusher facility, the mine shops, the haul roads, clinker (locally known as scoria) pits, topsoil stockpile, and highwall reduction zones and boxcut spoil zones, in addition to the mine pit itself. These disturbances are anticipated to total 1,627 acres of the 2,693-acre permit area.

1. Sandy Residual Soils

These soils are formed in material weathered from sandstones of the Tongue River member of the Fort Union Formation, which are weakly consolidated calcareous sandstones capping many of the many rolling hills in the Colstrip area. This group represents 44 percent of the 1,627-acre disturbed area. The Busby, Reidel, Yetull, and some areas of the Cooers soil series are included in this group (refer to Table 1, Appendix F).

Two landforms and vegetation types can be recognized within this group. Hilltops and ridges containing small knobs and weathering outcrops of sandstone commonly have sandstone within 40 inches of the surface. Scattered ponderosa pine (*Pinus ponderosa*) and skunkbush sumac (*Rhus trilobata*) occur in these areas, with an understory of tall and midgrasses.

In the gently rolling portions of this unit, sandy material commonly extends to a depth of more than 40 inches before sandstone is encountered.

TABLE II-12

CHARACTERISTICS OF GENERAL SOIL GROUPS
AREA C, BLOCK I

Soil Group	Acreage	Percent of Disturbed Area	Limitations	Proposed Salvage Depth (feet) Topsoil	Subsoil	Approximate Reclaimed Area Reclaimed Acreage*	Percent
Alluvial Loamy and Clayey Soils	710	44%	High salts in subsoil, occasional high clay	1.0	0.5-3.5	947	58%
Sandy Residual Soils	710	44%	Excess sand, depth to rock	0.5	1.0-2.5	580	36%
Clinker Soils	138	8%	Depth to fractured rock, slope	0.5	1.0-1.5	80	5%
Unbaked Shale and Siltstone Soils	69	4%	High salts, depth to rock, high clay	0.5	0-2.5	20	1%

* Assumes an average replaced topsoil thickness of 8" and replaced subsoil thicknesses ranging from 26-28".

Exhibit 3

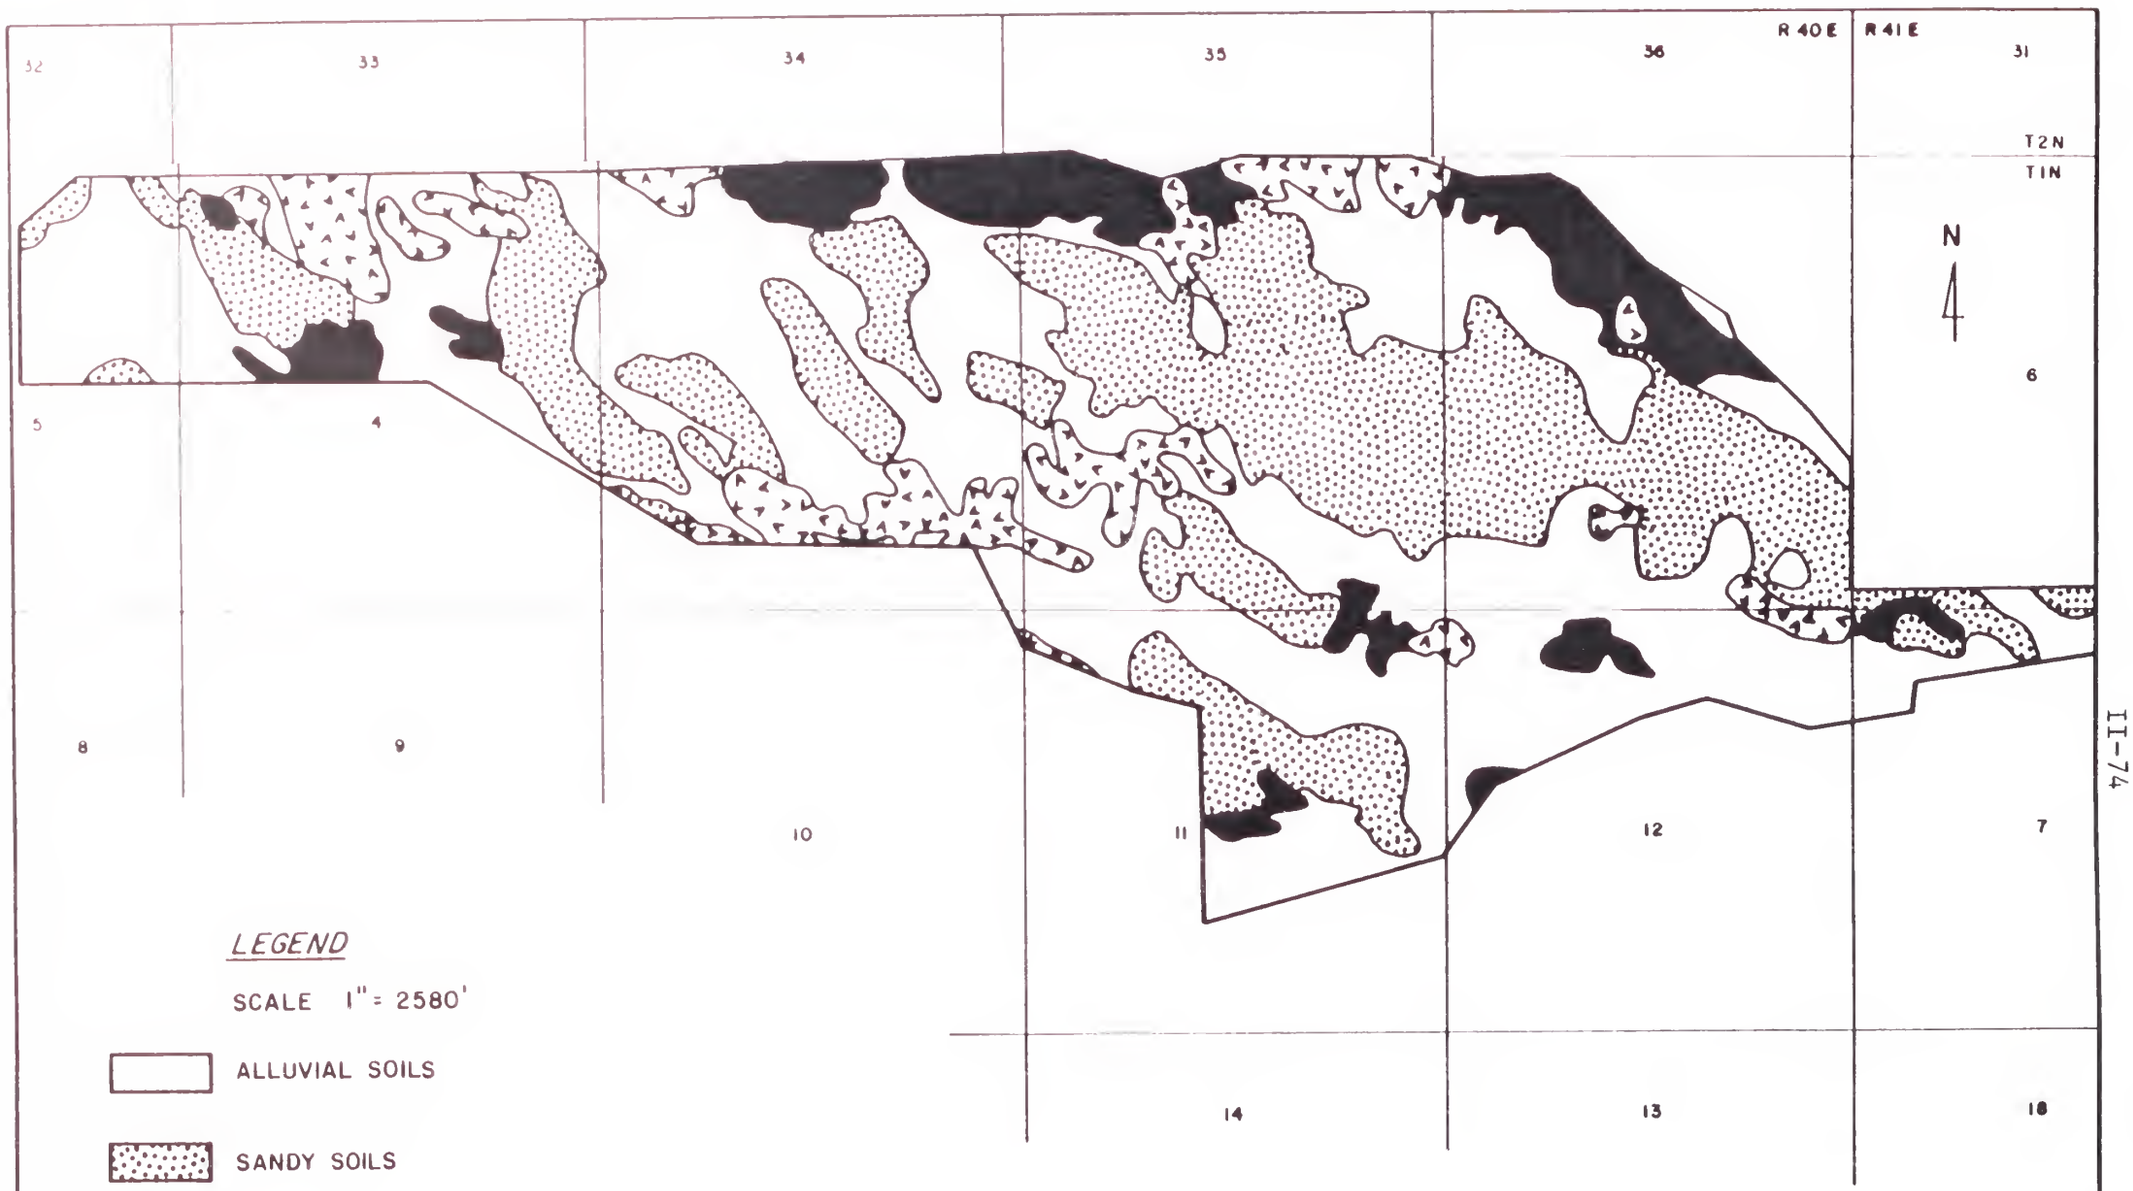

FIGURE II-19 GENERAL SOIL GROUPS, AREA C, BLOCK I

Exhibit 3

Ponderosa pine and skunkbush sumac stands are rare in these rolling areas; instead, cool-season grasses dominate the vegetation. The adapted climax community for this soil type includes a large component of productive deep rooted warm-season grasses (USDA-SCS, 1981).

Sandy residual soils are best suited to grazing use. Crop production is limited by low available water in the surface soil layers where most annual crops have their roots. This results in low crop yields and increased wind and water erosion, especially during drought years. Of the few areas where cropping has been attempted in Area C, Block I, most have been replanted to grass for grazing.

The soils of this group are limited for topsoil use by excess sand content. DSL guidelines suggest that soils containing an excess of 70 percent sand are a poor source of topsoil or subsoil. All of the soils in this group occasionally exceed the recommended limits of sand (see Technical Support Document).

2. Alluvial Loamy and Clayey Soils

Deposition of mixed loamy and clayey material has occurred at the bases of hills and on benches and terraces along the drainages of Area C, Block I. The soils occurring at these locations represent 44 percent of the soils to be disturbed in Block I, and include the Yamac, Kremlin, Lonna, Vanstel, Kobar, and Havre soil series and the undifferentiated unit referred to as Ustic Torriorthents. The major limitations for salvaging these soils include moderate to high electrical conductivities in some of the subsoil layers and occasionally excess clay.

The soils in this group commonly extend to 60 inches or more before bedrock is encountered, and have moderate water availability in the surface soil layers, which is critical to the successful establishment of crops. A majority of the land presently under cultivation in Block I occurs in the gently sloping portions of this soil group. This indicates that the soils of this group are well-suited to small grain production, limited only by regional characteristics of low rainfall and the short growing season. In soil areas containing natural vegetation, shallow-rooted cool-season midgrasses dominate the existing plant communities in association with big sagebrush (Artemisia tridentata) and silver sagebrush (Artemisia cana). The adapted climax plant community for this site is also made up of shallow-rooted, cool-season midgrasses, in association with a smaller component of shrubs.

Excess clay content may be encountered in the Kobar and Vanstel soils, and all of the soils of this group may contain layers with high salts (Technical Support Document). Generally, these soils are good sources of topsoil and subsoil.

3. Clinker Soils

On scattered hilltops within the Block I area, reddish- or purplish-colored baked sandstones and shales occur, known as clinker or locally

as scoria. This material commonly occurs along ridge tops and on the crests of hills. Much of the clinker that occurs within the Area C, Block I permit area will be mined as a source of road base construction material, or disturbed by placement of the boxcut spoils. This soil group represents eight percent of the total 1,627 acres to be disturbed. It includes shallow rocky soils formed directly in the clinker (Birney and Kirby series), and soils formed in close association with the clinker hills, including portions of the Cabbart and Cooers series.

Clinker soils consistently support stands of ponderosa pine and Rocky Mountain juniper (Juniperus scopulorum), and of all the soils found in the vicinity of the Rosebud Mine, clinker soils support the most vigorous stands of these vegetation types (Richardson, 1981). This is apparently due to the competitive advantage to trees due to the apparent availability of free water at depth where bedrock is encountered (McQueen, 1982; Stark, 1980). Grass and shrub understories are also well established on these soils, although they are less dense than in other communities because of shading by trees and the mulching effect of the surficial rock fragments (Richardson, 1981).

4. Unbaked Shale and Siltstone Soils

This soil group includes residual soils forming in material weathered from shales and siltstones. They are often found in association with the clinker soils, except that the bedrock has not been baked by burning coal. The soils are widely variant, and occur in complex terrain (i.e., with steeply rolling hills and ridges and limited small swales or valleys between the hills).

This group includes the Cabbart, Delpoint, Yawdim, and Rentsac soils and occupies four percent of the proposed disturbance area. A majority of these soils are Entisols, weakly developed soils that vary only slightly from the bedrock from which they were derived. Most of the soils have bedrock at depths between 15 and 30 inches and scattered rock fragments on the surface. The primary limiting factors of the soils in this group are depth to rock, high clay content, and high salt content. These soils support a sparse cover of shrubs and scattered junipers.

5. Soil/Plant Relationships

From the above descriptions, it is apparent that a wide range of vegetative types occur in Area C. For some, especially the warm-season grasses characteristic of the tall grass prairie and ponderosa pine, the Colstrip area is near the edge of their extent (Howard, 1982). Compared to other plant communities in the area, the ponderosa pines and skunkbush sumac probably occur in microsites with lower moisture stress conditions (F.A. Branson, unpublished data, see Technical Support Document), indicating that one of the major reasons for their presence in portions of the Colstrip area may be the availability of additional soil moisture.

Work by the Water Resources Division of the U.S. Geological Survey in the Hanging Woman Creek area not far from Colstrip (USGS, 1981) has shown that a wide variability of soil moisture availability and plant stress can occur in a small area, due primarily to the physical characteristics of the soil.

In general, crops and shallow-rooted, cool-season grasses such as the wheat grasses are most competitive in soils such as the alluvial soils in Area C in which infiltration is relatively moderate or slow, allowing the near-surface root system to use much of the precipitation received in these areas. Where infiltration is relatively rapid and precipitation results in deeper soil wetting, such as in the deep sandy residual soils, deep-rooted grasses and shrubs have the competitive edge. If, in addition, a bedrock layer allows water accumulation at deeper layers, trees can take advantage of this more readily available water. Trees and shrubs are also found where readily available deep soil water occurs along drainages.

In steep areas, rapid infiltration rates (such as in the clinker soils) will prevent excess runoff, whereas moderate or slow infiltration rates will result in increased runoff such as on the unburned shale and siltstone soils. Increased runoff effectively reduces the amount of moisture available to plants. The "gumbo knob" vegetation type (Appendix G) occurs on the unbaked shale and siltstone soils, and reflects the low productivity and dominance of drought-resistant shrubs and grasses common to such a situation. Table II-13 illustrates the general characteristics of moisture availability to which the present or potential vegetative communities would be responding.

There are many other variables that complicate the simplification presented in Table II-13, including seasonal fluctuations, annual variability resulting from low or high precipitation periods, the introduction of other stresses on vegetation such as insect infestations, grazing, or rodent activity.

TABLE II-13

GENERALIZED SOIL/PLANT WATER RELATIONS

Soil Group	Runoff	Infiltration	Generalized Water Availability* Near Surface	At Depth	Adapted Vegetation*
Alluvial Soils					
Uplands	moderate	moderate/slow	moderate	moderate	Shallow-rooted grasses, big sagebrush
Drainage ways	low	moderate	moderate	high	Silver sagebrush, chokecherries
Sandy Residual Soils					
Deep sands (rolling uplands)	low	rapid	low	moderate	Deep-rooted grasses
Sands over bedrock (hills and ridges)	low	rapid	low	high	Ponderosa pines, skunkbush
Clinker Soils	low	rapid	low	high	Ponderosa pines, skunkbush sumac
Unburned Shale and Siltstone	high	slow/moderate	low	moderate	Rabbitbrush sumac

* Highly competitive increaser species such as needle-and-thread grass and prairie junegrass are found in a majority of the area.

Exhibit 3

G. VEGETATION

The vegetation of the proposed permit area consists of a variety of grasses, forbs, shrubs, and trees. Cool-season perennial grasses are the dominant plants in terms of canopy cover and vegetative production. Several different native plant communities occupy various sites within the area. Ponderosa pine (Pinus ponderosa) is a highly visible species found growing in colonies on ridges and adjacent upper slopes. The native vegetation sites are used primarily for livestock grazing under present management systems. Existing vegetation also supplies important wildlife habitat and watershed protection.

Several sites within the permit area support introduced forage plants that are used for hay or pasture. A considerable acreage is presently cultivated for production of small grains, primarily winter wheat. Roads, ranch facilities, and localized mining of clinker (locally known as scoria) has resulted in the removal of vegetation from a small portion of the area. For the small areas involved, clinker mining has had only a minor impact or vegetation, the most obvious being the removal of ponderosa pine and the creation of small depressions in these areas. Coal mining on adjacent areas at the Rosebud Mine has not had a noticeable effect on the vegetation in Area C.

Of the total 2,693 acres within Area C, Block I, 71 percent (1,904 acres) is rangeland and ponderosa pine stands; 13 percent (334 acres) is hayland and pasture; 16 percent (436 acres) is cultivated for wheat; and one percent (19 acres) is disturbed land generally devoid of vegetation. No rare or endangered plant species have been identified in the area. The vegetative cover on the soils in these land use categories is further described in the following paragraphs.

1. Rangeland Vegetation

Western Energy has identified six rangeland plant communities in the proposed permit area. They have been identified and named according to the two or three plant species dominating the different sites at the time of examination. This approach identifies only the vegetation dominant when examined, a highly variable characteristic evidenced by the fact that the dominant and co-dominant plant species have changed for some communities even since measurements were begun in 1978. Therefore, in order to provide more basic ecological data for reclamation and management, the existing plant communities are compared with the potential communities of equivalent range sites, as described by the Soil Conservation Service in the Montana Technical Guide, Section II-8 (USDA-SCS, 1981). The key element of a range site is its ability to produce a characteristic plant community (USDA-SCS, 1976). A map designating range sites in Area C, Block I is provided in the Technical Support Document. This map correlates closely with Figure II-19.

Three basic vegetative types can be delineated from the six rangeland plant communities identified for detailed investigation. These are differentiated by major growth form and landscape position, and include: grassland, shrub-grassland, and conifer-shrubland as shown in Figure II-20.

Exhibit 3

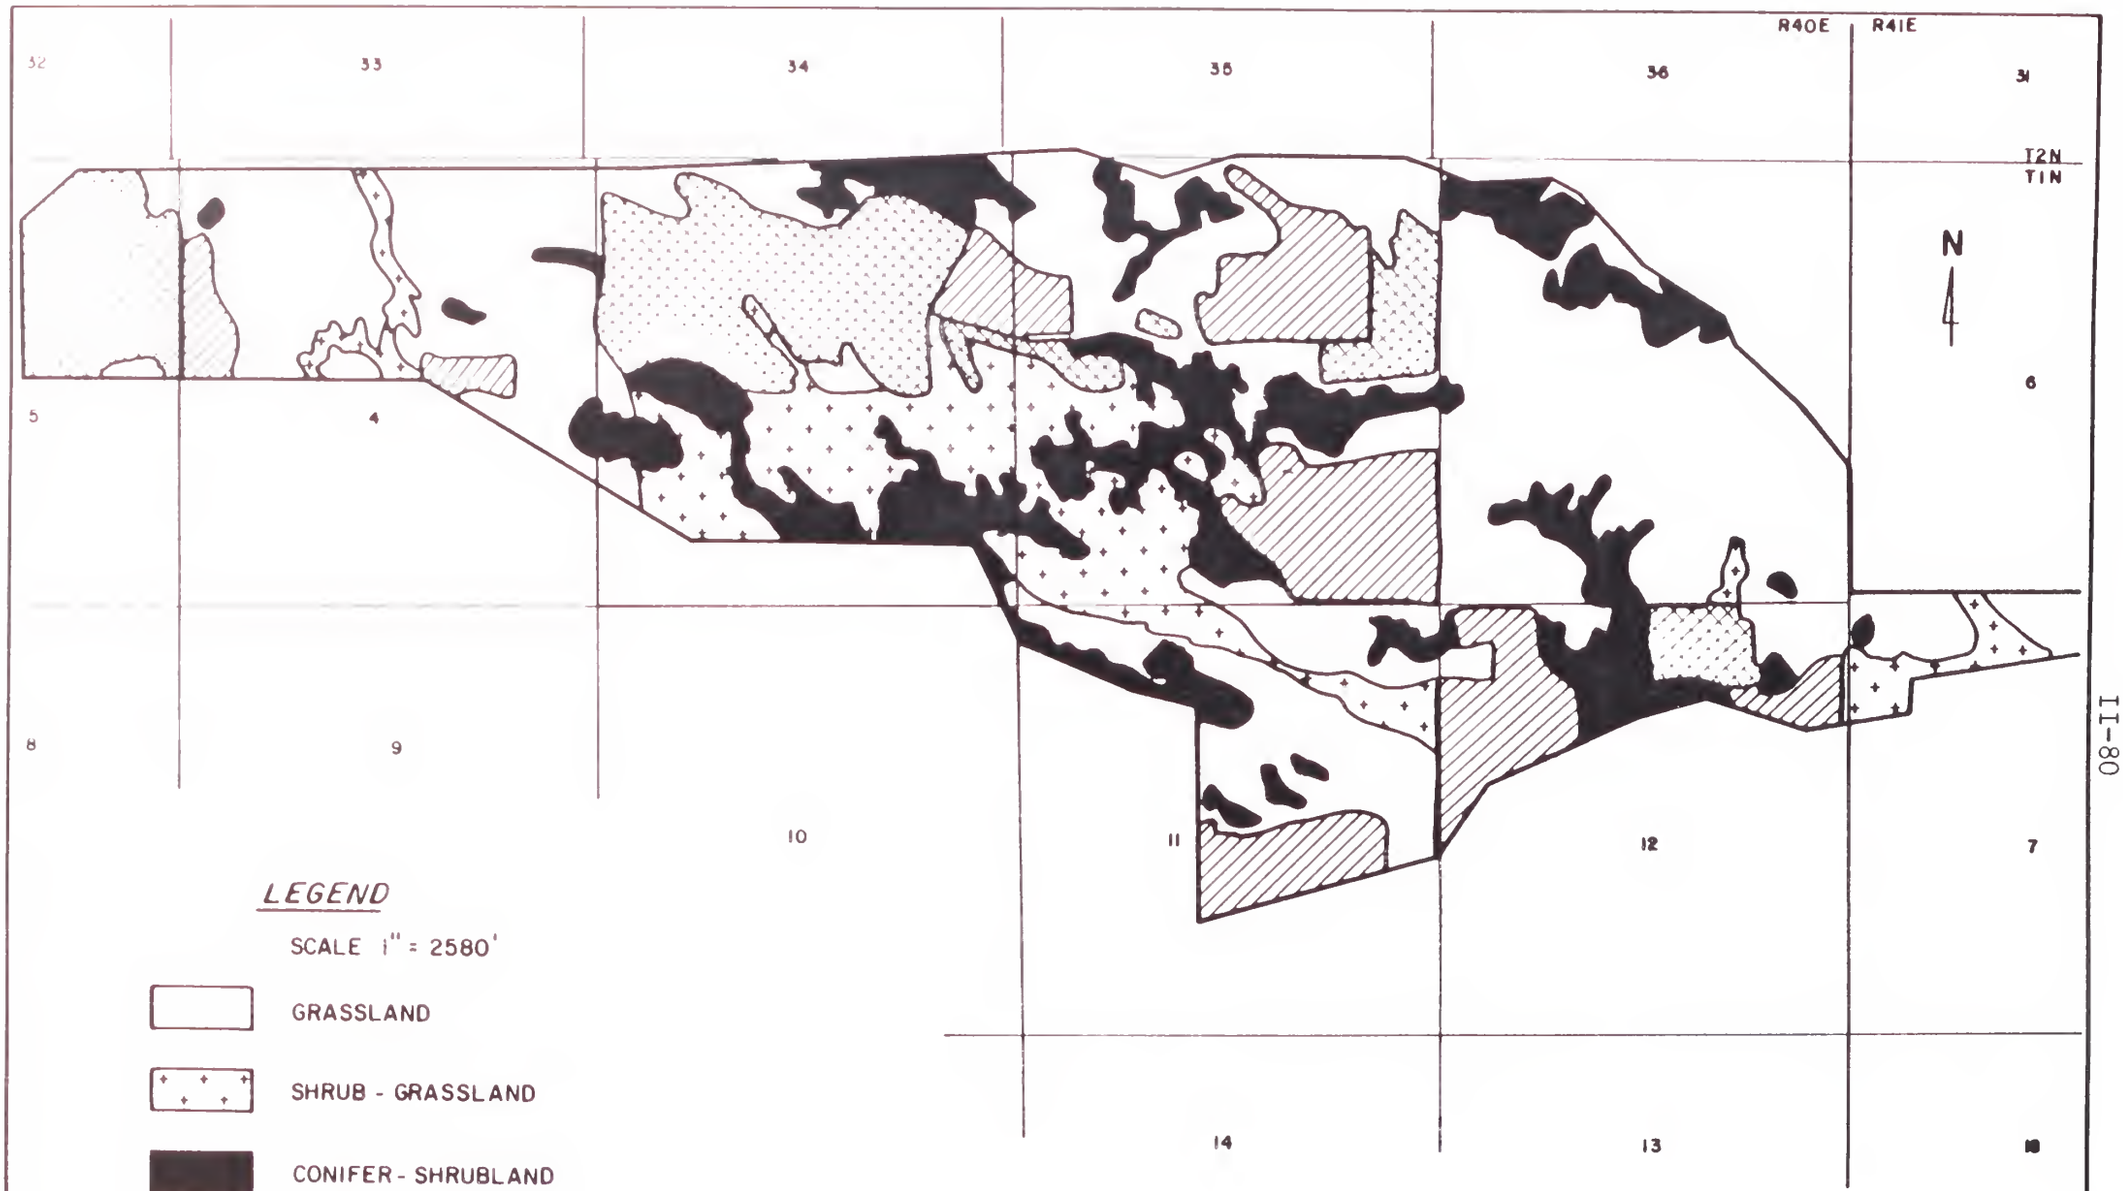

FIGURE II-20 GENERAL VEGETATION TYPES, AREA C, BLOCK 1

Exhibit 3

- Grassland. This is the largest plant community in Area C, Block I. It comprises 60 percent (1,147 acres) of the rangeland in the proposed permit area. At present, needle-and-thread (Stipa comata), western wheatgrass (Agropyron smithii), and prairie junegrass (Koeleria cristata) dominate the community. The grassland community occupies two range sites, silty and sandy, as described by SCS. The climax dominants on the silty site are western and thickspike wheat grasses (Agropyron smithii and A. dasystachyum), bluebunch wheatgrass (Agropyron spicatum), and needle-and-thread, all cool-season grasses. The climax dominants on the sandy site are prairie sandreed (Calamovilfa rongifolia) and little bluestem (Schizachyrium scoparium), two warm-season grasses. Needle-and-thread, thickspike wheatgrass, and big bluestem (Andropogon gerardii) are of secondary importance on the sandy site. Apparently past grazing patterns have favored the cool-season grasses at the expense of the warm-season grasses.

  Forbs and shrubs are relatively minor components of both the existing and potential vegetative communities.

- Shrub-Grassland. This vegetative type occurs primarily on deep loamy to silty soils. It includes three communities dominated by three different shrubs: big sagebrush (Artemisia tridentata), silver sagebrush (Artemisia cana), and rubber rabbitbrush (Chrysothamnus nauseosus). The shrub-grassland vegetative type occupies about 23 percent (435 acres) of the rangeland in the proposed permit area. Big sagebrush (Artemisia tridentata) is the dominant species in upland positions. Bluebunch wheatgrass (Agropyron spicatum), green needlegrass, and other native cool-season grasses occur in association with the big sagebrush and make up nearly 30 percent of the vegetative production. Forb coverage is high.

  In swale and bench positions, silver sagebrush (Artemisia cana) is the dominant shrub, with skunkbush sumac (Rhus trilobata), western snowberry (Symphoricarpos occidentalis), and big sagebrush also occurring in association with the silver sage. Numerous forb species are present. Western wheatgrass (Agropyron smithii) and Kentucky bluegrass (Poa pratensis) are abundant. Cool season grasses account for nearly two-thirds of the vegetative canopy. Minor areas dominated by rubber rabbitbrush (Chrysothamnus nauseosus) occupy steeper portions of this general vegetation type.

  The two sagebrush communities correlate with the silty range site. The principal difference between the present and climax plant communities is the dominance of shrubs in the existing communities. In the climax community shrubs account for less than ten percent of the annual vegetative production.

  The rubber rabbitbrush community occupies a shallow clay range site. The existing community is similar in species composition to the climax.

- Conifer-Shrubland. Ponderosa pine in scattered to moderately dense stands with adjacent areas of skunkbush sumac are characteristic of this site. Stand density ranges from 32 to 360 trees per acre (Western Energy Company, 1980). Rocky Mountain juniper (Juniperus scopulorum) is a minor component of the community. This community occupies 17 percent (330 acres) of the rangeland in Area C, Block I.

  The stands of pine have an average age of 50 years and an average height of 28 feet. The predicted height at 100 years of age is 48.7 feet. This community is generally found on the rocky, shallow, and moderately deep soils often associated with weakly consolidated sandstone or clinker outcrops. The presence of pine appears to be favored by soils having rapid infiltration and percolation rates, which cause precipitation to become readily available to tree roots. At the same time, a less favorable moisture regime is created for competing herbaceous plants, primarily grasses.

  Canopy cover of the understory and open areas consists of grasses, forbs, and shrubs, including silver sagebrush, prairie rose (Rosa arkansana), yucca (Yucca glauca), and shrubby evening primrose (Oenothera serrulata). Dominant grasses and grasslike plants include needle-and-thread, threadleaf sedge (Carex filifolia), and prairie sandreed.

  Because of the slow growth rate of ponderosa pine in the area, the stands have low potential for timber production. The site is considered to be rangeland rather than woodland. Its present value and function are primarily for wildlife habitat, aesthetics, grazing, and watershed protection. Range sites are usually thin sandy where this community occurs.

2. Range Condition and Production

Range condition is the present state of vegetation of a range site in relation to the climax (natural potential) for that site, and may be expressed as excellent, good, fair, or poor depending upon the degree that the present plant community reflects that of the climax. Forage production is usually related directly to range condition. Rangeland in fair condition can be expected to produce less than 50 percent of the site potential, while rangeland in good condition should produce 50 to 75 percent of the site potential. It should be noted that sites in lower range condition classes may produce greater total biomass than the preceding statement would indicate. This could occur when invader or secondary climax species dominate a site and growing conditions are favorable for their vegetative expression.

Overall range condition in Area C, Block I is fair. The suggested initial stocking rate is about five acres per animal unit month. At this stocking rate, the 1,904 acres of range will carry 63 cow-calf units for a six-month grazing period. Information on range condition and

production of the vegetative communities in Area C, Block I is summarized in Table 1 in Appendix G.

3. Cropland

The 436 acres of cropland in Area C, Block I are used primarily for production of winter wheat in a wheat-fallow cropping system. Average yields are reported to range from 20 to 30 bushels per acre (Hydrometrics, 1981). A majority of these areas occur in loamy and clayey soils. Vegetative cover is provided by the growing wheat crop, the standing stubble after harvest, and crop residues remaining after summer-fallow tillage. Aside from the grain produced, vegetative production on an air-dry basis ranges between 2000 and 3000 pounds per acre (Greb, 1977).

4. Pasture and Hayland

Vegetation on haylands and pasture consists primarily of introduced cool-season grasses and legumes. Various fields support a stand of either crested wheatgrass (Agropyron cristatum), alfalfa (Medicago sativa), or a mixture of the two species. Forage yields for hay are reported to range from one-half to two tons per acre annually, with the average yield being 1.2 tons per acre (see Land Use, Section J). These areas are not irrigated on a regular basis.

H. WILDLIFE

An extensive wildlife data base exists relevant to the Rosebud Mine. Western Energy has sponsored wildlife investigation programs that have been under way since before 1973. Under this program data has been collected on big game, upland game birds, raptorial birds, songbirds, waterfowl, mammalian predators, small mammals, and reptiles and amphibians. No specific studies were conducted on reptiles, amphibians, and fish. The study area is shown in Figure 1, Appendix H.

Although surface mining of coal in the Colstrip area has been active for many years, no mining has occurred in Area C. Mining in Colstrip areas prior to 1973 was not subject to reclamation requirements, consequently, most of the reclamation activity there has been recent. Areas A, B, and E have active reclamation plans designed to rehabilitate disturbed lands to productive condition. It is unknown what effect, if any, past and ongoing mining activities outside of Area C may have had on the wildlife populations of the area. The destruction of habitat by mining and related surface developments may have decreased the maximum potential wildlife carrying capacity of the area and increased exposure of wildlife to human activities may have adversely affected survivorship and production of wildlife, but the actual impact of such changes is unknown.

1. Big Game

Most big game data is from aerial surveys conducted throughout the year. Although aerial surveys can yield indications of abundance and distribution of big game and herd composition by sex and age class, absolute quantification of these parameters is seldom feasible. There are several potential sources of bias in this methodology, including:

- Flight speed, altitude, and spacing - flying faster, higher or more widely spaced transects reduces total data capture (observation or sampling efficiency).
- Topography and vegetation - topographic relief can shield animals from view; vegetation, particularly trees and shrubs, can hide or camouflage animals.
- Observation conditions - adverse weather, including precipitations, fog, or haze, and "bumpy" air can reduce observation efficiency; snow cover generally provides much improved observability.
- Number of observers - use of the aircraft pilot as observer for one side of the transect is less effective than two dedicated observers.
- Double-counting - movement of animals between sample flights or flight lines; contrast this bias with flightline spacing bias.

- Daily and seasonal activity patterns - animal behavior patterns may affect observation efficiency, for example diurnal use of wooded and shrubby habitats where animals are camouflaged or completely hidden from view; or seasonal herding behavior wherein groups are easier to detect than individuals.

In addition to the aerial surveys, big game habitat preference data were collected opportunistically on the ground. The biggest difficulties with this type of data are the lack of control over uniformity of coverage of the area, inability to define the relative level of sampling effort expended by habitat type, and the observability biases related to diurnal and seasonal activity patterns of the animals and accentuated difficulties with topographic and vegetation visibility barriers.

Therefore, the following big game descriptions emphasize indices of abundance and herd composition available from Western Enery's aerial survey data base and rely more heavily on published literature for general information on big game habitat requirements.

a. Antelope

Over the eight years that intensive big game investigations have been conducted in the Colstrip vicinity, the pronghorn antelope (Antilocapra americana) has been consistently the most numerous big game species (Ecological Consulting Service, 1973, 1974, 1975; ECON, 1976, 1977, 1978, 1979; Western Energy, 1980). The Wildlife Study Area does not have large tracts of preferred pronghorn habitat, big sagebrush-grassland. Shrub-grassland habitat is particularly important to pronghorns during the winter months when sagebrush may represent over three-quarters of total forage intake, and the relative scarcity of this habitat in the Wildlife Study Area accounts for the substantially reduced pronghorn population in the area during winter. Since grassland is the predominant habitat, the area is favorable for antelope use in spring, summer, and fall.

Productivity of the pronghorn herd in the study area as reflected in fawn/doe ratios has been similar to estimates for production in game management units in the region. Observations per hour (Table 1, Appendix H) indicate severe winter die-off for the 1978-79 winter. The fawn/doe ratios indicate increased survival subsequent to this decline. Suitable habitat is available in Area C for pronghorn fawning.

Pronghorn observations for Area C follow the same general pattern as the Wildlife Study Area as a whole. Pronghorn observations are generally common in spring, summer, and fall when use of grasslands and agricultural areas predominates, but infrequent during the winter months, although an occasional small herd may remain in the vicinity of Area C during mild winters. These wintering pronghorn range over suitable habitats in the upper East Fork Armells Creek, Upper Lee Coulee, and Stocker Creek drainages (Western Energy, 1980).

b. Mule Deer

Mule deer (Odocoileus hemionus) are widely distributed over the Wildlife Study Area. Although deer forage in open grassland and agricultural fields, particularly in spring, they show a marked preference for timber-grassland and shrub-grassland habitat types during all seasons. These types are particularly important for forage and shelter during the harsh winter months, especially when snow cover restricts availability of low-growing forage. Although there is fairly consistent mule deer winter use of the eastern end of the Greenleaf Ridge, there generally are no large winter concentrations of deer observed in the Wildlife Study Area (Western Energy, 1980). Moister creek/coulee bottom habitats are often favored by foraging deer in summer and fall. Timber and shrub habitats are more common in the rougher terrain of the northwest and north-central portions of the Wildlife Study Area, including the high land to the north of Area C and drainages leading northward into Stocker Creek (ECON, 1981).

The deer population in the area has undergone a substantial reduction since the early studies were conducted in 1974 as reflected in the number of observations per hour of aerial survey time (Table 2, Appendix H). The reason for the reduction in deer in the area is not entirely clear, although severe winters in 1977-78 and 1978-79 may have contributed (ECON, 1977, 1978; Bureau of Land Management, 1981). The impediment of snow combined with a prolonged and sometimes drastic reduction in quantity and quality of available forage frequently accounts for large-scale winter die-offs (Wallmo and Regelin, 1981). It is not known to what extent legal and illegal hunting and other human activities may have contributed to the overall decline in deer numbers; some increase in both types of hunting is an inevitable consequence of population growth in the area over the past decade.

c. Other Big Game Animals

The only other big game animals reported in the study area have been white-tailed deer (Odocoileus virginianus) and elk (Cervus elaphus). Such observations are infrequent since the area does not support a sizable number of white-tailed deer and no permanent elk population.

2. Other Mammals

Small mammals in the Colstrip area include bats, shrews, rabbits and hares, and numerous rodent species (see Table 3, Appendix H). Small mammals provide an important prey base for mammalian predators and for raptors. The black-tailed prairie dog is a species of concern in Montana (Flath, 1981). Additionally, prairie dog towns provide habitat for an endangered species, the black-footed ferret. Other mammals that have been observed in the area include porcupines and chipmunks, which inhabit conifer/shrub habitat, cottontails and marmots in rocky areas, and muskrats, which are found in stock ponds and Castle Rock Reservoir. No population estimates have been made for these species in the area.

3. Mammalian Predators

The most common large mammalian predator in the Colstrip area is the coyote (Canis latrans), with badger (Taxidea taxus), red fox (Vulpes vulpes), and bobcat (Felis rufus) seen infrequently (Western Energy, 1980). Habitats found in Area C could be used by all these large predators. Coyotes and red foxes range widely across open brushland, woodlands, and farmland; badgers prefer grassland, brushy areas, and disturbed sites; and bobcats prefer forested and shrubby areas like those found in the north-central part of Area C (Whitaker, 1980). Weasel and skunk have also been observed in the area. Mammalian predators known in the area are shown in Table 3, Appendix H.

4. Upland Game Birds

Sharp-tailed grouse (Pedioecetes phasianellus) are the most numerous native upland game bird in the Colstrip vicinity. Sharp-tail dancing grounds are fairly evenly distributed across the Wildlife Study Area; twenty dancing grounds were active in the area in 1980 (Western Energy, 1980). Eight years of sharp-tail investigations in the Colstrip vicinity have shown fairly consistent numbers of grouse in the area, with variable attendance at individul dancing grounds. During the years of study, some grounds were abandoned, while other, new grounds were apparently established (ECON, 1975, 1976). The Area C vicinity has three dancing grounds (numbers 8, 25 and 35; Western Energy, 1980) with dancing ground 8 being the only ground within Area C, Block I boundary (T1N, R40E, S1, SE1/4, SW1/4). Dancing grounds tend to be open, sparsely grassed areas, often on knolls or ridges, and nesting habitat is generally shrub-grassland and ungrazed or lightly grazed grassland with good ground cover typically within about one-half mile of the dancing ground (Hillman and Jackson, 1973). Upland habitat types are preferred by sharp-tailed grouse. Moderately dense grass or grass-shrub cover provides shade and protection from detection by predators. Small grain fields in Area C are an important supplementary food source.

Ring-necked pheasant (Phasianus colchicus) crowing counts have been conducted since 1975 in the Wildlife Study Area. The main concentration area for pheasants is in the East Fork Armells Creek drainage primarily in the rail loop track-Colstrip area; overall, the study area is marginal pheasant habitat as reflected by fairly low call count results. Barley and wheat plantings and a winter feeding program enhance pheasant survival and production in the vicinity of the rail loop track (Western Energy, 1980).

Lesser numbers of Hungarian (Gray) partridge (Perdix perdix) and Merriam's turkey (Meleagris gallapavo) are found in the Wildlife Study Area. The Hungarian partridge is most often observed in reclaimed areas with good grass cover whereas turkeys are most often observed in grassland, shrub-grassland, and timber-grassland areas typically in the portions of the study area with rougher topography. Few partridge or turkey observations have been made in the vicinity of Area C.

Sage grouse (Centrocercus urophasianus) are not numerous in the Wildlife Study Area and have not been observed in Area C.

5. Waterfowl

Waterfowl recorded in southeastern Montana, including the Wildlife Study Area, are included in Table 4, Appendix H. Several of these waterfowl are considered of high federal interest (Spear, 1980). Of these species, only the canvasback has been reported in the study area (ECON, 1979). Most waterfowl observations are associated with Castle Rock Reservoir, Area A sediment pond, East Fork Armells Creek, and several small stock impoundments. Area C does not presently have adequate available surface water to attract concentrations of waterfowl, however limited nesting habitat is available in Area C.

6. Songbirds

The Migratory Bird Act of 1973 (16 USC 703-711) placed most songbirds in the United States under federal protection. Table 4, Appendix H shows songbirds expected in the Colstrip area on the basis of published reports, and notes those observed as part of the Wildlife Study Area investigations (Ecological Consulting Service, 1973, 1974, 1975; ECON, 1976, 1977, 1978, 1979; Western Energy, 1980). Most of the observed songbirds have been species commonly associated with grasslands or with open pine forests, both found in Area C. No songbird species observed in the study area is listed as threatened or endangered (Federal Register, 1980). No songbird species of federal interest (Spear, 1980) have been recorded in the Wildlife Study Area, although it is within the range of and suitable habitat for several. State species of special concern that have been observed in the area include eastern bluebird (Sialia sialis) and western bluebird (Sialia mexicana).

7. Raptors

The most common raptors in the Colstrip area are the red-tailed hawk (Buteo jamaicensis), American kestrel (Falco sparverius), and harrier (Circus cyaneus) (Bricco, 1981; ECON, 1979). Other common raptors are the great horned owl (Bubo virginianus), prairie falcon (Falco mexicanus), and golden eagle (Aquila chrysaetos) (Martin, 1981; ECON, 1979; Western Energy, 1980). Table 4, Appendix H includes raptors expected to occur or actually observed in the study area.

Although all raptor species are federally protected, there are several known from the Wildlife Study Area that have been given special status by Montana (Flath, 1981) or the federal government (Spear, 1980; Federal Register, 1980). These species are discussed briefly in the following paragraphs.

Golden eagles and bald eagles are protected by the Bald Eagle Protection Act of 1940, as amended in 1962 (16 USC 668a). Golden eagles are observed fairly often in the Colstrip area, and have nested on a

sandstone cliff in Area C as recently as 1978 (ECON, 1978, 1979). In all, three golden eagle nest sites, two on sandstone cliffs and one in a ponderosa pine, have been identified in the study area. Rabbits and rodents are usually the primary food of golden eagles (Peterson, 1961).

Ferruginous hawk (Buteo regalis) was observed in the northern part of Area C during a 1978 bird survey (ECON, 1978), and is listed as a species of high federal interest (Spear, 1980). Ferruginous hawks may nest in trees, on cliffs, or on the ground in open rangeland, and have been known to feed on prairie dogs and ground squirrels (Udvardy, 1977).

Prairie falcons (Falco mexicanus), considered of high federal interest (Spear, 1980), are fairly common in the Colstrip area; four active prairie falcon nests were recorded in the study area in 1980 (Western Energy, 1980). These birds nest on cliff ledges and eat ground squirrels, other rodents, and songbirds in open country (Udvardy, 1977). A prairie falcon nest is located on the same sandstone outcrop in Area C as the golden eagle nest. These falcons are of special interest in the Colstrip area because of the number of known nests and occupied territories.

The burrowing owl (Speotyto cunicularia) was observed in the southwest corner of Area C in 1979 (ECON, 1979), is of high federal interest (Spear, 1980), and is thought to be declining in Montana (Bricco, 1981). This owl lives in burrows deserted by species such as prairie dogs or badgers, and hunts rodents, mostly by day. Considerable grasslands and scrublands in Area C provide suitable habitat for burrowing owls.

Several species of raptors observed during Rosebud Mine Wildlife Resource Studies are listed as species of special concern in Montana (Flath, 1981). These species are Cooper's hawk (Accipiter cooperii), ferruginous hawk, golden eagle, bald eagle, prairie falcon, merlin, burrowing owl, and long-eared owl (Asio otus).

8. Reptiles and Amphibians

No specific surveys have been made for reptiles or amphibians, but incidental sightings have been noted in the annual wildlife surveys at the Rosebud Mine (Western Energy, 1980). Prairie rattlesnake (Crotalus viridis) sightings were mentioned every year from 1976 through 1980. Bull snake (Pituophis melanoleucus) sightings were mentioned each year from 1977 through 1980. Other reptiles and amphibians mentioned in the annual wildlife survey reports included snapping turtles (Chelydra serpentina), painted turtle (Chrysemys picta), sagebrush lizard (Sceloporus graciosus), hognose snake (Heterodon sp.), racers (Coluber constrictor), salamanders (Ambystoma sp.), and frogs.

Table 5, Appendix H lists reptiles and amphibians expected to occur in southeastern Montana (Stebbins, 1966), and notes observations in the Rosebud Wildlife Study Area between 1976 and 1980 (ECON, 1976a, 1977a, 1978, 1979; Western Energy, 1980). Turtles, salamanders, and frogs are not likely to be common in Area C since they require a wet habitat, and

such habitat is limited in Area C. Hognose snakes, of special concern in Montana (Flath, 1981), may be present, especially in farmland in Area C. Prairie rattlesnakes inhabit virtually all of the habitat types present in Area C (Stebbins, 1966; ECON, 1981).

9. Threatened and Endangered Species

Bald eagles (Haliaeetus leucocephalus) (ECON, 1979) and a peregrine falcon (Falco peregrinus) (Martin, 1981) have been observed in the Wildlife Study Area during migration. These two birds are listed as endangered species (Federal Register, 1980); however, no critical habitat for either bird is known to be present in the Colstrip area. No specific studies for these species were conducted.

Because the endangered black-footed ferret (Mustela nigripes) is largely dependent on prairie dogs for food, the possibility of black-footed ferrets being present must be considered. There are not records of black-footed ferrets in Rosebud County. The only known prairie dog colony, approximately 100 acres in size, is north of Area C in the Stocker Creek drainage. In 1978 and 1979 the colony was inspected for black-footed ferret signs. Additionally, a black-footed ferret spotlight survey was conducted in 1979. None of these surveys revealed evidence of black-footed ferrets (ECON, 1978, 1979).

I. SOCIOLOGY AND ECONOMICS

1. Economic Conditions

Traditionally, agriculture has been the primary economic activity in Rosebud County, but during the past decade, agriculture has been declining in relative importance. The county is undergoing a transition from an agrarian economy to an economy primarily dependent on energy development. This fact is supported by substantial increases in personal income and employment for energy-related activities and a corresponding decrease in agricultural income and employment. All statistical data presented in the following subsections were derived from the Bureau of Economic Analysis, U.S. Department of Commerce.

a. Personal Income

Over the past decade, labor income has been the most significant contribution to total personal income in Rosebud County, more so than in the state of Montana as a whole. Labor and proprietors' income (sometimes called participation income) accounted for about 84 percent of total personal income during 1979 in Rosebud County and approximately 73 percent in Montana. In 1970, the corresponding figure was about 79 percent for Rosebud County and 78 percent statewide.

Table 1, Appendix I presents personal income by major source for Rosebud County and Montana during 1970 and 1979. Annual data for Rosebud County are shown in Table 2, Appendix I. These figures were converted to constant 1980 dollars.

In 1979, agriculture accounted for only 2.7 percent of total personal income, compared to 18.7 percent in 1970, however, mining and construction have shown sizable gains. In particular, mining increased from 3.9 percent of total personal income in 1970 to 20.9 percent in 1979. Despite the downward trend, the relative importance of agriculture in Rosebud County continues to be slightly greater than the figure for Montana. However, the relative importance of mining employment in Rosebud County is more than four times the figure for Montana.

Per capita income figures for Rosebud County and Montana from 1970 to 1979 are presented in Table 3, Appendix I. Per capita income is equal to total personal income divided by population; in other words, it is average income per person. In order to correct for inflation, per capita income was converted to constant 1980 dollars.

Per capita income in 1979 for Rosebud County was $6,948 (1980 dollars), or about 19 percent below the Montana average of $8,601 (1980 dollars). During the 1970s, real per capita income in Rosebud County grew at about the same rate as in Montana; between 1971 and 1979 it rose 26.5 percent in Rosebud County and 26.4 percent statewide. The stability of real wages in the county from 1970 to 1979 indicates that Colstrip Units 1 and 2 did not cause significant increases in labor costs to local businesses (Polzin, 1981). Per capita income in Rosebud County was much

more variable than in Montana during the 1970s, reflecting the wages paid during the construction of Colstrip Units 1 and 2, and the fact that agricultural income is highly cyclical.

b. Employment

As shown in Table 4, Appendix I, total employment in Rosebud County rose from 2,465 in 1970 to 4,472 in 1979, an increase of about 81.4 percent. Annual data for Rosebud County are presented in Table 5, Appendix I. In Montana, total employment increased from 279,091 to 373,409, or 33.8 percent during the same period.

The decline of agriculture and manufacturing, and the rise of mining, services, construction, government, transportation, and public utilities employment is evident, as shown in Table 4, Appendix I. In 1970, agriculture was the largest employer, but by 1979, both services and government employed more people.

Labor market trends may also be analyzed in terms of employment in basic and derivative industries. Basic industries depend on nonlocal markets or are otherwise influenced by factors originating outside the area. Derivative industries, on the other hand, serve the local population. Economists believe that changes in basic industries lead to further changes in derivative industries. Employment data for Rosebud County have been organized into basic and derivative categories, presented in Table 6, Appendix I. The decreasing relative importance of agriculture and the increasing importance of mining, construction, transportation, and public utilities to the economic base of Rosebud County is reemphasized by this data.

2. Demographics

The 1970 and 1980 populations of Colstrip, Rosebud County, and Montana are presented in Table 7, Appendix I. Estimates of the populations of Colstrip and Rosebud County have been used rather than census figures to more accurately present actual growth in the area. The timing of the census and the boundaries of some census enumeration districts distorted the count of actual area residents. Population estimates were developed by Western Analysis, Inc. (1982), based upon actual area employment and population employment multipliers. The populations of Colstrip and Rosebud County increased dramatically during the 1970s; Colstrip's 1980 population was more than 13 times as large as its 1970 population. The Rosebud County population nearly doubled during the same period. By comparison, the population of Montana increased 13 percent between 1970 and 1980 (U.S. Bureau of the Census, 1981).

A comparison of age and sex compositions of the 1970 and 1980 Colstrip and Rosebud County populations is shown in Table 8, Appendix I. A comparison of age cohorts expressed as a percentage of total populations is presented in Table 9, Appendix I for Colstrip and Rosebud County populations. The age composition of both populations has shifted toward the younger adult age groups (23 to 44), with corresponding decreases in

the proportions of older adults. This phenomenon is more pronounced in the Colstrip population, where the age 25 to 34 cohort proportion of the population has doubled during the decade. Slight increases in the proportion of younger children (ages up to nine) also occurred in the Colstrip population. The sex ratios of Colstrip and Rosebud County populations show a slight surplus of males in 1970. In 1980, the surplus of males in the Colstrip population had increased ten percent; a much smaller proportionate increase in males occurred in the Rosebud County population.

3. Baseline Economic/Demographic Forecast

Table 10, Appendix I contains the annual employment, population, and per capita income forecast for Rosebud County. Similar quarterly information is presented in Table 11, Appendix I. Table A, Appendix I presents the personal income projections for Rosebud County.

As displayed in Table 12, Appendix I, per capita income in Rosebud County is projected to increase during the construction of Colstrip Units 3 and 4 and then return to normal levels by 1985. Per capita income is projected to increase from $7,986 (1980 dollars) in 1980 to $9,090 in 1983, then to decrease to $8,250 by 1985. Beyond 1985, real per capita income is projected to grow throughout the forecast period.

Total employment and population for Rosebud County and Colstrip are expected to peak the fourth quarter of 1982, then decrease until 1990, then increase through 2010 and then decrease thereafter as illustrated in Tables 10 and 11, Appendix I. Peak basic employment, total employment, and population for Rosebud County are 6,001; 8,414; and 16,913 persons, respectively. Colstrip population is expected to peak at 7,665 persons in the baseline forecast. Nonbasic employment is forecast to increase through 2010 and then decrease thereafter.

Between 1980 and 1985, basic employment, total employment, and population follow the construction cycle of Colstrip Units 3 and 4. Turbine roll is expected the fall of 1983 for Unit 3 and the fall of 1984 for Unit 4 (Kelley, 1982). Between 1990 and 2010, basic employment, total employment, and population in Rosebud County and Colstrip are forecast to increase due to basic growth in the trade, services, and nonfarm proprietors industries. The service industry in particular experienced significant growth after the completion of Colstrip Units 1 and 2 and is expected to continue to expand throughout the forecast period. It was assumed in the report that coal mining in Rosebud County would cease after 2018.

Despite a projected decrease in agricultural employment, agriculture will continue to have an important role in Rosebud County as a large employment category and source of personal income. Agricultural experts are optimistic about the outlook for both grain and cattle during the coming decades. The trend toward larger and more capital-intensive farms and ranches should continue. The Rosebud economy will, however, become less dependent on agriculture and more dependent on energy development during the baseline forecast period.

4. Social Life

a. Social History

The earliest nonmilitary white settlers in the Rosebud County area were range livestock operators, who began to arrive in 1876. Population growth in the area was gradual until the siting of the Northern Pacific Railroad in 1882, when access and immigration to the area increased. Economic activity in the area was agricultural or tied to the railroad (Western Historical Publishing, 1907). Agriculture and derivative service employment remain the primary economic activity in Rosebud County, except for the Colstrip area.

The presence of a company town and industrialization in the Colstrip area are not new phonomena. Colstrip was developed as a company town after coal strip mining was initiated in 1924 by the Foley Brothers, on contract to Northern Pacific. During this initial mining period, Colstrip evolved into a community center serving agriculture and industry. The Colstrip School became a focal point of community and social activities for area residents. The maximum area population during this mining period appears to have been about 550 residents in 1950 (Douglas, 1982). Mining ceased in the area in 1958 when diesel engines replaced steam locomotives. After mine closure, the residual population comprised a maintenance crew for the mine properties, school personnel, and ranchers (Rosebud County Bicentennial Committee, 1977). The town has continued to serve as a primary social focal point for the surrounding area, until large-scale coal and energy development resumed.

Mining operations were resumed in 1968 by Western Energy, a subsidiary of Montana Power Company, followed closely by construction of power plants and additional mines in the area. The population of Colstrip jumped from 250 in 1970 to about 1,500 in 1972. The population peaked during the 1970s at an estimated 2,800 people in 1975, during construction of Colstrip Units 1 and 2 (Rice, 1982). The present population is estimated to be approximately 5,800 (Western Analysis, Inc., 1982).

The scale of recent energy development in the Colstrip area was a phenomenon to the area's residents and intensified conflicts between agricultural and industrial interests. Sources of conflict have included resource development and land management issues, economic impacts of industrialization upon agriculture, loss of political influence and community identity among long-time area residents, and differing value systems (Gold, 1974, 1975).

A recent survey was conducted by Western Analysis, Inc. (1982) to characterize social life in the Colstrip area. The information presented in the following sections addressing the social life of Colstrip was drawn from three sources. Those sources were:

- Lengthy personal interviews of 31 Colstrip and Rosebud County residents who were selected on the basis of their reported knowledge of the study area

- o A quality of life survey of 243 Colstrip households conducted by Western Analysis (1982)

- o Various statistical reports published by federal and state agencies

The items discussed below are distinct definable characteristics of most human groups, whether communities or aggregations. These characteristics can be and are used to describe the social life of human groups. They also can be and are used to indicate change and the effects of change in the social life of human groups.

b. Community

Colstrip remains a company town. Decisions regarding development of Colstrip are made by the Montana Power Company. A recent voter initiative to incorporate Colstrip as a self-governing municipality was defeated. Reportedly, only a small proportion of the present town residents identify themselves with Colstrip or consider Colstrip "home." Those Colstrip residents who predate the recent development boom and comprised the Colstrip community are fewer in number and are submerged within the larger, "new" Colstrip. The ranching community, traditionally the dominant group in the Colstrip area, reportedly has severed most ties with Colstrip and exists as a parallel (and diminishing) community outside its bounds. According to area informants, relatively few residents of Colstrip know any member of, or have much in common with the ranching community. Further, few Colstrip residents reportedly possess ties to, or interest in the remainder of Rosebud County. Most present residents of Colstrip are said to identify themselves most strongly with their occupations or employers.

Several characteristics of Colstrip appear to have inhibited its development as a social community: its status as a company town, its rapid growth, and the large number of temporary jobs available. Community is defined as a human population living within a limited geographic area and possessing an interdependent life under common cultural and institutional regulations. Virtually all decisions concerning community development rest in the hands of persons not elected by the residents. The costs of improvements to city properties are borne in large measure by Montana Power Company. The physical structure of new parts of the city developed in response to company plans, rather than to pressures from the residents. In the early stages of city development, housing shortages resulted in segregation of residents by employer (Western Energy, Montana Power Company, Bechtel, and Long Construction) and by type of employment (blue collar or white collar). The rate and degree of growth overwhelmed the older, existing community. Many newcomers reportedly were from urban, industrial areas and had little in common with the existing, particularly rural, residents. Finally, the short-term nature of many jobs discouraged the development of community identification.

The consensus of informant opinion suggests that Colstrip has not yet regained a true community identity as defined above. Further, these

residents suggest that a community identity cannot be formed until the transient construction and management crews depart upon completion of Colstrip Units 3 and 4. Despite this, the basis of a Colstrip community exists and is comprised of those residents who have remained in Colstrip for several years, are employed in permanent jobs, and intend to remain in Colstrip.

c. Social Structure in Colstrip

City residents consistently divided the Colstrip population into three major groups:

- Transient workers, usually craftsmen, but also including some supervisory personnel.
- Technicians/operators, usually employed in permanent jobs, who have been in Colstrip more than two years and intend to stay.
- Management/high level supervisory personnel, usually employed in permanent positions, but including some long-term temporary personnel (e.g., Bechtel personnel).

Area informants stated that school personnel formerly had constituted a fourth group, but now are being assimilated within the management and technical/operators groups.

Twenty-two formal social organizations in Colstrip list their meeting dates in the local newspaper. City informants state that these groups constitute the primary social organizations in the area, although other, smaller, and very informal organizations also meet from time to time. Of the organizations listed, nine exist for recreational purposes. Four youth organizations (scouting) are listed. Three organizations have community service functions: the PTA, the Women's Club, and Parents Against Drug Abuse. A fourth group of a similar type, addressing the problem of spouse abuse, reportedly is being organized. Only two organizations appear to serve purely social or fraternal purposes. The remaining groups are concerned with alcoholism, obesity, commercial matters, and governance of the local library. Religious groups also exist in Colstrip, in connection with approximately ten church congregations.

Area informants state that membership in the formal social organizations is a matter of personal interest. Reportedly, none of the organizations is exclusive except the commercial and fraternal ones. Despite the nonexclusive policies of these organizations, temporary residents reportedly are far less likely to join than the permanent residents. Most organization members are said to be from the technician/operators social group, which is the larger of the two groups comprising the more permanent residents of Colstrip.

d. Social Interaction in Colstrip

Social interaction between individuals and groups in Colstrip reportedly is now less dependent upon occupation or employer than in previous years. As mentioned in Section b. (Community), during the initial population boom period engendered by construction of Colstrip Units 1 and 2, a housing shortage forced segregation of residents by company and reportedly by occupation (white collar and blue collar). As a consequence, most social interaction in Colstrip is between employees of the same companies and within like occupational groups. This segregated social interaction is further strengthened by company practices that provide social and recreational activities for company employees only. More recently, in some instances Western Energy has allowed residents to purchase company-built houses as they have become vacant. This situation has broken the earlier, segregated housing pattern and has made social interaction across company and occupational lines more possible among homeowners.

A substantial majority (more than 70 percent) of Colstrip survey respondents indicated that Colstrip residents are friendly, helpful, and sociable. Over 50 percent of respondents indicated that it is easy to get to know people in Colstrip, that length of residence and income have little effect upon community acceptance or influence, that the more long-term residents are friendly. However, one's occupation does affect his influence within Colstrip, according to more than 50 percent of the residents. The perceived occupational distinction is drawn between white collar and blue collar workers. Some blue collar workers are as well paid as white collar workers, but have less influence within Colstrip. A plurality of respondents (45.1 percent) indicated that there is "some" or "a great deal of" status consciousness in Colstrip.

Colstrip informants agreed that residents in Colstrip townsite are friendly and added that social interaction across occupational and company lines is increasing. Nevertheless, social interaction reportedly remains somewhat bound by occupation, and to a lesser degree, by employer. Length of residence in Colstrip and the permanence of one's job often were identified as influences that govern the likelihood of social interaction. Those who hold permanent or long-term jobs are more apt to socialize and to do so across company lines. Those employed in temporary positions are less apt to socialize. Further, craftsmen employed in temporary positions reportedly are apt to socialize almost exclusively with other members of their own craft, rather than with all crafts at a given site.

The apparent selectivity of social interaction in Colstrip among the more permanent residents reportedly is determined more by opportunity than by intent. Conversely, patterns of interaction among craftsmen reportedly are by choice. Nonetheless, many informants stated that there are many lonely people in Colstrip and added that loneliness in Colstrip can be particularly intense, given the town's isolation and limited recreational facilities. Some Colstrip residents reportedly do not interact with others.

e. Colstrip Lifestyle

Colstrip informants were unable to describe a uniform "Colstrip lifestyle," but did identify several common characteristics of life in Colstrip. Informants agreed that life in Colstrip has little in common with the remainder of Rosebud County or with Colstrip before coal development resumed. Due to a high degree of turnover in crafts employment, the job market in Colstrip reportedly is quite good and the population of the town is in a state of flux. The proportion of workers earning relatively high wages is greater in Colstrip than in the surrounding area. The minimum salary for non-clerical personnel at the MPC and Western Energy operations in Colstrip is roughly $400 to $450 per week. There are very few low income or unemployed people in Colstrip. There are very few organized recreational opportunities and facilities in Colstrip, relative to the size of the population. Although many informants insist there is plenty to do in Colstrip, they also indicated that many residents are bored, in part because they are not accustomed to entertaining themselves. Boredom reportedly accounts for the heavy consumption of alcohol that is said to be characteristic of Colstrip residents and for the exodus from Colstrip each weekend. Unemployed wives are said to be especially bored with life in Colstrip.

Distinctions are drawn between the lifestyles of transient (primarily crafts) residents and the more permanent technicians/operators. The latter are said to be more home- and family-oriented and to lead more routine, predictable, and community-oriented lives. The transient residents are said to lead less stable, less home-oriented lives, and to display less interest in the community. Temporary crafts employees very often were characterized as leading "work hard, play hard" lives. Temporary employees also were described as less apt to have families in Colstrip and to be less family-oriented.

Most informants agreed that life in Colstrip can be inconvenient and stressful to those accustomed to more urban environments. Colstrip is isolated, has very few commercial resources for its size, and very few outlets for those not employed. Although a community recreation center does exist (and is well used), and a small women's welcoming club serves newcomers, Colstrip's infrastructure provides very few opportunities for casual social interaction. Further, there is very little public land in the immediate area for recreational purposes.

f. Values

Colstrip informants who predate the resumption of coal development (about 30 percent of those interviewed) distinguish between the values of the newer residents of Colstrip and those who were in residence before redevelopment. Pre-redevelopment residents were said to value family, community, neighbors, hard work, frugality, and an independent, self-reliant approach to life. Post-redevelopment residents are described as placing less emphasis upon community, neighbors, frugality, and work for work's sake; and more emphasis upon money, materialism, and more immediate gratification of wants. Colstrip informants also draw distinctions between the values of temporary and more permanent residents. The more

permanent residents are said to place a higher value on home and family life and upon what the informants labeled as a stable, responsible, and predictable lifestyle than do the more temporary residents. The temporary residents were described as valuing community life and stability the least of all Colstrip groups and as placing higher value upon material goods and immediate gratification of wants.

Education reportedly is no longer a value among Colstrip's children. This circumstance is said to be strikingly different from pre- and early redevelopment periods in Colstrip's history. Reportedly, a large number of students regard an education as less important, particularly in light of their assumptions that quite lucrative jobs will be available to them in the construction industry at Colstrip and elsewhere without an education. Colstrip informants were in general agreement that although most residents appear to value education primarily as an economic tool, the attitude of children toward education distresses most parents. The informants were not able to state with any consistency whether the children's perceptions of education were influenced by their parents' lifestyles or occupations.

g. Conflict

There is little overt, formalized conflict between social groups in Colstrip, according to informants. Conflict between the rural agricultural community and the Colstrip coal community no longer is as visible as in the early and mid-1970s. Specific objections to specific aspects of coal development are still made by members of the agricultural community, but the opposition reportedly lacks the scope and intensity of that in previous years. Conflicts concerning trespass largely have been resolved through formal, legal channels; in addition, a deputy is now assigned to patrol the rural areas adjacent to Colstrip.

Conflicts within and between temporary and permanent groups apparently exist on an individual, informal basis. Several informants suggested that the Colstrip population is so diffuse and fluid that there has been no opportunity for conflicting groups to develop. Individual conflicts within the transient population reportedly are resolved through mutual avoidance, or in a few cases, through overt conflict; whereas avoidance of overt conflict reportedly is the mode of choice of the city's residents. Some conflict over construction of new schools and the busing of children to the schools has arisen recently. In this instance, no coherent, formal, group-based positions have developed as yet.

Area informants uniformly state that Colstrip residents are remarkably apolitical. Many stated that the residents are too passive politically. County elected officials have stated that development in Colstrip has not resulted in identifiable or attributable shifts in the political balance of the county.

h. Religion

There are ten active churches in Colstrip, some of which reportedly have very small congregations. The congregations are described as being evenly divided between mainline and fundamentalist orientations. There reportedly is little ecumenical spirit among the various congregations; the ministerial association is said to have collapsed from lack of interest. A plurality (45 percent) of Colstrip survey respondents indicated that some or few residents attend church regularly; 21 percent of respondents did not know whether residents attend church or not. One minister suggested that perhaps 15 percent of town residents attend church regularly. Informants suggested that permanent residents were more apt to attend church than transient residents. Over 70 percent of survey respondents considered religious activities to exert an average or minor influence on community affairs. Nearly 22 percent had no idea of religion's influence on community life.

i. Family Life

Family life reportedly is very important to most residents who have families. Sixty-seven percent of surveyed residents have children living at home; an average of two children reside in those households with children living at home. Colstrip informants suggested that life in Colstrip exerts a very strong influence on families. Whether this influence is positive or negative depends upon the nature of the family. If a family is close and "healthy," life in Colstrip can exert a positive influence. Conversely, if the family is "unhealthy" or unstable, life in Colstrip reportedly can exert a very negative influence. Family problems reportedly include spouse abuse, child neglect and, less often, child abuse, excessive drinking, marital infidelity, and divorce. No reliable data were available to substantiate these perceptions. Several informants and social service professionals described Colstrip as a testing ground for family life. The limited availability of recreational and other alternatives to family life forces family members to spend more time together and thereby intesifies the strengths and weaknesses of family relationships.

j. Social Problems

Divorce, family instability, and drug and alcohol abuse were mentioned consistently as the major social problems in Colstrip. However, law enforcement officials indicated that the incidence of major crimes in the area was surprisingly low and added that the majority of crimes with which they deal are petty crimes (Ash, 1982). Various statistics support some of these perceptions, although such statistics may be compromised in part by the presence of the Northern Cheyenne Indian Reservation within the county. Indian reservations often have high rates of alcoholism, divorce, crime, illegitimacy, teenage pregnancy, family instability, suicide, death, and morbidity. The presence of the Northern Cheyenne Reservation in Rosebud County <u>may</u> raise the level of some of these indicators at the county level.

Alcoholism rates (as measured by admissions to institutional treatment programs) are nearly three times higher in Rosebud County than in Montana. The rate of out of wedlock births in Rosebud County is nearly twice the state rate. Comparative rates of admissions to the state mental hospital were much higher in Rosebud County than in Montana (over twice as high) in the years 1970 through 1974, but were lower than the state rate after those years. This statistic may be compromised by the greater availability of community mental health programs (which divert patients from institutional treatment) in the rest of Montana and the much more stringent statutory criteria for admission to statewide institutional treatment facilities. Contrary to community perceptions, the divorce rate in Rosebud County has been consistently below the corresponding state rate since 1970. No data are available to refute or support the perceptions of informants and service professionals that spouse abuse and child neglect are problems in Colstrip.

5. Social and Community Services

a. Law Enforcement

Law enforcement in Colstrip is provided by the Rosebud County Sheriff. The sheriff's jurisdiction in Colstrip includes all areas except the generating station and construction sites. Six deputies, five dispatchers, and one dogcatcher are assigned to the Colstrip office. An additional deputy patrols the rural area south of Colstrip to Ashland. All deputies are graduates of the Montana Law Enforcement Academy. Law enforcement personnel and equipment are located in the Colstrip Community Service Center. Detention facilities, located in the same building, comprise four cells, each with two bunks. The cells are arranged to provide segregation of prisoners by sex and by age. The Colstrip detention facility is used only as a holding facility, pending adjudication of prisoners. Persons sentenced to jail terms are transferred to Forsyth. The Colstrip office is provided with three patrol cars and one pickup truck. Communications are provided by a low frequency band radio system, with transceivers in each motor unit. The sheriff's office provides communications and dispatching services for the local emergency medical service and fire protection organizations.

All vehicles within the sheriff's fleet are replaced on a planned and budgeted biennial schedule. The detention and office facilities were constructed in 1976, and are in excellent condition. The office's radio equipment is also in good condition and will require replacement in the near future only if Montana law enforcement agencies change to high-frequency equipment. The sheriff considers his manpower and equipment to be adequate to serve the present population (Ash, 1982). Over 60 percent of surveyed residents considered law enforcement services to be good to average.

b. Fire Protection

Fire protection services in Colstrip are provided by a 22-member volunteer fire department. Only the chief is certified at present. All

volunteers are in training and are expected to be certified within six months. Fire flows in Colstrip are considered adequate for present and future needs and are expected to improve with scheduled modifications of the city water distribution system. The fire department is equipped with the following:

- One 1957 International Harvester 1,000-gallon pumper
- One 1980 Superior 1,000-gallon pumper
- One 1972 International Harvester 1,500-gallon tanker with a 300-gallon-per-minute pump

An additional 1,000-gallon pumper will be purchased and should be delivered by the fall of 1982. Equipment storage is provided at the Colstrip Community Services Center and is considered adequate. A two-stall garage is to be constructed in the vicinity of the Pine Butte School in the northern end of Colstrip in the fall of 1982. The new fire truck will be stationed at that facility.

The fire station is located on the west side of railroad tracks that bisect Colstrip. An overpass on the northern end of town allows access to all areas of Colstrip in the event that the railroad crossings are blocked by a train.

The Colstrip fire chief considers his department adequate to meet the fire protection needs of Colstrip for the present and the foreseeable future. No plans have been made to replace any equipment in the immediate future (Durham, 1982). Fifty-five percent of surveyed residents considered fire protection services to be good to average.

c. Sanitary Sewer

Wastewater treatment in Colstrip is accomplished with an oxidation ditch facility. That system is to be supplemented by an aerated lagoon, which is to be installed at the site of an older, now unused three-cell lagoon system. The town's wastewater will be retained in the aerated lagoon for a ten-day treatment period, after which it will be discharged to the oxidation ditch. The remaining two cells of the old lagoon system are to be used as sludge drying beds (Mountain West Research, 1981). Although construction of the aerated lagoon was completed in January 1982, the lagoon has not been filled for fear that it will freeze. As a result, the oxidation ditch facility is operating at levels above its hydraulic capacity. The new lagoon will be filled as soon as the weather permits, at which time the combined system is expected to function properly. The new treatment system is considered adequate to meet the needs of the present and projected peak construction population of Colstrip (Miller, 1982). Over 73 percednt of surveyed residents considered sewer services good to excellent.

d. Water Supply

The Colstrip public water supply is drawn from Castle Rock Lake, a surge pond built to supply make-up water to the Colstrip electrical generating units. The water right to the water is held by the Montana Power Company. The lake is filled with water piped from the Yellowstone River. Two water treatment and distribution systems, with a combined capacity of 2,200 gallons per minute (gpm), serve Colstrip. One system, an upflow clarifier and filtration system, supplies 1,000 gpm. The other, a diatomaceous earth filtration unit, operates at 1,200 gpm. Three high-volume service pumps transfer treated water from a 30,000-gallon clearwell to the distribution system. Storage for treated water is provided by three reservoirs with a combined capacity of three million gallons. The present system is inadequate to meet projected peak demands. Western Energy is constructing an expanded water treatment plant that will include a 4,000 gpm direct filtration unit, a 390,000-gallon clearwell, a new high-volume pumping station, and an additional 680,000-gallon storage facility (Mountain West Research, 1981). The new system should be operating by April 1982, and will replace the two older systems. The 1,000-gpm upflow clarifier/filtration unit will be maintained as a peak demand backup unit. The new treatment system is considered adequate to meet the needs of the present and projected peak construction populations of Colstrip (Miller, 1982). Over 76 percent of surveyed residents considered the water supply to be good to excellent.

e. Solid Waste

Solid waste collection and disposal services now are the responsibility of Rosebud County, and are met by a rural refuse disposal district. The district is served by a three-man crew and is equipped with one truck with a 25-cubic yard compactor. Solid wastes are buried in old strip mine cuts that have been sealed with clay; old mine spoils are graded over the solid wastes. The present dump site serves Rosebud and Treasure Counties; the Northern Cheyenne Reservation reportedly also will use that disposal site in the near future. No capacity or groundwater contamination problems are foreseen at the current dump site for either the present or projected peak populations of the service area. Four groundwater quality monitoring wells have been installed near the dump site, and are checked at six-month intervals. Solid waste collection capacity is adequate at present, with one pickup-day per week. The cost of an additional collection unit has been estimated at about $55,000 (Tusler, 1982). Over 67 percent of surveyed residents considered local waste disposal service to be good to average.

f. Social Welfare

The social welfare programs provided by the Rosebud County Department of Public Welfare are identical to those available in all county offices in Montana. These programs include:

- Aid to Families with Dependent Children (AFDC)
- Medical Assistance (Medicaid and County Medical Assistance)

- o Foster Care
- o Food Stamps
- o Social Services (e.g., Homemaker Services, Meals on Wheels, etc.)
- o General Assistance
- o Transient Assistance

All of these services are available to Colstrip residents; however, some of the services must be obtained directly from the Forsyth office. The income status of most Colstrip residents precludes their eligibility for many programs; therefore, most services rendered in Colstrip are child protection services.

The Colstrip Community Welfare Office is staffed by one social worker, whose workload primarily consists of investigating referrals of child abuse or neglect, placing children in foster homes, supervising foster homes, and following up on AFDC cases (Polley, 1982). In 1981 (fourth quarter), there were 61 child protection cases in Colstrip (Gabel, 1982).

Colstrip reportedly is adequately staffed at this time. During the peak construction of Units 3 and 4, however, an additional social worker or paraprofessional will be required to meet Colstrip's expanded needs (Kennedy, 1982). Most survey respondents (75 percent) had no opinion of the adequacy of local welfare services.

g. Medical Services

The outpatient medical needs of Colstrip are served by the Colstrip Medical Clinic, a Southeastern Montana Rural Health Initiative (SEMRHI) clinic. Counties that are served by SEMRHI, namely Rosebud County, are considered medically underserved and are funded by a grant from the Department of Health and Human Services. The clinic's professional staff includes two general practitioners (one National Health Service physician and one contracted physician), two part-time registered nurses, and one x-ray technician (Catapano, 1982). There are three examining rooms, an x-ray unit, a laboratory, and a fully-equipped emergency room (Palm, 1982). The medical staff and facilities are adequate to serve the Colstrip community (Viall, 1982). Fifty percent of survey respondents considered local medical services to be good to average; 32 percent considered them fair to poor.

The Colstrip Dental Clinic and Optometrist are located in the same building (Colstrip Mall) as the Medical Clinic. There are two dentists, two dental assistants, and one dental hygienist (May, 1982). The optometric office staffs one part-time optometrist (two days a week) and an optometric assistant (Porter, 1982).

The Eastern Montana Community Mental Health Center of Miles City administers the Colstrip mental health services. The Colstrip Mental Health Center, which is staffed by one psychologist, handled approximately 50 cases in 1981 (Mountain West Research, Inc., 1981). The Mental

Health Center is at its maximum capacity now (Peterson, 1982). Over 60 percent of respondents had no opinion of the adequacy of these services.

There are four ambulances in Colstrip; two are owned by Bechtel Energy Company and two by the Colstrip Emergency Medical Service (EMS). Helicopter and fixed-wing air ambulance service is available through Saint Vincent Hospital in Billings. EMS is staffed by 11 volunteers, all of whom are either Emergency Medical Technicians (EMTs) or in EMT training (Kampf, 1982). This emergency service is adequate for current needs (Mountain West Research, Inc., 1981). Over 64 percent of surveyed residents considered emergency medical services to be good to excellent.

Rosebud Community Hospital in Forsyth is the closest hospital to Colstrip (approximately 33 miles). It staffs 36 personnel: five registered nurses, three licensed practical nurses or licensed vocational nurses, and 28 other personnel (Montana Department of Health and Environmental Sciences, 1980). The hospital has 18 licensed beds, maternity care, emergency facilities, x-ray department, and a part-time pharmacy (Montana Department of Health and Environmental Sciences, 1980). During 1980, the hospital had a 20.9 percent occupancy rate (patient days/ licensed beds x 365 days x 100%). Over 60 percent of respondents considered hospital service to be of poor to fair quality.

Forsyth is also the closest city offering nursing home facilities to Colstrip residents. The Rosebud Community Nursing Home has 39 skilled-care beds and eight intermediate-care beds, and experienced an 82.9 percent occupancy rate in 1980 (patient days/(skilled beds + intermediate beds)/days reporting x 100%) (Montana Department of Health and Environmental Sciences, 1980). Most respondents (75 percent) had no opinion of nursing home care or stated that it was not available.

h. Housing

Total housing units in Rosebud County increased from 2,055 in 1970 to 4,363 in 1980, or 112.3 percent. Of the 1980 count, it is estimated that 3,764 were occupied households (see Table 13, Appendix I). This is based on the assumption that the 576 housing units counted in Colstrip that were in addition to the 1980 census count were occupied. Mobile homes accounted for almost 60 percent of all new housing units in Rosebud County between 1970 and 1980, due to the reliance of energy growth areas on this type of housing (U.S. Bureau of the Census, 1981). About 42 percent of the county's housing unit increase occurred in Colstrip (Mountain West Research, Inc., 1981). The rapid growth in mobile homes in the county is reflected in the differences between Rosebud County and the state in 1980 housing mix. Whereas the share of total housing units that are multi-family is similar, mobile homes comprise 36 percent of the county's housing stock, and only 12 percent of the state housing stock.

Baseline projections of housing demand (households) in Rosebud County through 2020 are presented in Table 13, Appenddix I. These estimates of average household size for permanent and temporary population applied to the population projections given above yield a peak projected

baseline housing demand of 5,624 units in 1982, 1,860 more than the 1980 figure. Households are then projected to decline by 1,672 by 1985, remain stable through 1990, and increase by 820 from 1990 to 2010 (Western Analysis, 1982).

Prior to 1968, the townsite of Colstrip was owned by the Northern Pacific Railroad, and consisted of about 63 houses. In 1968, the Montana Power Company (MPC) bought the community, and has controlled the pace and scope of commercial and residential development since. Through its subsidiary, the Sunlight Development Company, MPC has (since 1970) financed and/or constructed single-family dwellings, multi-unit apartments, mobile home spaces and recreational vehicle (RV) pads, and temporary housing for the construction work force associated with Colstrip Units 1 through 4, and Western Energy mining operations (Colstrip High School Bond Prospectus, 1981).

Between 1970 and 1980, Western Energy and MPC developed about 960 housing unit in Colstrip. It has been estimated that in 1980, 1,050 units were avilable in Colstrip (Mountain West Research, Inc., 1981). Of the total, 250 were single-family homes, 292 were multi-unit dwellings, and 508 were mobile homes (Reardon, 1982).

In January 1982, the Sunlight Development Company reported that 1,403 permanent housing units and 906 temporary units are available, and 405 more units are under construction. In addition, 124 additional single-family units are proposed, and 224 additional lots are available for development (Reardon, 1982).

Costs of housing are higher in Colstrip than Forsyth. Homes that cost $80,000 to $85,000 in Colstrip are priced at $50,000 to $60,000 in Forsyth. Apartment rentals in Colstrip are $155 per month for a one bedroom, $205 to $350 per month for a two bedroom, and $255 to $450 per month for a three-bedroom unit. Houses rent for over $500 per month. Installed mobile homes rent for $280 to $370 per month (Mountain West Research, Inc. 1981; Reardon, 1982).

There are few vacancies in Colstrip today. Roughly twelve unsold homes are being held for permanent operator personnel at Colstrip Units 3 and 4. Few, if any, houses are available for rent. Some trailer and RV spaces are available. The bachelor camp is at 96 percent of capacity (Reardon, 1982).

Current plans are to convert the Big Timber, Sweet Grass, and Stillwater mobile home pads to single-family lots after the construction phase for Colstrip Units 3 and 4. This would make available 550 more lots, in addition to the 224 potential lots mentioned above. The temporary construction work force housing will be maintained after the construction phase to house the yearly maintenance crews (Reardon, 1982).

Baseline projections of housing demand in Colstrip are contained in Table 13, Appendix I. Housing demand is expected to peak in the fourth quarter of 1982 at 2,731 units, decline 62 percent to 1,042 units in

1985, and gradually increase to 1,171 units in 2010. The projected baseline peak housing demand is 152 units fewer than the existing units, plus those under construction and proposed (Western Analysis, 1982).

i. Education

Colstrip School District #19 currently operates two elementary schools and a junior-senior high school complex. The Isabelle Bills Elementary School is a masonry structure completed in 1978. It includes a large library and gymnasium, in addition to classroom and office space. In mid-January, 1982, the enrollment was 370 students. Instruction is offered from kindergarten to sixth grade. Class sizes range from 17 to 28 pupils and the average class size is 20.6. Children attending the Isabelle Bills School live predominantly in the original section of the Colstrip townsite and Castle Rock neighborhoods (Tokerud, 1982).

The Big Timber, Sweet Grass, and Stillwater mobile home neighborhoods, located north of the original Colstrip townsite, are served by the Pine Butte Elementary School, a modular, wood-frame building. It is intended to be a temporary facility until a new Pine Butte School (under construction) is ready for student occupancy in the fall of 1982. The mid-January, 1982 enrollment at Pine Butte School was 340 students, in kindergarten through sixth grades. Class sizes range from 14 to 21 students, with an average class size of 17. (Tokerud, 1982).

Both elementary schools have large physical plants and have space for many more students. Accreditation standards for class size established by the State Board of Education are the principal limitation to increased school enrollments. Current minimum accreditation standards limit elementary classes to a maximum of 24 students in kindergarten, 26 students in the first and second grades, 28 students in the third and fourth grades, and 30 students in grades five through eight (Montana Board of Public Education, 1976). At present, two kindergarten sessions in the Isabelle Bills School, each with 28 students, exceed accreditation standards. All other classes are well below the accreditation standards. Using the minimum accreditation standard as a guide, the existing elementary school classroom configuration could accommodate up to 321 students. There are 119 available vacant student spaces in the Isabelle Bills facility and 202 available spaces in the Pine Butte School. In mid-January, 1982, the Colstrip elementary school district was being operated at approximately 69 percent of capacity (Hofeldt, 1982).

Colstrip Junior High School is located behind the high school in a modular, wood-frame structure that was erected in the early 1970s to accommodate increased school enrollments associated with the construction of Colstrip Units 1 and 2. The building will need to be replaced in the near future. The seventh- and eighth-grade enrollment is 158 children and the average class size is 21.1 students, well below the accreditation maximum class size of 30 students (Tokerud, 1982).

Colstrip High School is a masonry structure. It was erected in 1944 and remodeled in 1966 and 1978. A modular wood-frame structure was recently added to the north side of the high school for temporary use

until the proposed new high school is completed. The new high school building will occupy 136,000 square feet of space and accommodate 500 students. It will include space for the basic educational program, vocational education, a 600-seat auditorium, 2,000-seat gymnasium, indoor swimming pool, and central food facility for the entire school district. The new high school will cost $13,074,250, of which $3,367,833 is being paid for by a grant from the Montana Coal Board. When the new high school is completed in the fall of 1983, the current high school structure will be converted to a middle school for grades six through eight (Schye, 1982).

Secondary school accreditation standards limit class sizes to 30 students except in instrumental and choral music, physical education, and typing, where classes can be larger. In addition, individual teacher/student loads are limited to a maximum of 160 students except in the areas noted above (Montana Board of Education, 1976). In mid-January, 1982, the Colstrip High School enrollment was 323 students. Class sizes ranged from one to 23 pupils, with an average class size of 9.1 students (excluding study hall). The largest individual teaching load for an instructor was 77 students. Given the size of its current physical plant and student/teacher ratio, the Colstrip High School enrollment could practically double before significant expenditures for instructional staff or facilitites would be necessary (Hofeldt, 1982).

Colstrip School District #19 currently employs 170 persons, including 12 administrators, 106 professional staff, and 52 support personnel (e.g., secretaries, custodians, cooks, etc.) (Montana Board of Education, 1976).

6. Public Finance

The following analysis of public finances in Rosebud County includes the three taxing jurisdictions of Rosebud County, High School District #19 (Colstrip), and Elementary School District #19 (Colstrip). It also includes the townsite of Colstrip, which is owned by Montana Power Company and managed by the Sunlight Development Company. The historical analysis includes an examination of historical revenues, expenditures, taxable valuation, and mill rates. The historical analysis was used in conjunction with information provided by informed officials familiar with the study area in making the baseline projections to the year 2018. The projections were developed using PUFMOD, a local government public finance simulation model developed by Western Analysis, Inc. (see Technical Support Document).

For the purpose of analysis and projections, all dollar figures have been converted to constant 1980 dollars using the GNP implicit price deflator.

a. Historical Conditions

During the period 1970 to 1980, real per capita taxable valuation increased 8.31 percent annually in Rosebud County due to industrial and

coal development in the area around Colstrip. Similar increases were experienced by the two school districts in Colstrip. In comparison, real per capita taxable valuation declined or increased at a much lower rate in comparable jurisdictions. Since 1975, the addition of generating Units 1 and 2 has increased Rosebud County taxable valuation about 30 percent. The additions of Units 3 and 4 are projected to increase the county's taxable value another 15 percent by 1986. Units 3 and 4 will thereafter decline in terms of relative importance as the property depreciates.

For Rosebud County and both Colstrip school districts, total operating expenditures and total expenditures increased significantly between 1970 and 1980 (Table 14, Appendix I). On a real per capita basis, the average annual rate of increase was 8.19 percent for total expenditures and 5.61 percent for total operating expenditures. Because of the sizable enrollment increases in the Colstrip schools, ranging from 150 percent to 444 percent during the period from 1970 to 1980, real total school expenditures per average number belonging (ANB) increased at most by 0.15 percent annually. Despite the real increases in virtually all major expenditure categories, mill levies in these three taxing jurisdictions decreased at an annual rate of between 5.43 percent and 6.72 percent. These declining mill rates reflect the increase in taxable valuation during this time period due to coal and industrial development.

Revenues experienced similar increases during this same time period. At the county level, total revenues increased 8.19 percent annually in real per capita terms. However, local revenues increased only 4.42 percent annually. The lower rate of increase in local revenues occurred in large part due to the change in the proportion of intergovernmental transfers as a revenue source. In 1970, intergovernmental revenues represented five percent of total revenues for the county; by 1980 they represented 34 percent of total revenues. This change in the revenue mix was consistent with comparable jurisdictions. A similar change was experienced by all governing units in the county due to the influx of Coal Board Grants received to mitigate the impacts of coal development. Of the $32 million of Coal Board Grants issued since 1977, approximately 51 percent of this money has gone to governing units in Rosebud County.

The historical public finance analysis for the Colstrip townsite covered the period from 1977 to 1980. Changes in accounting procedures precluded the inclusion of prior years in the analysis. However, the 1977 to 1980 period included much of the permanent population settlement and infrastructural development associated with the industrial and coal mining development in the area. The townsite has experienced a sizable increase of 30.30 percent annually in total real operating expenditures per capita, while locally generated revenues per capita have increased 22.57 percent annually, in real terms. The relatively higher rate of increase in per capita expenditures vis a vis revenues can be explained by the residential, infrastructural, and community service development that has occurred in order to establish and serve the growing permanent population in the townsite. Despite the differences in rates of increase between revenues and expenditures, the townsite operation has remained economically viable for Sunlight Development Company, based on available information (Reardon, 1982).

Exhibit 3

b. Baseline Fiscal Projections

Baseline fiscal projections for Rosebud County, the two Colstrip school districts, and the Colstrip townsite were estimated to the year 2018. Balanced budget scenarios were developed using PUFMOD for the three taxing jurisdictions. The Colstrip townsite projections were developed using per capita rates of change for each of the revenue and expenditure categories in the simulation model.

The balanced budget approach used in these projections provides an indication of what property taxes must be in order to balance the budget, given a predetermined level of expenditures and nontax sources of revenues. Using estimates of the expected taxable valuation and given the corresponding year's property taxes, the mill levies needed to generate that level of property taxes can be determined. Tables 15 through 17, Appendix I, contain the projections for Rosebud County, Colstrip High School District #19, and Colstrip Elementary School District #19.

The initial annual increases in real operating expenses per capita in Rosebud County result from the continuance of historical annual increases in general government and public safety expenses of 4.46 percent and 16 percent, respectively, through fiscal year 1983, when the population peaks. Thereafter, public safety expenditures increase at a declining rate until 1987 when the population stabilizes. Public services and transportation expenditures are assumed to continue their historic real per capita annual rates of increase of 1.17 percent and five percent, respectively, through 1986. These forecast percentage increases permit the continued development of these county services during this period of population growth. Thereafter, all operating expenditures are held constant in real per capita terms.

Infrastructural development is assumed to be near completion with regard to the county government, therefore capital outlays are assumed to be cut in fiscal year 1982 to their historic per capita level. Since Coal Board Grant funds for impact mitigation are expected to fall off dramatically, as are federal transfer payments, intergovernmental revenues are reduced by over 50 percent, bringing them back to prior years' per capita levels.

Based on these assumptions for Rosebud County, the estimates contained in Table 15, Appendix I show an increase of 25 percent to 47 percent in the major expenditure and revenue categories through fiscal year 1983. Thereafter, throughout the forecast period, there are moderate fluctuations in real terms reflecting changes in population. Between 1982 and 1990, mill levies decrease approximately 48 percent and thereafter rise by 2.17 percent annually. The later mill levy increase is due to projected declines in taxable value caused by decreasing coal production and the declining real values of industrial plant and equipment.

Operating expenditures per capita are held constant at 1981 levels in both the high school district and the elementary district, with one

exception. Elementary instruction expenditures are assumed to increase 6.50 percent through 1984, bringing per capita instructional expenditures back up to the 1980 peak of $2,171 per ANB. Since the additional teachers are expected to be only temporary, after 1984 instruction expenditures are assumed to return to historic levels.

The baseline projections for the high school district include the sale of $9.7 million in bonds, with debt service payments beginning in 1983 and extending through 2002.

Nonproperty tax school revenues are held constant in real per capita terms, with two exceptions: 1) county funds to the elementary district continue their historic 3.66 percent annual increase to supplement the funding for the additional temporary teachers; 2) per ANB federal funds to the high school decline 11.50 percent due to recent federal funding policies.

Tables 16 and 17, (Appendix I), contain details of the baseline forecasts based on these assumptions. As expected, revenues and expenditures are forecast to peak in 1983 and will thereafter exhibit moderate, generally downward-trending fluctuations.

Mill levies in these two balanced budget scenarios are more erratic than those forecast for the county due to the relatively greater influence of coal production and prices on the taxable valuation of the school districts.

Colstrip townsite baseline projections presented in Table II-18, Appendix I, include three major capital outlays as part of the baseline assumptions. All three projects are expected to be funded solely by Coal Board Grants. They include: 1) $1.1 million water treatment plant in 1981; 2) $150,000 for a new fire truck and storage facility in 1982; and 3) $300,000 for a snow blower and street cleaner in 1983 (Workman, 1982). No additional capital outlays are included in the baseline projections.

Operating expenditures are assumed to remain constant in real per capita terms with the exception of general expenditures, public services, public utilities, and housing expenditures. These four expenditures are assumed to increase in real per capita terms at their historic annual rates through 1984 (i.e., general expenditures, 3.05 percent; public services, 8.01 percent; public utilities, 14.29 percent; and housing, 16.19 percent). This will enable the continued development of townsite infrastructure and services for as long as the population continues to grow. The growth in residential and community services is assumed to be necessary to attract and maintain a permanent work force.

Real per capita revenues from housing rents and trailer park rents are forecast to decline after 1984, when the population peaks. Housing unit sales are projected to increase at a declining rate until 1987, when the population stabilizes (McIntosh, 1982).

Given the above assumptions, the Colstrip townsite managers can expect a 40 percent increase in real operating expenditures per capita by 1984, with no change thereafter. Real annual total expenditures and operating expenditures are forecast to peak in 1983 when the annual population peaks. Thereafter, expenditures, like revenues, fluctuate moderately with a downward trend through the remainder of the forecast period.

Exhibit 3

J. LAND USE

1. Present Land Use

The land use pattern and productivity of the 2,693 acres in Area C, Block I are similar to the rest of the Western Energy leasehold at the Rosebud Mine. Approximately 1,904 acres (71 percent) of Area C, Block I is rangeland, with 436 acres (16 percent) cultivated for wheat and 334 acres (12 percent) in hayfield production. The remaining acreage (1 percent) includes sandstone outcrops, clinker (locally known as scoria) pits, and a ranch yard. By comparison, rangeland uses make up about 67 percent of the Western Energy leasehold, 78 percent of Rosebud County, and 74 percent of the 45 million-acre Yellowstone River subbasin (Rosebud County Planning Board, 1979).

Coal development in Rosebud County has temporarily displaced about 3,350 acres of rangeland and 200 acres of cropland (Montana Department of State Lands, 1981). About 77 percent of the disturbance is due to the Rosebud Mine (Table II-14). Additionally, about 550 acres of land at Colstrip and Forsyth have been permanently converted to urban and industrial uses (Montana Department of State Lands, 1981). The cumulative impact of coal mining to date represents about 0.1 percent of rangeland in Rosebud County and about 0.2 percent of Rosebud County's cropland.

The cropland in Area C, Block I represents less than 0.6 percent of the 130,000 acres of cropland in Rosebud County. Principal crops are dryland winter wheat and alfalfa. Average production in Area C, Block I is about 30 bushels per acre for wheat and about 1.2 tons per acre for hay, while average production for Rosebud County is 29 bushels per acre for winter wheat and 1.5 to 2.0 tons per acre for dryland alfalfa (Prinkki, 1982). Production comparisons are presented in Table II-15 and field locations are shown on Figure II-21. Relic irrigation structures occur along Stocker Creek and operational irrigation structures occur along East Fork Armells Creek, but cropland within Area C, Block I is presently farmed on a dryland basis. This cropland is designated as class three and four lands under the Soil Conservation Service Land Use Classification System. Although this classification is considered marginal for crop production as compared to the United States as a whole, it is the best classification of croplands possible, given the regional constraints of low rainfall and a short growing season.

The rangeland in Block I represents less than 0.07 percent of the 2.5 million acres of rangeland in Rosebud County. Presently, rangeland productivity in Area C, Block I is about 0.15 AUMs per acre for grassland and shrubland, based on the Montana Soil Conservation Service Technical Guide (1979) for rangeland in "fair" condition, and about 0.2 AUMs per acre for ponderosa pine areas. Under optimum management, this could be increased to about 0.45 AUMs per acre for grassland and shrubland, and to about 0.23 for ponderosa pine (Appendix G, Table I). The average production level for southeastern Montana ranges from 0.25 to 0.30 AUMs per acre (Montana Department of State Lands, 1981).

TABLE II-14

SUMMARY OF LAND USE IMPACTS OF THE ROSEBUD MINE

Land Use Category	Pre-mining Use	Present Use[a]
Rangeland		
Grassland and Shrubland	16,500	14,683
Ponderosa Pine	7,440	7,290
Cropland	1,420	1,220
Mining Disturbance	640[b]	315
Mine Facilities and Associated Disturbance	0	424
Reclamation	0	2,011
Bond Release	0	57[c]
	26,000 acres	26,000 acres

[a] Estimated as of 1981 (Montana Department of State Lands, 1981).

[b] Unreclaimed spoils remaining from the original Northern Pacific Mine, and Burlington Northern railroad right-of-way spoils.

[c] County road

Exhibit 3

TABLE II-15

FIELD PRODUCTION IN AREA C, BLOCK I

Field[a]	Crop	Acres	Production[b]	Acres to be Disturbed
1	wheat/speltz	122	27 bu/ac	90
2	winter wheat	185	33 bu/ac	185

b Based on land owner interviews conducted in September, 1980 and 1981 as reported in Western Energy Company's Application for a Surface Mining Permit Area C, Block I. Production figures reported by Burlington Northern (Western Energy Company, 1981) are somewhat lower.

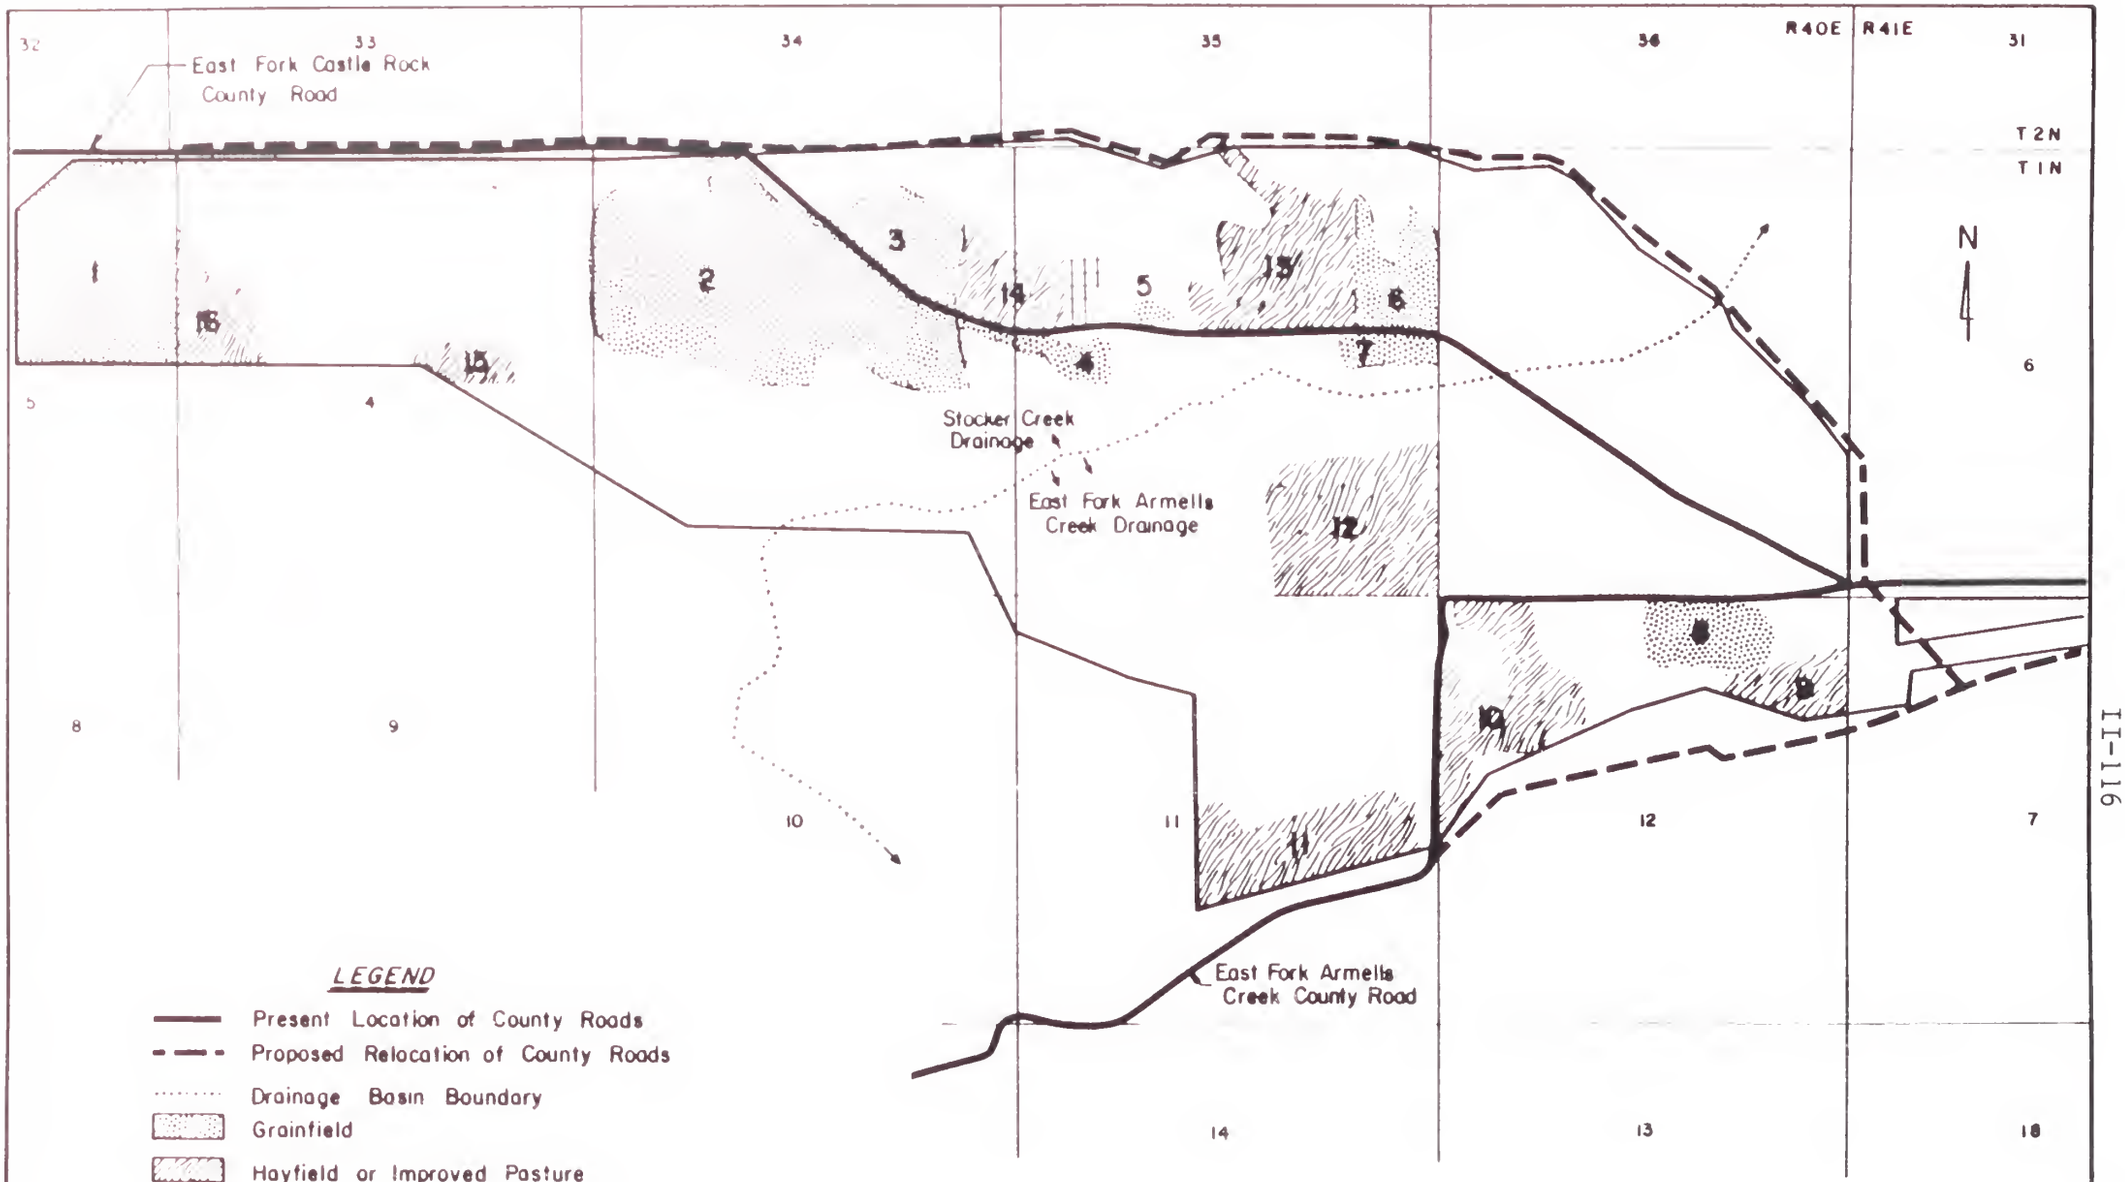

FIGURE II-21 AGRICULTURAL USE IN AREA C, BLOCK I

Exhibit 3

2. Federal Planning

Portions of the coal in the Rosebud Mine are federally owned and administered by the Bureau of Land Management. The BLM has developed a land use plan called the Management Framework Plan for the South Rosebud Planning Unit. The mining plan described in the mine permit application for Area C, Block I is compatible with the recommendations made in the Management Framework Plan.

3. Local Land Use Planning

The future land use plan for Colstrip is contained in the Rosebud County Planning Data Book and Comprehensive Plan (1979). Since Colstrip is a privately owned company town, it is not subject to city council-adopted regulations or zoning plans. The future land use plan for Colstrip as designed for Montana Power Company has been approved by the Rosebud County Planning Board.

K. TRANSPORTATION

Rosebud County's transportation network consists of a series of roadways, two railroads, five commercial truck lines, a bus line, and a county-owned and operated airport located in Forsyth. Road travel is the most common mode of transportation in Rosebud County. Graveled county roads and two-lane state highways service the Colstrip area (Figure II-22). Federal Aid Primary (FAP) 39 connects Colstrip with Interstate 94, the major east-west highway to the north, and with FAP 37 (US 212), a heavily used east-west highway to the south. Access to Area C, Block I is along FAP 39, located about three miles east of the area, and by Castle Rock County Road running adjacent to the area.

The Montana Department of Highways is in the process of reconstructing 31 miles of FAP 39 in order to meet the increased traffic demand resulting from coal development in the area. A seven-mile section south of the intersection with I-94, and a 5.8-mile section at Colstrip have already been completed, with the entire project scheduled to be completed in spring, 1983 (Randall, 1982). The reconstruction consists of widening the roadway, resurfacing, realignment where needed, and providing grade separations at the four places where FAP 39 and the Colstrip railroad spur intersect. The theoretical capacity of the reconstructed highway is estimated to be 200 vehicles per hour (Colbert, 1982). These reconstruction projects are financed in part by coal severance tax augmented with Federal Aid Primary Funds.

FAP 37, which intersects FAP 39 at Lame Deer, leads west to Busby, Crow Agency, and Hardin, and east to Broadus in Powder River County. This road is heavily used by trucks and the Department of Highways is currently planning to reconstruct 27 miles of FAP 37 between Crow Agency and Busby, although there is no scheduled completion date at this time.

Traffic on the major highways leading to Colstrip has increased considerably since coal development at Colstrip (Table II-16). Traffic on FAP 37 increased about 77 percent from 1968 to 1980. Traffic on FAP 39 from Colstrip to I-94 increased about 562 percent from 1968 to 1981. The majority of the increase in traffic levels is due to power plant construction with about 20 percent of the increase contributed by mining activity. This increased traffic and the deteriorating road conditions made FAP 39 extremely unsafe (rated 1 on a scale of 20 by the Montana Department of Highways), but the scheduled reconstruction projects should alleviate many of the dangers involved in driving this highway.

A railroad spur connects Colstrip and the Burlington Northern mainline about 25 miles to the north of Colstrip (Figure II-22). This spur serves both Western Energy's Rosebud Mine and Peabody's Big Sky Mine, 7.5 miles south of Colstrip. Coal from the Rosebud Mine is shipped to such places as Billings, Montana; St. Paul, Minnesota; and Bayfront, Wisconsin. On certain occasions, the Colstrip spur is also used to haul heavy machinery for construction projects. An average of three loaded unit trains per day used the Colstrip spur in September, 1981 for a total of six trips per day, counting returning empty trains (Coefield, 1982).

L. RECREATION

1. Urban Recreation Resources

Most formal recreational activities in Colstrip are provided by the Colstrip Area Recreation and Parks Association (CARPA), a citizen organization concerned with recreation in Colstrip. The organization is supported by contributions from the energy corporations located in Colstrip (about 90 percent of the total capital and operation budget) and fees from association memberships. At present, CARPA numbers 287 family, adult, and youth memberships (Noyd, 1982). Resources available under the aegis of CARPA include a 51-acre park system, a swimming pool, a wading pool, three tennis courts, three basketball courts, and five playgrounds for young children. Indoor facilities are provided at the Colstrip Community Center and comprise 16,000 square feet of space allocated to two handball/racquetball courts, a weight/exercise room, a basketball court, and a meeting room (Colstrip High School Bond Prospectus, 1981). Other indoor facilitites include a library and a former construction dining hall, which has been converted and is currently used for meetings and other social gatherings (CARPA Recreation Guide, 1980). Colstrip is in the process of creating a new outdoor recreation complex, to be named Stillwater Park, which will comprise two softball and one baseball fields, a soccer field, an outdoor basketball court, and a playground area (Mountain West Research, Inc., 1980).

Nearly 60 percent of surveyed residents considered the adequacy of organized recreation in Colstrip to be good to excellent. Over 51 percent considered Colstrip area recreational opportunities to be adequate to great; about 45 percent considered them to be limited or insufficient. Popular organized recreational activities of surveyed residents include baseball/softball (40 percent), movies/dining (83 percent), dancing (55 percent), and bowling (46 percent). Facilities for these activities are limited in Colstrip except for baseball/softball fields.

2. Nonurban Recreation Resources

Developed, public recreation resources in the area are limited. Four federal, four state, and one private nonurban recreation site have been developed within the county. Table II-17 summarizes facilities and activities available at the sites.

The U.S. Forest Service manages 95,827 acres of forest land for recreational purposes within the county and maintains 217 road miles of access within that area (Montana Department of Fish and Game, 1978). In addition, some 230,000 acres of public land managed by the Bureau of Land Management are available to public use. A motocross course, rodeo grounds, and the Rosebud Park are available in the Forsyth vicinity (Montana Department of State Lands, 1981).

The Tongue River Reservoir, located in Bighorn County, about 55 miles south of Colstrip, is the only major water impoundment in Rosebud

Exhibit 3

County. The reservoir is largely undeveloped for recreation, although three primitive camping areas exist nearby. The reservoir fishery offers a number of warm-water game species. The Tongue River below the reservoir also offers recreational resources and opportunities and sustains a trout fishery in its upper reaches and a warm-water fishery in the area downstream of Birney. Access to the river upstream of Ashland, however, is limited by private owners and the Northern Cheyenne Indian Reservation. The Yellowstone River also is available for boating, fishing, and other recreational activities; two fishing access sites and two recreation areas are located on the river near Forsyth (Mountain West Research, 1980). Montana Power Company allows access to Castle Rock Lake, the 152-acre surge pond that provides make-up water for the Colstrip generating units and the Colstrip public water supply (Williams, 1982).

The results of recreation surveys conducted in 1976 and 1977 by state authorities indicated that area residents prefer recreation in undeveloped, natural areas. A survey conducted by Western Analysis (1982) confirms these findings. Over 75 percent of surveyed adults camp, picnic, hunt, or fish. Sixty-seven percent enjoy swimming. Outdoor recreation in the Colstrip area reportedly is not now approaching the capacity of the area's recreational resources (Montana Department of State Lands, 1981). Still, federal authorities anticipate increased demands for recreation, particularly motorized recreation, picknicking, overnight camping, and fishing. Federal land resources are to be managed to satisfy such demands (Mountain West Research, 1980).

M. CULTURAL RESOURCES

Several cultural resources surveys have been conducted since 1971 that include some or all of the lands within Area C, Block 1 (the direct impact area) and surrounding one-mile buffer zone (the indirect impact area). DSL requires a buffer zone to preserve, to the extent possible, important cultural resources from the effects of blasting. The seismic effects of blasting can affect rock art, rock shelters, and historic sites with standing structures. Table 1, Appendix M summarizes this survey information. A summary of cultural resources found and their National Register eligibility follows.

1. Area C, Block 1

Nine cultural resources sites were recorded during surveys within Area C, Block 1. Five of these are prehistoric, one is historic, and three are of unknown affiliation. These sites are summarized below and in Table 2, Appendix M.

a. Prehistoric Sites

- The Cooley Site (24 RB 1059). This site was first recorded in 1973 (Fredlund and Fredlund, 1974) and re-evaluated in 1980 (Fredlund, 1980) and 1981 (Steere, 1982). The applicant's archaeological consultant (Mineral Research Center) reports the site to be a prehistoric temporary campsite. It consists of a lithic scatter located next to a spring and evidences subsurface cultural deposits (Steere, 1982). The 1981 reevaluation and testing indicate the site is much larger than initially thought (Steere, 1982).

- The Medicine Root Site (24 RB 879). This site was recorded in 1981 as a prehistoric occupation site. It consists of a large lithic scatter, and initial testing revealed the presence of subsurface cultural deposits (Mineral Research Center, 1982).

- The Fadhl Kill Site (24 RB 299). This site was first recorded in 1973 (Fredlund and Fredlund, 1974) and was reevaluated in 1981 (Steere, 1982). The site is recorded as a prehistoric bison impoundment, kill, and processing site. The consultant feels it may also represent an occupation site. All test pits revealed subsurface cultural deposits (Mineral Research Center, 1982).

- The Tripoint Site (24 RB 873). This site was first recorded in 1981 as a prehistoric hunting lookout, lithic workshop, and temporary occupation site. Testing revealed no subsurface cultural deposits (Mineral Research Center, 1982).

- The Farley Lookout Site (24 RB 1058). This site was first recorded in 1973 (Fredlund and Fredlund, 1974), reevaluated in 1980 (Fredlund, 1980), and tested in 1981 (Steere, 1982). The site was recorded as a hunting lookout and temporary campsite. Testing in 1981 revealed subsurface cultural deposits (Steere, 1982; Mineral Research Center, 1982).

b. Historic Sites

- Fadhl Homestead (24 RB 884). This historic homestead complex, still in use today, was first recorded in 1981 (Mineral Research Center, 1982) and is thought to be underlain by portions of the prehistoric Fadhl Kill Site (Steere, 1982). The complex includes thirteen standing wood frame buildings that date back to the 1920s when the site was first homesteaded. Numerous historic documents on the homestead allow compilation of a detailed ownership history (Mineral Research Center, 1982; Steere, 1982).

c. Sites of Unknown Affiliation

- The Three Ring Site (24 RB 1060). This site was first recorded in 1973 (Fredlund and Fredlund, 1974) and reevaluated in 1980 (Fredlund, 1980). The site consists of three stone circles of unknown cultural or temporal affiliation. The rings may be prehistoric tent rings or may be associated with the nearby Cooley Place Homestead. No artifacts were found in association with the stone rings (Fredlund and Fredlund, 1974; Fredlund, 1980).

- The Lynn's Square Site (24 RB 1071). This site was first recorded in 1973 (Fredlund and Fredlund, 1974) and reevaluated in 1980 (Fredlund, 1980). The site consists of a rectangular sandstone rock structure. No cultural material was found associated with the feature or in the test pit. The feature's function and origin are unknown (Fredlund and Fredlund, 1974; Fredlund, 1980).

- Gene's Vision Quest Site (24 RB 1072). This site was first recorded in 1973 (Fredlund and Fredlund, 1974) and reevaluated in 1980 (Fredlund, 1980). The site consists of two rock structures located on the crests of two knolls adjacent to the historic Doc Taylor's Homestead site. The origin and function of these features are unknown. The consultant suggests it could be a prehistoric vision quest site or could be associated with the historic homestead and may possibly be children's forts (Fredlund, 1980).

Based on the information currently available on the nine sites, the Three Ring, Lynn's Square, Tripoint, and Gene's Vision Quest sites appear to be ineligible for nomination to the National Register based on the lack of potential for yielding additional information on the prehistory or history of the area. Although the Medicine Root site has been tested, its extent indicates the need for additional testing in order to evaluate its potential eligibility. The Cooley, Fadhl Kill, Fadhl Homestead, and Farley Lookout sites may be eligible for nomination because of their potential to yield additional information on the history and prehistory of the area.

DSL, the State Historic Preservation Office (SHPO), and the Office of Surface Mining (OSM) had not yet received the final report on the Archaeological Survey of Area C, Block I and buffer zone when this EIS was finalized. These agencies will review the report and assess the potential of the sites for National Register eligibility at the earliest possible date. Determinations of eligibility will be sought from the keeper of the National Register prior to any disturbance.

2. One-Mile Buffer Zone

Twenty-four cultural resources sites and one "Minimal Activity Locus" (MAL) were recorded during surveys within the one-mile buffer zone around Area C, Block 1. A "Minimal Activity Locus" is defined as a location that has a small amount of cultural debris and has the potential to yield limited information to the interpretation of prehistoric or historic cultural activity (Fredlund, 1980). Sixteen of these are prehistoric, six are historic, and three are multi-component sites consisting of both historic and prehistoric components. A brief synopsis of these sites is presented in Table 3, Appendix M.

Of the 24 sites recorded within the buffer zone, only one (How Dry I Am Site) has been determined ineligible for nomination to the National Register (Montana State Historic Preservation Office, 1981). This determination was made as a part of the review of an adjacent area of the Rosebud Mine (Area B). Fifteen other sides (McDonald Quarry, Lovelace Memorial, Petro City, Rabbit Ridge, Rocky Top, Dusty Shelter, Caskey 320, Castle Rock Post Office and Homestead, P.E. Davis Rock Art, Wheatfield Vista, Connie's Gallery, Pottery, Sunburn Out, Pigeon, and Normand Estates sites) appear to Western Energy to be ineligible for the National Register based on their lack of potential to yield useful information and/or their lack of integrity as a site (due to natural deterioration, destruction, alteration, etc.). The Forsite, East Fork, and Albino Deer sites need testing before National Register recommendations can be made. This however, would be necessary only if mining were to expand into these portions of the buffer zone at some future point. It is recommended that testing be done on the minimal activity locus (MAL 1401) to determine whether it warrants a site designation prior to considering a National Register recommendation. The Sly Bison, Insite, Cooley Place, Doc Taylor's Place, and the Muskrat Homestead sites are potentially eligible for the National Register and official determinations of eligibility will be sought.

No Native American concerns as defined under the American Indian Religious Freedom Act of 1978 were identified for Area C, Block I or the buffer zone. However, much of the work conducted in the area was done prior to the law's enactment and no consultations with Native American groups have been made.

Exhibit 3

N. AESTHETICS

Determination of the aesthetic values of any given place is a subjective process determined by each individual's perceptions, tastes, and values.

Texture, color, relief, and contrast make up most of what we see in a landscape. At the Rosebud Mine, Area C, Block I, the texture varies from the even range grasses on gentle slopes to smooth, linear sandstone outcrops, to the jagged profile of ponderosa pines on the skyline. Colors are mostly neutral: pale yellow, tans, browns, and greys, with dark greens in the timber and scattered orange, rust, and purple clinker outcrops. Relief is low to moderate and slopes are generally broken only by the scattered sandstone or clinker ledges on the upper slopes and ridges. The most striking contrast is between the light range grass covering open slopes and the dark ponderosa pine stands along the higher ridges and divides. In cropland areas, a distinctive contrast exists between the long, straight plow rows (and subsequent linear crop lines) and the free-flowing, gradational contacts between natural vegetative types.

The sounds that currently dominate Area C, Block I, are typically natural and rural, associated with ranching, rangeland farming, and light traffic on the county road. Block I is sufficiently removed from the present mining activity around Colstrip that the sounds of that activity cannot readily be heard.

CHAPTER III

ANALYSIS OF IMPACTS

A. GEOLOGY

1. Topography/Geomorphology

The post-reclamation topography would approximate the existing landscape in Area C. A general smoothing of the topography and a slight reduction in elevation would be the obvious changes, with drainages and divides restored to their approximate pre-mine location. The current Block I plan does leave an undisturbed sandstone ridge in part of the southern permit area. This would be the only undisturbed bedrock in the permit area. A proposed post-mine topographic contour map for Area C, Block I is included in the mine permit application and in the Technical Support Document.

While the topography of Area C would be modified, the landforms would largely be constructed and continue to develop on reclaimed spoils materials. Due to the proposed reclamation techniques (see Section F, Soils), these surficial materials would be highly variable over space and with depth. Consequently, broad landscape units would not develop, but rather a range of land forms would develop on a single anisotropic medium.

The characteristics of the surficial materials anticipated under post-reclamation conditions are summarized in Table III-1. The characteristics of these materials, which determine their erodibility, are in themselves strongly influenced by the techniques employed during reclamation.

Studies of currently reclaimed spoils in the Colstrip area and estimations of source area sediment yields under post-mining conditions (see Technical Support Document for detailed studies), suggest that yields would be moderate in comparison with undisturbed conditions. The highest yields can be anticipated on topsoiled spoils on which only a limited vegetation cover has developed. As vegetation cover (including root density and soil organic content) increases during reclamation, source area sediment yields will decrease.

Other large scale sources of instability in the reclaimed landscape could include accelerated erosion at the highwall interface and subsidence due to settling of the spoils. The long-term significance of these problems are difficult to assess.

There is a potential for increased infiltration along the highwall zone, which could result in piping and the formation of gullies. Differential erosion rates between the competent bedrock and the spoils materials may also occur at the interface, which could result in modification of drainage profiles and base levels, accelerated erosion, and local diversions of drainages. Subsidence and differential settlement may also result in a range of problems.

TABLE III-1

GENERALIZED CHARACTERISTICS OF RECLAIMED LANDSCAPE

Nature of Surficial Materials	Range of Slope Gradient (%)	Vegetative Cover (%)	Drainage Density (Mi/Ml^2)	Infiltration Rate (In/hr.)	Estimated Source Area Sediment Yield ($Acre/Ft/Mi^2$)
Unconsolidated spoils material with sandy loam or loam texture. Bulk densities of 1.3 to 1.8.	Smooth rolling topography <20%. Only limited areas over 10%.	First 3 years after disturbance: 25%. 3-10 yrs. following revegetation: 70% of weeds + grass.	5-8 mi/mi^2	Highly dependent on treatment. 2-4 in/hr.	0.04
Overlain by topsoil. Low organic content (1-2%) and very little armoring.		After 10 years: 75% vegetative cover			

Note: method of calculation discussed in detail in Technical Support Document.

Exhibit 3

2. Stratigraphy

The portion of the Tongue River Member that constitutes the Rosebud coal overburden would necessarily be disrupted in mining the Rosebud coal seam, and the backfilled material would not have the same stratigraphic characteristics as the undisturbed unit. Inasmuch as the overburden has no unique or intrinsic value, the disruption to this stratigraphic section would not produce a significant impact.

3. Overburden

Mining of the Rosebud coal using conventional dragline overburden removal techniques would nonselectively strip and mix the overburden materials. Studies by Dollhopf et al., (1978, 1979) indicate that "normal spoiling" of overburden results in as good a mixing of the spoiled material as can be reasonably achieved with a large dragline. While large-scale mixing would be achieved, the degree of such mixing is limited by the size of equipment to be employed. Pockets of essentially unmixed and undiluted overburden would be preserved in the reclaimed spoils. Dollhopf et al. (1981) state that materials (exceeding state suspect levels) found in the overburden that make up less than five percent of the overburden in a single test hole are almost never detected in the post-mine spoils. They further found that materials (exceeding state suspect levels) constituting 5 to 15 percent of a hole were generally found in pockets in the spoils, though often diluted. Overburden materials exceeding state suspect levels and constituting greater than 15 percent of the overburden tested were always found exceeding state suspect levels in some sample(s) from the spoils. Table II-2 shows the overburden holes in which suspect materials in the overburden exceed the state suspect levels and what percentage of the samples are in exceedance for each suspect parameter.

Table II-2 suggests that manganese and cadium do not exceed suspect levels in significant volume in Area C, Block 1. The remaining parameters (electrical conductivity, nickel, molybdenum, and sand) all exceed state suspect levels in enough samples to be potentially significant.

An uncertainty exists regarding the drawing of inferences about spoils geochemistry based on the available overburden data. This uncertainty is related to the findings of Dollhopf et al. (1981) in their Western Energy Company Area B study that overburden sampling on a grid pattern with hole density similar to that of Area C (1500- to 2000-foot centers) is only about 50 percent reliable in predicting the occurrence of unsuitable overburden material. (Note: The DSL is currently reviewing its guidelines regarding overburden sampling procedures and sampling density requirements.)

Nevertheless, review of the existing overburden data relative to Western Energy's mining plan suggests that, while stripping and replacing the overburden would result in a material having the same overall bulk chemistry characteristics as the undisturbed materials, several other impacts would likely occur, as follows:

Near-surface electrical conductivity across the mined area would be generally reduced.

- o Localized areas of molybdenum, nickel, and sand concentrations above DSL suspect levels may be created in the near-surface spoils.
- o Very localized areas where cadmium concentrations may exceed DSL suspect levels in the near-surface spoils may be created.
- o Present near-surface materials with high soluble salt contents (electrical conductivity) would be buried in the spoils, thus making the soluble salts available for solution in groundwater.

A discussion of the significance of trace element concentrations, electrical conductivity, and sand content in reclaimed spoils is presented in Chapter III, Sections B and F, and in more detail in the Technical Support Document.

4. Structure and Paleontology

There would be no foreseeable impact on the geologic structure or paleontology of the area as a result of strip mining. However, the structure, particularly the inferred faults in Area C, may have an impact on the recovery of coal in the proposed mine. Mining through a fault having a displacement of 70 feet paralleling the highwall would necessitate a discontinuous pit development in the fault area to get the pit floor down to the coal level. Such a mining procedure would probably leave one or more cuts of coal unmined and irretrievable.

5. Geologic Hazards

No major geologic hazards would result from strip mining, though some instability due to settling in the spoils would occur for a number of years after reclamation. Minor settlement problems have been noted by DSL personnel in spoil areas at the existing mine. settlement cracks ranging up to three feet deep in a small area of newly-graded but untopsoiled spoil in Area B, an area of small "sinkhole" features at the toe of a slope in a topsoiled and seeded portion of Area B, and a recent subsidence feature where spoil is settling away from the crest of a backfilled endwall. These problems have occurred within the first three years after regrading. The instability of the backfilled spoils may preclude construction of large structures on the reclaimed spoils until they are stabilized. Normal agricultural use of the reclaimed spoils would probably not be affected.

The proposed limitations on blasting, in terms of weight of explosive per delay charge and associated ground motion in the vicinity of structures, meets the requirements of 10 CFR 715.19. There is some evidence that the proposed limit of one in/sec. peak particle velocity

may allow minor damage in structures, consisting of small plaster cracks or loosening of paint. The limitation on explosive weight would likely generate ground motions that are much lower than the suggested limit, based on analyses of numerous blasts at other surface coal mines. There is no evidence that this shallow blasting would cause earthquakes.

Generally, the effects of blasting on groundwater supplies adjacent to Western Energy's or Peabody Coal Company operations is believed to be insignificant. According to a seismic study conducted in Montana by Ernest Bond, neither groundwater flow nor quality were adversely affected. Another study conducted by Berger Associates states that aquifers show little or no affect to coal mine blasting activities. The report states the maximum effects extend out from the blast hole a distance ranging from 140-160 feet. Water quality samples obtained after the blast indicated no change in water quality characteristics.

6. Resources

Coal resources would be diminished by the 23.7 million tons of Rosebud coal to be mined in Area C, Block I. In addition, approximately 9.6 million tons of McKay coal in Area C, Block I would probably become an irretrievable resource if not mined when the Rosebud is removed. Any reserves that may be calculated in the Stocker seam would also be irretrievably lost, since it is highly unlikely that either the Stocker or the McKay would ever become more economic to produce than at the time of mining the overlying Rosebud seam.

B. HYDROLOGY

The hydrologic impacts section addresses the influence of both existing and proposed mining on the groundwater and surface water flow, quality, and use within the hydrologic study area (Figure II-3). This section examines the anticipated impacts for the five-year mine plan period in Area C, Block I and considers Rosebud Mine Areas A, B, C, D, and E and Peabody's Big Sky Mine, with respect to cumulative impacts on groundwater use and surface water flow and quality over the entire mine life and 100 years beyond.

1. Groundwater

The purpose of the groundwater section is to specifically address the influence that existing and proposed mining activities would have on the quantity and quality of groundwater, either originating in or flowing through the hydrologic study area. The potential for impacts by disturbing the groundwater flow system are straightforward. It must be determined: 1) whether or not mining would deplete or contaminate aquifers to the extent that it would affect existing or future users of groundwater; or 2) if groundwater discharge to surface water would be depleted or contaminated to the extent where the potential for surface water use is affected.

a. Impacts Through Five-Year Permit Period

1) Groundwater Flow

a) Aquifer Properties

The spoiling of Rosebud overburden and removal of the Rosebud coal would modify hydraulic properties in the Rosebud Mine area. As a result of rubblizing the Rosebud overburden, the porosity of the backfilled material would be double that of the original material. The post-mining increase in effective porosity would allow for increased groundwater storage. However, this increase in effective porosity would also result in the slight retardation of the recovery of groundwater levels. Horizontal hydraulic conductivities of spoiled materials would be equivalent to pre-existing horizontal hydraulic conductivities. However, vertical hydraulic conductivity values would increase significantly from pre-mining values, and would be equivalent to horizontal hydraulic conductivities. The high vertical hydraulic conductivities would increase the potential for post-mining groundwater recharge. However, vertical hydraulic conductivity of spoils is only one of several factors affecting actual recharge rates.

b) Groundwater Movement in Water-Bearing Strata

A regional, three-dimensional computer modeling effort was undertaken for this study because of the complex nature of the hydrologic study area. The geology consists of multiple thicknesses of geologic strata with variable hydraulic properties, cut by surface water drainages. Superimposed on this system are the five mine areas at the Rosebud Mine (A, B, C, D, and E) and the Big Sky Mine. Mining is in various

stages of progress in four of these areas: Rosebud A, B, and E, and Big Sky. The model has been used to depict the changes in the groundwater flow system as a consequence of mining.

The flow modeling performed at the Rosebud Mine has several limitations.

- o The model is regional in nature and includes assumptions on regional aquifer properties.

- o The model was calibrated with quantifiable known stresses included. If data did not exist such as for the proposed fly ash ponds, or if the stress was insignificant compared to the regional flow system such as the existing fly ash pond leakage it was not included in the model.

The modeling effort is considered to be a tool to determine the regional impacts on the flow system caused by mining. It represents a best estimate of how that system will react based on input parameters. The aquifers may respond differently when the stress of mining is imposed on the flow system because of stress induced aquifer property variation. It is impossible to quantify these variations until after they occur. If significant regional variation is the flow system is observed after mining has been taking plan for a time then it is advisable to reexamine and remodel the study area.

The model has allowed for a computation of changes in the groundwater system as existing pits are backfilled (slowly resaturating), while new pits opened (causing localized lowering of water levels).

Inflow to the Area C, Block I - initial boxcut pit has been estimated to be less than 125 gallons per minute (gpm) for each 14,000-foot pit using the method described by McWhorter (1980). The result of modeling for maximum boxcut pit inflow produced a "worst-case" inflow rate estimate of 110 to 120 gpm for a 14,000 linear foot pit.

After the boxcut has been developed and groundwater is removed from storage the average pit inflow for a 14,000 linear foot pit is estimated to range from 35-40 gpm. Based on the modeling results future pit inflows can be estimated to equal approximately 2.5 3.0 gpm per 1,000 foot of highwall.

Table III-2 shows the ranges of "worst case" results obtained by computer modeling for each mine area. The table presents the amount of drawdown at various distances from pit centers for each mine area for the five-year Area C mine plan. It can be seen that drawdown is usually small at a distance of 2,000 feet for any given year, except where the 2,000-foot radius includes previously mined and spoiled acreage (e.g., mine Area E). Actually, this manifestation is not drawdown, but rather, a slow recovery of water levels in spoils after mining.

The only water-bearing unit of significance that would be affected by mining is the Rosebud coal. The Rosebud overburden and interburden would

be impacted by mining, but neither stratum is consistently saturated; thus, the impact on these strata is not significant.

c) Recharge/Discharge Relationships

The impacts to be addressed within a discussion of recharge/discharge are: 1) whether or not recharge to the aquifer would be significantly impaired during the five-year mine permit period, and 2) whether or not there would be a significant change in the rates of discharge to surface water that would diminish surface water flow.

As stated in the description of the existing hydrologic environment (Chapter II, Section B), Rosebud Mine Area C is a probable recharge zone. A majority of East Fork Armells Creek above Colstrip receives groundwater (bedrock) discharge as do the coulees tributary to Rosebud Creek farther to the south.

The potential for impacts on recharge, particularly in Area C, can be gauged indirectly by examining the influence of mining on the potentiometric surface in the recharge zone. A computer program was used to determine that where Area C would be mined, there would be a maximum drawdown of 82 feet with a maximum radius of significant influence of 6,000 feet (Table III-2). This suggests that at some future time recharge loss would be reflected in the groundwater flow system.

A reasonable measure of changes in recharge, may be changes in discharge. Table III-3 shows a comparison, based upon results of computer modeling, of changes in groundwater discharge rates for each drainage area between 1983 (pre-mining effects) and 1987. The results show that no influences are seen within the mine plan period. A decline in water levels within a recharge area may cause some noticeable changes in discharge at some time. Despite increased evapotranspiration accompanying revegetation, the potential recharge capacity of the spoils would be higher than that of pre-mining conditions in Area C. In the long-term, mining Area C may increase recharge, resulting in increase flow in the Rosebud aquifer.

d) Groundwater/Surface Water Relationships

The potential for impact to surface and groundwater communication has been discussed in the previous section. Table III-3 shows the of influence of mining on discharge. By subtracting discharges between 1983 and 1987 shown in Table III-3, the maximum change in flow for East Fork Armells Creek and Stocker Creek has been estimated. The results of flow modeling show an average increase of 0.6 acre-foot per year in East Fork Armells and a net loss of one acre-foot per year in Stocker Creek.

The discharges to area drainages from the groundwater system are generally greater after mining (Table III-3). The larger discharges to surface waters are caused by a lowering of the water levels by mining. The changes in discharge are relatively small except for Miller and Coal Bank Coulees.

* Figures on this table were corrected from what they appeared in DEIS and Errata sheet. Refer to letter Nos. 17,Responses to Comments at end of text.

** % change from 1983 discharge amount

Exhibit 3

The discharge to these two drainages is controlled by mining at the Big Sky Mine. There are no studies completed for either coulee so it is not clear whether there is a real increase in groundwater discharge or whether the discharge is returning to pre-mining levels.

The changes in discharge are fairly small. In areas where discharge increases, water levels would increase. Because of these small changes it is anticipated that downgradient water levels would rise only slightly. This slight rise would be insignificant because of increased evapotranspiration. Decreases in discharge along Stocker and Rosebud Creeks and Richard Coulee would have the opposite effect.

2) Groundwater Quality

a) Valley Fill

Mining in the Rosebud Mine area would, over time, lower the water quality of valley fill material adjacent to spoils materials (refer to Figure II-15). However, in the first five years water quality in valley fill aquifers is not expected to change as a result of mining Area C, Block I. Waters discharging from existing spoils aquifers would continue to recharge the adjacent valley fill of East Fork Armells Creek and Stocker Creek. The TDS concentration in the valley fill of East Fork Armells Creek presently ranges from 1,600 to 2,300 mg/l. Recharge from the spoils would increase the TDS concentration in the valley fill material to approximately 2,500 to 3,500 mg/l, as is presently seen in the valley fill adjacent to the spoils in Areas A and B. These increases are due to existing mine activity and activity occurring over the first five years of the permit period.

There would be very little impact from spoils water discharge to Stocker Creek valley fill because the existing TDS values for Stocker Creek valley fill groundwater are equivalent to predicted spoils water TDS values. TDS values farther downstream in the valley fill of Stocker Creek presently range from 1,600 to 1,800 mg/l due to dilution by bedrock groundwater inflow from the west. Since this dilution effect should continue, the overall valley fill water quality should not change as a consequence of mining in Area C during and beyond the five year period.

Current valley fill in the study area TDS ranges from 1340 - 6000 mg/l with a mean of 2590 mg/l. Currently the water is being used for livestock watering, subirrigated hay fields and by WECO to water roads for the control of fugitive dust. Since water in excess of 4300 mg/l TDS is currently being used for these purposes in Cow and Pony Creeks, it is believed an increase of groundwater valley fill water quality from 2500 to 3500 mg/l will have little or no effect on future land uses. Those increases are caused and would be caused only by on-going mining during the first five years of the permit period.

*Indicates the first appearance of a term defined in the Hydrology Glossary.

b) Rosebud Overburden

In order to estimate the quality of Rosebud spoils water, a relationship was established between electrical conductivity* of extracts from the Rosebud overburden and actual TDS values for spoils groundwater located in mine Areas A, B, and E.

TDS values were calculated for 26 bore hole extract composite electrical conductivity (EC) values in Area C. TDS values obtained ranged from 1,600 to 8,800 mg/l. The highest TDS values occurred where the ratio of shale and clay to sand in Rosebud overburden material is highest. The average calculated TDS values for spoils water in Sections 1, 2, and 3 (from east to west) in Area C, Block I are 2,400, 2,500, and 5,200 mg/l, respectively, and compare favorably to measured TDS values from spoils wells in Areas A, B, and E, which range from 1,700 to 5,000 mg/l.

c) Rosebud Coal

This water-bearing unit would be essentially removed in Area C, Block I, except for the areas underlying the sandstone ridge. This pocket of coal would be isolated from the original recharge areas, and would receive recharge from the surrounding spoils in the future. With time, the better quality water in this pocket of Rosebud coal would be replaced by spoils water and would eventually become indistinguishable from spoils water.

d) Rosebud/McKay Interburden

The spoils aquifer in Area C would be in direct contact with the interburden and mixing may take place in localized areas because of potentiometric head differences. Areas of increased TDS in the interburden caused by spoils water would disperse through the unit with time.

e) Deeper Aquifers

Because of differences in potentiometric head, sub-McKay aquifers should not be impacted by mining in Area C.

3) Water Use

a) Water Quantity

Mining within the hydrologic study area has the potential for impacting present and future users of the groundwater resource. Mining would actually remove most existing wells and springs and would have drawdown effects on several others in the Rosebud Mine area. The dewatering effects of mining can cause a drawdown of the potentiometric surface. Wells would still penetrate the water-bearing unit, but the dewatering results in a greater depth to water.

Table III-4 lists the affected wells and springs that lie within the hydraulic area of influence, as calculated the computer model. The

[1]Will be mined out prior to 1987 and replaced

[2]Will be mined out post-1987 and replaced

[3]Indicates a well or spring that will not be removed by mining

[4]Three radii (2,000, 4,000, and 6,000 feet) were drawn from a point within each pit that would be mined for the year of the greatest effect due to mining (greatest drawdown)

(Refer to Plate B-2 in Technical Support Document for locations of wells and springs.)

Private wells without water rights designations are numbered as PW; those wells with water rights designations are WR, and developed springs are designated as SP.

table also shows the maximum possible drawdown throughout the life of the mine for affected wells and springs. It should be noted that the existence of some of these wells and springs is suspect.

Most of the wells and springs would eventually be mined and replaced. Each water well and developed spring lost directly because of mining would be replaced by a well completed in the sub-McKay aquifer.

The results of computer modeling show that twelve water wells and four springs (Table III-4) would not be destroyed by mining, but would experience declines in water levels. Although it is difficult to tell the exact influence this water level decline will have on spring flow without a site-specific study, it is possible that the effect of drawdown would be either to diminish flow or dry up these springs.

In the case of the twelve wells, the increased depth to the water level would not dry up the wells, but pumping costs would increase as a result of the pump having to lift water from a greater depth. The following summarizes, in a general way, the magnitude of pumping cost increases that may occur in the situation where a well has an original static water level of 150 feet, where the wire-to-water efficiency is maintained at 0.5 and desired discharge is fixed (Anderson, 1979).

Decline in Water Level (in feet)	Kilowatt Hours per 1,000 gallons	Electrical Pumping Costs (in cents per 1,000 gallons)
0	0.942	7.0654
10	1.005	7.54
20	1.07	8.03
30	1.13	8.48

If a value for electrical power of 7.5 cents/kwh is assumed (personal communication, Intermountain Rural Electrical Association), it can be seen that an increase in pumping costs of about 1.5 cents per 1,000 gallons would occur if water levels were drawn down by 30 feet.

For the average water user the change would not be significant because the difference in cost per month would be a matter of a few pennies.

If a spring is disturbed or affected by mining and if a future water supply is required to sustain the existing or future land uses, the company would be required to install a well and maintenance costs would be borne by the land owner. The estimated cost to complete a well, assuming that electricity is available at the site, and that the groundwater quality would not require treatment, is approximately $4300 to $4550.

WELL CONSTRUCTION AND COMPLETION COSTS

Well Construction	
Drilling[1] $75 - $90 an hour 10 hours	$750 - $900.00
Pipe[2] 6" - PCV - Schedule 80 150' @ $5.00 a foot	750.00
Gravel Pack/Mud/Cement/Stabilizers	250.00
Screen - PCV - 6" Schedule 80 Slotted 20' @ $7.50 a foot	150.00
Subtotal	$1900 - $2150.00

Well Completion	
Pump - 4" Sumbersible 1/2 hp 230 volt - single phase 5 gpm pumping rate	$450.00
Water Supply Control Switches	100.00
Electical Wiring - 400' @ $0.75 a foot	300.00
Pipe - PCV Schedule 80 150' @ $1.00 a foot	150.00
Surface Pipe - 100' @ $4.00 a foot	100.00
Adapter, Miscellaneous Material	200.00
Subtotal	$1300.00
Surface Pipe and Storage Installation	
Backhoe - 10 hrs @ $50.00 an hour	500.00
Storage Tank	600.00
Subtotal	$1100.00
TOTAL	$4300-4550

b) Water Quality

(1) Valley Fill

During the first five years of the permit period no changes in valley fill water quality or water use would be experienced due to mining in Area C, Block I. On-going mining activity will result in an increase in TDS concentrations in valley fill water adjacent to mined areas, and would lower water quality in valley fill material in East Fork Armells Creek and Stocker Creek making it slightly less suitable for stock watering than at present. However, the water would still be within the limits of the water quality standards presented in Chapter II.

(2) Rosebud Overburden and Rosebud Coal

These aquifers will no longer be available for use in mined portions of Area C, having been replaced by Rosebud spoils. The TDS concentrations predicted for the spoils aquifer will be about one and one half the concentration in the existing Rosebud overburden. However, concentrations should still be within limits for stockwater use and would be suitable for livestock watering.

(3) Other Aquifers

None of these lower aquifers would be impacted sufficiently to affect their present or future uses.

b. Impacts in the Rosebud Mine Area through the Life of Mine and 100-Years Beyond

This section addresses the influences that existing and proposed mining activities would have on the regional groundwater system in the Rosebud Mine area. As in the previous section addressing the impacts in the first five years of mining, the impacts on the groundwater system during the life of the mine and 100 years after mining are addressed. The anticipated cumulative impacts have been predicted by analysis of the results obtained from the application of the two groundwater models to the regional hydrologic system over the long-term.

It has to be determined: 1) whether anticipated mining would deplete or contaminate aquifers to the extent present or future users would be adversely impacted; or 2) if groundwater discharge to surface waters would be depleted or contaminated and the extent to which potential surface water use will be affected.

1) Groundwater Flow

a) Impacts to mine area potentiometric levels

The data obtained from the application of the three-dimensional model provides predictive information for groundwater flow in the Rosebud mine area. The data generated by the model has been displayed as groundwater drawdown maps of the Rosebud Coal in Figures III-1, III-2, and III-3, for the years 1988, 2017, and 2118. 1988 is the last year of the Area C, Block I permit period. 2017 is the last year of mining and 2118 is one hundred years after the last mine pit has been spoiled. Drawdown is measured from 1983 potentiometric surface values.

From these maps, the amount of drawdown at various distances from the mine pits has been determined. Table III-2 is a tabulation of the maximum anticipated drawdown. The amount of drawdown is dependant on numerous factors. These factors include the upgradient or downgradient location of the spoiled pits; the proximity to surface discharge sites and the location of pre-1983 spoiled areas where increased recharge has taken place. Figures III-4 through III-9 are time-drawdown plots for the

Rosebud coal in the various mine areas. They represent drawdown versus time for a central point in the mine area. The values have been taken from the 0 radius column in Table III-2.

The increase in recharge is a result of the previously discussed increase in effective porosity of the spoils material. The potentiometric surface in the area of increased recharge to the spoils have, in some cases, returned to greater than original potentiometric levels. This is illustrated by the negative drawdown values on Figures III-4 and III-9.

b) Recharge/Discharge Relationships

The increased recharge and changes in the direction of groundwater flow in the mine area have and would cause changes in the flow patterns throughout the mine area. Potential impacts to the groundwater recharge/discharge relationship in the long term may involve: 1) the effect that mining and spoiling would have on the recharge to the aquifer, and 2) whether there would be a significant change in discharge to surface water.

After spoils replacement, the recharge to the Rosebud and McKay aquifers will increase. The negative drawdown values shown on Figures 4 and 8 indicate that recharge has been enhanced by mining. Table III-3 provides the discharges to the various surface drainages in the area prior to mining and at 5, 34, and 135 years after mining commences. An inspection of the data indicates that the cumulative discharge to the surface drainages in the mine area would decrease during the life of the mine. However, the amount of this decrease in discharge is not significant throughout the area. Individual drainage discharge variation is at times significant. Specifically, the 14.8 percent reduction in the combined East Fork Armells Creek and Stocker Creek in 2017. This combined reduction in discharge is 4 percent in 2118 and it can be assumed that it would recover to its original amount at some time after 2118. This reduction in groundwater discharge to the East Fork Armells Creek and Stocker Creek drainages would serve to lessen the severity of the downstream water logging problems presently occurring along East Fork Armells Creek.

The overall effect of mining in 2118 would be the 0.8 percent increase in discharge over pre-mining amounts. This is indicative of the increased recharge to the mine spoils throughout the area.

As outlined above, mining activity will not have a major impact on the quantity of flow in the valley fill system. However, the impact of non-mining activities, i.e. municipal and industrial development, would continue to impact the quantity of flow in the system.

The increase in population in Colstrip has resulted in an increase in municipal water use. This has resulted in an increase in the amount of sewage lagoon discharge to East Fork Armells Creek to 210 acre-feet/year (Hydrometrics, 1982). The discharge represents 20 percent of the

total surface flow in East Fork Armells Creek at the gauging station 7.5 miles downstream of Colstrip. This along with the increase in urban runoff and seepage and the increase in precipitation amounts in recent years (Brandt, 1981; Hydrometrics, 1981), results in increased flow in the valley fill system. The result has been an increase in valley fill groundwater levels and higher stream-flows in East Fork Armells Creek downstream of Colstrip. The increased levels and flow contribute to the water logging problems presently being experienced at the Lee Ranch downstream of Colstrip.

2) Groundwater Quality

Based on existing data, it is not likely that total dissolved solids (TDS) in the spoils would exceed a mean concentration of 3500 mg/l. The major cations and anions within spoil water are expected to be calcium, magnesium, sodium, and sulfate. Areas most likely to encounter significant groundwater quality changes are areas in which clay rich overburden materials occur within restored aquifers.

An estimate can be made of the time required for spoil water to recover to pre-mine conditions. This type of estimate involves a number of assumptions and involves the use of experimental data. Notably column leaching studies done by Van Voast et al., 1978, have been used, in which Rosebud spoils were leached with distilled water and the electrical conductivity of leachate was monitored over time, as an indication of changing water quality (lower E.C. is indicative of lower total dissolved solids).

In order to view this situation in light of the worst circumstances affecting spoils water quality the leaching studies results were used in conjunction with recharge rates to project the time for recovery of spoils water. Specifically the average recharge rates were used to calculate the total length of time necessary in order for a certain number of pore volumes to pass through the replaced spoil as unsaturated flow. Most investigations have used column leaching studies in conjunction with the resaturation of spoils and consequent through flow as groundwater levels recover. Such projections do not model the worst case since recovery and groundwater through flow occur more quickly than recharge. However recharge quantities can in no way be discounted as insignificant. For example, on an annual basis, at a recharge rate of 0.12 inches per year, recharge on just an acre of land amounts to 3,258 gallons.

Some of the assumptions and data used are as follows:

1. Greatest decline in EC takes place in the first 3.4 pore volumes, where the electrical conductively drops from an initial value of 11,000 to 4,000 micromhos per centimeter. Specific conductance continues to decline with leaching to a value of 1,500 micromhos per centimeter at 17 pore volumes (this represents better water quality than pre-mining conditions).

2. It is assumed that flow of groundwater into and through spoils will occur more quickly than unsaturated flow from recharge and hence the unsaturated flow component from recharge will be the limiting factor in terms of leaching and hence spoil water quality improvement.

3. It is assumed that a reasonable average for spoil thickness is 80 feet. Actual post-mining spoil thicknesses will vary betwen 0-150 feet.

4. It is assumed that spoils have an average porosity of 30%.

5. Model calibration has indicated that at equilibrium the undisturbed overburden has a recharge rate of 2.5×10^{-5} ft/day. For purposes of modeling it was assumed that spoils recharge would be 10% higher or 2.75×10^{-5} = 0.12 inches/year

Based on the data and assumptions it can be calculated that the 3.4 pore volumes will pass through the spoil in 8160 years, while it will take 40,800 years for 17 pore volumes to pass. It must be noted that existing field data shows that undisturbed overburden has mean groundwater E.C. values of 1563 mmhos/cm, undisturbed Rosebud groundwater mean values for E.C. of 1741 mmhos/cm and relatively fresh Rosebud spoil water has a mean E.C. value of 3,450 mmhos/cm. The reader is cautioned that the results of column leaching studies may be used to predict general trends but the actual E.C. values obtained from leaching tests are not indicative of anticipated water quality in Rosebud spoils.

The variability of groundwater discharge to surface water drainages will also have changing effects on the quantity of water available from the groundwater system in the Rosebud Mine area. This will be a result of increases or decreases in discharge to the valley fill system or the potential reduction in spring flows as discussed previously.

3) Water Use

The variability of the potentiometric surface in the Rosebud mine area over time will cause variations in the ability to recover water from the Rosebud coal.

total surface flow in East Fork Armells Creek at the gauging station 7.5 miles downstream of Colstrip. This along with the increase in urban runoff and seepage and the increase in precipitation amounts in recent years (Brandt, 1981; Hydrometrics, 1981), results in increased flow in the valley fill system. The result has been an increase in valley fill groundwater levels and higher stream-flows in East Fork Armells Creek downstream of Colstrip. The increased levels and flow contribute to the water logging problems presently being experienced at the Lee Ranch downstream of Colstrip.

2) Groundwater Quality

Based on existing data, it is not likely that total dissolved solids (TDS) in the spoils would exceed a mean concentration of 3500 mg/l. The major cations and anions within spoil water are expected to be calcium, magnesium, sodium, and sulfate. Areas most likely to encounter significant groundwater quality changes are areas in which clay rich overburden materials occur within restored aquifers.

An estimate can be made of the time required for spoil water to recover to pre-mine conditions. This type of estimate involves a number of assumptions and involves the use of experimental data. Notably column leaching studies done by Van Voast et al., 1978, have been used, in which Rosebud spoils were leached with distilled water and the electrical conductivity of leachate was monitored over time, as an indication of changing water quality (lower E.C. is indicative of lower total dissolved solids).

In order to view this situation in light of the worst circumstances affecting spoils water quality the leaching studies results were used in conjunction with recharge rates to project the time for recovery of spoils water. Specifically the average recharge rates were used to calculate the total length of time necessary in order for a certain number of pore volumes to pass through the replaced spoil as unsaturated flow. Most investigations have used column leaching studies in conjunction with the resaturation of spoils and consequent through flow as groundwater levels recover. Such projections do not model the worst case since recovery and groundwater through flow occur more quickly than recharge. However recharge quantities can in no way be discounted as insignificant. For example, on an annual basis, at a recharge rate of 0.12 inches per year, recharge on just an acre of land amounts to 3,258 gallons.

Some of the assumptions and data used are as follows:

1. Greatest decline in EC takes place in the first 3.4 pore volumes, where the electrical conductively drops from an initial value of 11,000 to 4,000 micromhos per centimeter. Specific conductance continues to decline with leaching to a value of 1,500 micromhos per centimeter at 17 pore volumes (this represents better water quality than pre-mining conditions).

2. It is assumed that flow of groundwater into and through spoils will occur more quickly than unsaturated flow from recharge and hence the unsaturated flow component from recharge will be the limiting factor in terms of leaching and hence spoil water quality improvement.

3. It is assumed that a reasonable average for spoil thickness is 80 feet. Actual post-mining spoil thicknesses will vary betwen 0-150 feet.

4. It is assumed that spoils have an average porosity of 30%.

5. Model calibration has indicated that at equilibrium the undisturbed overburden has a recharge rate of 2.5×10^{-5} ft/day. For purposes of modeling it was assumed that spoils recharge would be 10% higher or 2.75×10^{-5} = 0.12 inches/year

Based on the data and assumptions it can be calculated that the 3.4 pore volumes will pass through the spoil in 8160 years, while it will take 40,800 years for 17 pore volumes to pass. It must be noted that existing field data shows that undisturbed overburden has mean groundwater E.C. values of 1563 mmhos/cm, undisturbed Rosebud groundwater mean values for E.C. of 1741 mmhos/cm and relatively fresh Rosebud spoil water has a mean E.C. value of 3,450 mmhos/cm. The reader is cautioned that the results of column leaching studies may be used to predict general trends but the actual E.C. values obtained from leaching tests are not indicative of anticipated water quality in Rosebud spoils.

The variability of groundwater discharge to surface water drainages will also have changing effects on the quantity of water available from the groundwater system in the Rosebud Mine area. This will be a result of increases or decreases in discharge to the valley fill system or the potential reduction in spring flows as discussed previously.

3) Water Use

The variability of the potentiometric surface in the Rosebud mine area over time will cause variations in the ability to recover water from the Rosebud coal.

2. Surface Water

A surface runoff model, HYMO (Hydrologic Model) was combined with a grid model of East Fork Armells Creek and Stocker Creek to describe the pre- and post-mine surface water flow regimes. The HYMO model was designed for forecasting floods, planning flood prevention projects, and general hydrologic research.

Another model, the grid model, was used to determine input parameters for the HYMO model as well as to forecast pre- and post-mine erosion magnitudes and to compare pre- and post-mine topographies (see Technical Support Document, Section B.3 for details). For the flood routing procedure of the HYMO model, East Fork Armells Creek and Stocker Creek were divided into subbasins (Figure III-10). These subbasins range from 0.14 square miles (mi^2) to 9.63 mi^2 (Table III-5), and have average slopes ranging from 0.038 feet per foot (ft/ft) to 0.109 ft/ft. Stream channels in these subbasins have slopes ranging from 0.003 ft/ft to 0.025 ft/ft. The grid model was used to compute slopes, hydrologic SCS curve numbers, and general soil losses from each subbasin (see Technical Support Document, Section B.3), and for computation of input parameters used in the HYMO model. The results of the grid and HYMO modeling used to predict impacts are presented in the following sections.

a. Impacts Through Five-Year Permit Period

1) Reclaimed Drainage Basin Characteristics

In area C reclamation will not have progressed very far during the first five years. In other areas mining will be on-going and therefore reclamation will be in progress throughout this period. Few cumulative impacts are anticipated. Over the short term some incipient gullying may take place in newly reclaimed areas. It is anticipated, however, that the mining company will re-grade those areas which begin to erode due to high intensity storms.

Generally the characteristics which a drainage basin may adopt will not be much different from premining conditions, but would take decades to become established.

2) Stream Channel Characteristics

Within the five year period it is not expected that stream channels will experience significant changes. Probably the most significant changes may occur below sediment retention ponds where clear, discharging water which will be released after large storm events will have a higher erosive potential. This may create some channel incision below retention ponds and slight deposition immediately above ponds. As ponds are removed (in other areas during the first five years) then slight aberrations in grade may cause the channel to undergo selective erosion and deposition in order to reestablish grade.

Exhibit 3

3) Basin Sediment Yields and Geomorphic Stability

Before vegetation is reestablished on reclaimed slopes, storm runoffs will induce high erosion and hence high sediment yields. Downstream sediment yield would not increase because the runoff from mined areas would be channeled through sediment retention ponds (water held in the ponds must be released within 15 days of the storm event).

During the life of the mine, the company would construct sediment ponds to control sediment and peak flow runoff from disturbed areas. A preliminary listing of proposed ponds as provided by Hydrometrics (written communication, 1982) is presented in the Technical Support Document. A compilation of information for the proposed sediment ponds by mine area follows.

Mine Area	Run off Volume[1] ac.ft.	Sediment Volume ac.ft.	Total ac.ft.
A	180	88.8	268.8
B	89.1	58.9	148
C Block 1	77.2	51.5	128.7
C	685.6	117.1	802.6
D	145	103.1	248.1

According to Western Energy (personal communication, 1982, Pete Norbeck), 50 percent of the structures will be installed and maintained at any given time, therefore the net storage per mine area is estimated to be approximately 135 acre feet for Area A, 74 acre feet for Area B, 115 acre feet for Area C, Block I, 400 acre feet for Area C and 124 acre feet for Area D.

If the average impoundment size is approximately 10 acre feet with a depth of 15 feet the impoundment surface area will be approximately 0.67 acres (personal communication, 1982, Pete Norbeck). If the water is retained in the structure for a period not to exceed 15 days, as stipulated by DSL, the potential evaporation rate would be approximately 0.16 feet.

Based on these assumptions the net evaporative consumption use from East Fork Armells, Stocker, Pony, and Cow Creek would be 65, 20, 1, and 1 acre feet per 10-year 24 hour storm.

The net impact to the hydrologic regime is a water reduction of less than 4% for East Fork Armells, 2% for Stocker, 0.2% for Pony, and 0.01% for Cow Creek.

Exhibit 3

There is no data available to estimate the seepage from the ponds to the valley fill aquifer system. If seepage does occur, it would attenuate away from the ponds. As the time from the occurrence of the event increases the seepage moving in the groundwater system would approximate the existing slope of the water table.

A simplified worst case assumption indicates that if the specific yield of the valley fill along East Fork Armells Creek is 0.2, the total area of the valley fill is approximately 30,000 acres and the valley fill is approximately 10 feet thick throughout the area there is roughly 60,000 acre-feet of water in the valley fill aquifer. If all of the runoff from the sediment ponds seeped into the East Fork Armells Creek drainage, which is not likely since some ponds are on other drainages and all of the water won't leak, it would represent only a one percent increase in the volume of water in storage in the aquifer. This one percent volume increase will translate into a water level increase which will very probably become subject to evapotranspiration and will be consumptively used.

In summary the seepage from sediment ponds to the valley fill groundwater system is not expected to impact the quantity or the quality of the valley fill aquifers.

Sediment ponds would have the effect of lowering and delaying peak surface flows along the drainages that they are on. The impact of this activity could be considered beneficial since this in effect lessens the effect of flood events.

It is probable that some geomorphologic changes would occur in the first five years. However those changes would all be confined to mined areas. Adverse changes which are possible include piping and differential erosion. A more detailed discussion is included in the TSD geomorphology section.

4) Flow Rate Analysis

Mining itself would have little effect on flow rate except to:

a) attenuate peak flows by impoundment and slow release, and

b) in some instances increase slow releases from retention ponds due to the addition of pit pumpage necessary because of direct precipitation into the pits.

A possibly greater change in flow within the East Fork Armells Creek drainage area may result indirectly from mining. Mining of additional coal is planned in conjunction with construction of additional power generating units in Colstrip. Operation of these units will require that more water be imported from outside the drainage basin to be used for cooling purposes. It is expected that addition of water to the

existing surge pond will result in higher losses to the alluvial system. These losses may magnify downstream drainage problems which already exist.

It is not possible to quantify the downstream flow increase from an expanded power generating facility. However, it is probable that these changes would overshadow direct mine induced changes to surface water flow.

5) Water Use

Stock watering will not be directly influenced at all by changes in surface water flow. Most flow diversion for irrigation takes place during high flows. Although extremely high flows would be trapped in some drainages by retention ponds prior to release for the most part the short term retention would have no influence on irrigation water use from an availability or suitability standpoint. Three ponds would be removed during mining of Area C, Block I (Figure III-11), when the ponds are restored water quality is expected to be the same as it is at the present.

6) Water Quality

Adverse surface water quality changes could only occur if degraded groundwater discharges to surface water, if surface water leaches salts exposed at the surface, or if other factors (such as the power plant expansion) contaminate surface water via groundwater flow.

It is not anticipated that groundwater would have any affects on surface water within the first five years of mining. It is also projected that the only run-off induced quality changes might be increases in sediment loads. However sediment loads would be largely removed in sediment retention ponds.

It is anticipated that increases in the wastewater treatment plant discharge and an increase in power plant capacity with attendent increases in cooling water may cause some minor changes in surface water quality. However the specifics of those increases and the dynamics of both engineered and natural improvement in water quality are indeterminate.

b. Impacts through Life of Mine and 100 Years Beyond

1) Reclaimed Drainage Basin Characteristics

The reclaimed drainage basins would approximate those of the pre-mining environment. Evidence from existing, reclaimed basins in the Colstrip area suggests that the reclaimed drainage basin characteristics would be strongly influenced by the engineering techniques and equipment used to reclaim the spoils.

After reclamation, it is likely that the channel network would expand, creating a higher density of short stream segments formed by headward erosion. Such a development would reflect an adjustment of the

Exhibit 3

channel network to the reclaimed hydrologic system, similar to that observed in the currently reclaimed areas. If proper mitigations are performed, this impact would be minimal.

2) Stream Channel Characteristics

As planned by Western Energy, the development of channel profiles that are concave and without knickpoints will decrease the potential for widespread initial instability in the channel. However, both natural and man-induced processes are likely to result in changes to channel geometry, because the reclaimed ephemeral channels in this area will be as inherently unstable as the pre-mine ephemeral channels. The development of gullies can be expected (see Technical Support Document, Section B.4). If left unmitigated, gully development will be a serious impact, but probably no more so than already exists with pre-mine channels. During the bonding period, rills and gullies would be mitigated, but after bond release it would become the surface owners obligation.

Perhaps the most significant man-induced influence on the post-mining channels throughout the study area will be the construction of sediment ponds. Upstream of the ponds, changes in channel geometry may be induced by a new base level imposed on the system. This can result in a pattern of cut and fill similar to that observed in the undisturbed channels.

Downstream of the sediment ponds, further changes may occur in response to the reduction of peak flow magnitudes and the removal of sediment by the ponds. There could be two major consequences: channel incision and aggradation*. The result of these changes will be a reduction of the low-flow channel capacity (see Technical Support Document, Section B.4 for details).

If there is frequent intermittent flow in the channel, incision may occur below the sediment pond dam. This impact is considered insignificant considering the relatively short (10 to 20 years) life of the sediment ponds. However, if the ponds are to become permanent, this impact will become greater, possibly causing a lowering of base level downstream.

The most significant impact of the sediment ponds is likely to occur after reclamation, when the ponds are removed and the undersized, aggraded channels are again subjected to uncontrolled discharges from the basins. The probable effect may be an episode of high erosion and downstream sedimentation accompanying entrenchment of the main channel.

3) Basin Sediment Yields and Geomorphic Stability

On a large scale, the proposed reclaimed landscape appears to be stable, although increased rates of erosion may be associated with problems of subsidence or differential erosion at a highwall interface (see Geology, Section A).

The Universal Soil Loss Equation (see Technical Support Document, Section B.4) was applied to the grid model to predict post-mine erosion rates* in all basins and to compare these rates to pre-mining erosion. Results indicate that in general the post-mine erosion rates would be very close to, or slightly less than, pre-mining conditions. This is mainly due to the elimination of short, steep slopes in reclamation and an increase in vegetative cover, assuming reclamation is successful (Vegetation, Section G).

Figure III-12 illustrates the general post-mine erosion surface, showing the relative magnitudes of erosion rates. Figure III-13 illustrates those areas where the post-mine erosion rates exceed those of the pre-mining environment. Erosion rates during mining, however, can be expected to be greater than those in the pre-mining environment. Those areas where post-mine erosion is greater than pre-mine erosion were located along the permit boundaries in areas where post-mine slopes were greater than pre-mine slopes (Figure III-13). These areas, if properly stabilized, should not cause a serious impact. Basin sediment yields or the actual amount of sediment moved out of the basin, however, would be considerably less than the erosion rate due to deposition of eroded material while in transit. Sediment yields would be highly dependent on the efficiency of the reclaimed channels in transporting sediment.

Area-wide settling is common in most post-mining landscapes and occurs during the first ten years after the completion of contouring. A swell factor of 22 percent has been assumed. With time, these materials would settle and approach a density similar to that which existed prior to mining. Groenweld and Rehm (1980) indicate that there would be less settlement and it would occur more rapidly with sandy material as compared to silty material. Settlement is likely to be less significant at Colstrip than in many other sites because of the sandy character of the spoils.

Piping is a phenomenon associated with subsidence and may be a severe and long-term problem in the post-mine landscape. At the surface or near-surface, piping begins as a crack either in the surface of the exposed spoils or at the topsoil/spoil interface, allowing surface runoff to flow into the sub-surface of the spoils. However, surface cracking would not always result in the development of piping. Piping is most likely to occur when an avenue for potential water movement is present in the subsurface of the spoils. Such an avenue of flow can result from fracturing within the spoils due to settling between differentially compacted areas, or within areas of poorly compacted spoils. Such differential settlement is most likely at the highwall interface between coherent overburden and the spoils materials, and between areas of spoils handled by different equipment. If left unmitigated, piping and the consequent gullying it causes would be a serious impact to the stability of the reclaimed landscape.

4) Flow Rate Analysis

The HYMO model was used to compare pre- and post-mine surface flows. Surface flows occurring during mining were not evaluated quantitatively due to the changing nature of the drainages as reclamation

progresses. One of the impacts on surface flows during mining is attenuation of peak flows due to the impoundment of snowmelt and storm runoff in the sediment ponds. This impact would also cause base flow to be prolonged slightly due to the gradual release of flow from the ponds after treatment. The major impact to surface flows during mining, however, would be a decrease in total volume of flow from the mined areas due to increased evaporation and seepage from the sediment ponds and the use of sediment pond water for dust suppression.

Post-mine flow volumes and peak flows would be slightly reduced assuming that reclamation is successful, due to a slight increase in vegetation densities and infiltration rates. Tables III-6 and III-7 illustrate this difference between pre- and post-mining surface flows. Sediment ponds will have only a minor effect on the post-mine surface flow regime since most or all of these would be removed when the reclamation bond is released.

5) Water Use

Surface water use in the Colstrip area should not be significantly modified by mining. Slightly less water would be available for stock ponds during mining as a result of sediment impoundments and the resulting loss from seepage and evaporation; however, the water quality in the ponds should be the same as present water quality and would be suitable for present-day use.

Flood irrigation downstream from the townsite of Colstrip would likewise be little affected mining activities in the study area. Stream flow is used for irrigation only during periods of high flow when adequate quantities are available and the quality is good. This would continue to be the situation after mining and the water quality should be about the same. Water quality during low flow periods is suitable for livestock watering, and would remain so after mining. During mining, sediment ponds would cause peak flow attenuation that may have short-term affects on flood irrigation. Long-term effects (post-bond release) should be negligible, although a decrease in flow volume and peak flows is expected.

As indicated by Table III-3 groundwater discharges to surface water will not change significantly from the present.

a) Ponds

When the ponds are restored in the reclaimed mine area, the water quality is expected to be generally the same as the present pond quality. During precipitation events, low concentration water will be stored. This water will evaporate and increase in concentration with time, as it does under present conditions.

b) Springs

Any new springs issuing from the mined area would likely have TDS concentrations similar to the other springs in the area.

Exhibit 3

c) Streams

Water flowing across the surface of the reclaimed mine areas throughout the study area as a result of a storm or snowmelt runoff would have much lower TDS values than, for example, spoils water. This is because earth/water contact time is relatively short during runoff and the surface soils would be leached of soluble salts.

Water discharging from a mined area directly to streams during high flow should have a very small impact on stream quality.

During low flow conditions, any flow is predominantly groundwater from the valley fill. Existing average low-flow TDS values for drainages in the hydrologic study area are in the same range with predicted spoils water TDS values. Consequently, the influence of spoils water on base flow surface water would not be significant. And most importantly will not affect the use of water for stock watering purposes.

It is not possible to project cumulative changes in spoils water as it may migrate from one mined area to another. Concentrations of important constituents will increase at a lower rate as concentrations get higher. Also the rate of leaching is a function of the site-specific geologic and mineralogic conditions, the age of spoils and the rapidity with whch leaching occurs. For example unreclaimed spoils may produce low concentration leachate more quickly than reclaimed spoils because more water is trapped in unreclaimed spoils, causing anomolously high net infiltration rates.

d) Other Surface Water Features

Much of the activity in the vicinity of Colstrip has a greater potential for impacting study area surface water. Some of the activites include indirect contribution from the surge pond and fly ash pond, irrigation return water (both directly as runoff and indirectly as groundwater) and the seepage treatment plant discharge. It is apparent from the information on groundwater versus surface water levels that the surge pond, fly ash pond, and irrigation practices have an affect on surface water flows. With respect to the sewage treatment plant the average discharge is 130 gpm but there is no evidence that constituent levels present any difficulties for downstream users (irrigation and stock watering).

6) Water Quality

As stated previously the potential for surface water impacts due to mining are minimal. There are two possible ways in which a surface water quality change might take place: by changes induced directly from surface runoff/overland flow; and by changes induced due to modifications in groundwater quality which then discharges to the valley fill/surface water system.

During the long-term, little if any direct impact on surface water quality is anticipated due to runoff. Before mine bond release, any flow which occurs would be routed through sediment retention ponds where

sediment would be trapped. Water released should be cleaner than under natural conditions. After the bonds are released the sediment ponds would be removed. Due to the change in grade induced by the presence of the sediment ponds through the life of mine all surface water drainages would reestablish grade when the ponds are removed. This process would result in a small amount of channel incision (erosion) and deposition, but it is not anticipated that the phenomenon would produce noticeable increases in suspended sediment.

Because of post-mining vegetative reclamation requirements it is likely that for some period of time after vegetation is reestablished, mined areas would be more densely vegetated than non-mined areas. The effect of the extra vegetative cover would be to decrease sheet and rill erosion and decrease the peak flood flows by detaining some runoff and aiding infiltration. Storm runoff, for this reason may, in fact have less suspended sediment than during pre-mining flood flow conditions.

Greater potential exists for long-term affects on surface water quality via groundwater. This potential impact is examined in the following discussion.

To reiterate, normally no flow exists in East Fork Armells Creek above Colstrip or any of the tributaries to Rosebud Creek except during runoff periods. All groundwater which discharges from bedrock to East Fork Armells and tributaries to Rosebud Creek becomes part of the valley fill system but does not flow as surface water. Hence, although there is a potential for spoils water from various mined areas to affect valley fill water quality, only below Colstrip do the valley fill water levels get high enough for surface water flows to take place. Therefore, along East Fork Armells Creek only below Colstrip is there a potential for spoils water to affect surface water.

Assuming post-mining groundwater equipotentials are reestablished in approximate conformance with existing equipotentials, then groundwater flow lines would be similar to those under pre-mining conditions (shown on Figure II-10). Examination of this figure indicates that under existing conditions Areas C, B, and part of A plus the Big Sky Mine contribute to flow in Lee, Miller and Hay Coulee while Cow Creek receives contributions from Area D, E, and part of A. Pony Creek receives a minimal amount of flow from Area D.

In the Cow Creek Drainage, a water balance indicates the potential for all natural groundwater discharge from Areas D, E, and parts of A to move into Cow Creek alluvium and then be evapotranspired in areas identified as being subirrigated (Figure II-14. The potential for salt accumulation in these areas is uncertain, however, since salinity problems have been reported in subirrigated areas (DSL, 1980) the inflow of additional TDS would exacerbate the problem. Not included in the analysis are the systems input due to precipitation, snowmelt and runoff within the Cow Creek drainage.

A potential for additional salt loading on the Cow Creek system exists due to a proposed fly ash (scrubber sludge) pond in T1N, R42E, Section 5 and 6. It is uncertain whether the pond would be constructed

in colluvium or alluvium, however, it will clearly be constructed within the Cow Creek drainage area. The design specifications indicate a maximum seepage rate of 170 af/year of water with a TDS of 32,000 mg/l (10 times greater than background levels). Whether some leakage occurs into bedrock or whether effectively all of the seepage moves into Cow Creek alluvium depends upon the exact location of the ponds.

As indicated in the discussion on subirrigation along Cow Creek, the total computed potential evapotranspiration is 319 af/year. The available water from groundwater is 131 af/year (year 2118) while the fly ash pond would contribute another 170 af/year, for a total of 301 af/year. This would still be less than the total potential evapotranspiration.

The potential problem derives from the very severe salinity hazard posed by the fly ash pond water. Using the correlation TDS = 1081 E.C. + 1043 (TDS in mg/l, E.C. in mmhos), it can be calculated that a TDS of 32,000 mg/l correlates with an E.C. of 28,630 micromhos (See TSD, Figure B2-3). For a point of reference, water with an E.C. of 5,000 micromhos is classified as very high salinity water "not suitable for irrigation under ordinary circumstances" (USDA, 1954). This water moving into the valley fill or alluvial system, would be toxic (unusable) to vegetation and could create substantial areas of salt deposition in the Cow Creek drainage.

It should be pointed out that although seepage of high salinity water from the fly ash pond could cause severe impacts to the Cow Creek drainage, various mitigative measures are proposed.

These possible migitation and abatement measures are described as follows in a report by Hydrometrics, 1981, "Cumulative Hydrologic Impacts, Rosebud Mine, ..."

"... construction of a slurry trench to eliminate seepage through permeable material peripherial to the pond, the use of a pond liner in portions of the pond and installation of a groundwater interception system peripherial to the pond."

More specific design specifications are necessary before a judgment can be made about how successful each measure might be in reducing the potential problem. Each measure taken by itself would not be an absolute solution to the problem.

It is also important to determine (if only in an approximate manner) how mining could affect surface water quality versus the potential affects of activities not directly related to mining (e.g., operation of the power plant).

A mass balance estimate was made to approximate these changes. The approximation incorporates the following assumptions and postulates:

a. It is assumed that the valley fill/surface water is represented by a single water quality for low flow periods. This is reasonable since surface water flow comes from valley fill groundwater base flow during low flow periods.

b. In the mining scenario it is assumed that all of the water entering the valley fill system from groundwater has increased from 2,500 to 3,500 mg/liter TDS.

c. The "water balance" utilizes only the input parameters since none of the outputs (losses to the system) change because of mining or the other activities considered.

d. For most of the inputs to the surface water system reasonable TDS values are assumed. Although in some cases the actual values may differ somewhat from the values used in this approximation, the assumed reasonable values can be used in a trend analysis to determine the magnitude of change mining would have on surface water low flows.

e. It is assumed that the sewage treatment outfall as a constant contribution to baseflow below Colstrip. It is also assumed that only a small portion of the 204 acre-feet per year (afy) of runoff contributes to recharge of valley fill and hence contributes to baseflow. For these purposes it has been assumed that approximately 10 percent of runoff on 20 afy contributes to baseflow.

If all of the water input to the system is added and all of the TDS is added it is possible to project the composite resulting water quality.

VALLEY FILL/SURFACE WATER SYSTEM INPUT

Input	Amount of Input Acre feet per year (afy)	Estimated TDS value (mg/l)
Sewage outfall	210	1,000
Surge Pond	175	500
Boston Ash Pond	13	35,000
Cooling Tower and Blowdown Pond	24	10,000
Other Power Plant Processing Ponds	15	35,000
Annual Runoff	20	500
Groundwater Discharge to East Fork Armells Creek	146 (year 2118)	2,500[1] 3,500[2]

Total water = 603 afy or 7.72×10^8 liters/year

TDS = 3.26×10^{12} milligrams/year (no spoils water effects)

= 3.38×10^{12} milligrams/year (spoils water effects included)

[1] This value represents average pre-mining groundwater discharge to valley fill.

[2] This value represents average spoils water discharges to valley fill.

Exhibit 3

Mass balance calculations using the above data show the resulting surface water quality flow would be 4378 mg/l with mining affecting groundwater inflow to East Fork Armells Creek and 4222 mg/l with no mining.

It must be emphasized that the preceding calculations are useful in establishing trends. The trend indicates that all of the human activity (non-mining) in the Colstrip area will render changes in base-flow surface water quality due to mining difficult to detect.

C. CLIMATE

The proposed mining of Area C, Block I would not have any impact on the climatic regime in the area.

Ertec evaluated four possible avenues for climatic modification by the project:

1. Major increases in area atmospheric moisture content

2. Changes in surface albedo due to surface disturbance

3. Changes in increasing radiation caused by increased suspended particulate matter

4. Changes in cloud formation caused by increases in condensation nuclei (from suspended particulate matter)

There are no major sources of atmospheric moisture. Increases from vehicular exhaust and evaporation of water used for dust suppression would be very small compared to moisture levels needed to produce climate changes. Only a very small percentage of the disturbed acreage would have a significantly different color than the existing surface. Consequently, surface albedo would not be significantly altered by the project. As documented in the visibility degradation analysis in the air quality section, suspended particulate concentrations would have little effect on light transmission, thus there would be no expected change in incoming solar radiation. Finally, the particulate matter would occur close to the surface, where the availability of condensation nuclei is not the limiting parameter in cloud formations (Wallace and Hobbs, 1977).

D. AIR QUALITY

A mining development such as the proposed Area C operation can impact air quality in several ways:

- o It can increase the ambient concentrations of various pollutants in the air
- o It can increase the rate at which dust or other particulate matter settles on surfaces near the mining operation
- o It can degrade the ambient visibility in the area

In this assessment, an evaluation of each of these effects has been made. The basic methodology is to develop an inventory of the various project-related sources of air pollution emissions and estimate their emission rate. These estimates are then used, together with the meteorological data presented in Chapter II, as input to a mathematical simulation model of atmospheric pollutant behavior. The model provides estimates of increases in ambient concentrations expected from the proposed project. From these concentrations, deposition and visibility degradation can be estimated.

Both the state and federal governments require that proposed new sources be evaluated for potential air quality impacts. Government agencies have established legal limits on pollutant levels (Table II-8). Western Energy has applied for an air quality permit to construct and operate from the Montana Air Quality Bureau (MAQB) for the planned Area C, Block I operations. The MAQB has issued a preliminary determination to issue this permit. The Area C, Block I mining operation would be located on the boundary of a non-attainment area for TSP. Normally, a new project in such a location would be required to comply with the non-attainment provisions of the Clean Air Act amendments of 1977, which are now incorporated in Montana law. The Prevention of Significant Deterioration (PSD) requirements would not apply because Area C, Block I is located in a nonattainment area. The nonattainment regulations require that a source obtain an offsetting reduction in emissions equal to or greater than the proposed project emissions. Also, the new source is required to demonstrate that it will attain the lowest achievable emission rate (LAER). To be subject to the nonattainment review process of the Clean Air Act Amendments, a source must have at least 250 tons per year of nonfugitive emission. Since the nonfugitive emission estimates for the proposed Area C, Block I mining operations do not exceed this limit, the nonattainment review does not apply. However, Section 16.8.1401 of the Montana Air Quaility Rules still requires the LAER must be attained.

The only pollutant of major concern would be particulate matter. By far, the most significant component of the particulate matter emission would be fugitive dust from heavy equipment movement on the unpaved surfaces in and around the mine, and from coal and overburden handling. Major sources would include haul roads, draglines, wind erosion, scrapers, and bulldozers.

Although the crushing and conveying operations would be sources of dust emission, they are not "fugitive" sources since control equipment would be installed on these units to reduce dust emissions.

Additionally, small amounts of particulate matter and gaseous pollutants would originate from the exhaust of diesel equipment used in the mining operation. The most significant of these gaseous pollutants would be oxides of nitrogen (NO_x). Total annual emissions of NO_x are estimated to be 134 tons from diesel equipment and an additional 35 tons from blasting with an ammonium nitrate and fuel oil mixture. This emission rate could be expected to increase ambient nitrogen dioxide (NO_2) concentrations in the project area by a small percentage, but impacts would be restricted to the mine area alone and would be less than 20 percent of the ambient standard for annual-average NO_2 concentrations. Emissions of carbon monoxide (26 tons per year), hydrocarbons (9 tons per year), and sulfur dioxide (9 tons per year) would not constitute a significant impact on the project or regional area. Since these emissions would be small, and would not be likely to create any impact, only fugitive dust emissions are considered.

A summary of the emission inventory prepared by the air quality study team for this EIS (with the coordination and approval of the MAQB) is shown in Table III-8. Details of the computations can be found in the Technical Support Document. The emission inventory refers to emission rates characteristic of those expected if the Area C, Block I operations are in full production.

In addition to the emissions caused directly by the project, there would be secondary emission sources, resulting from the increase in population and services accompanying the project and emissions from other simultaneous new projects in the area. Table III-9 lists the other (nonproject) emission sources and the estimate of annual average emission rates. Emission rates are presented for two years. The year 1980 was selected to be representative of current emission rates while 1988 was selected to represent future conditions. These dates were selected primarily because data were readily available for these years. Details of the computations for these emission rates are presented in the Technical Support Document.

The Ertec Mining Air Quality (EMAQ) model was used to predict ambient concentrations resulting from the proposed Area C, Block I operations. The model is described in detail in the Technical Support Document. It is basically a Gaussian plume-based model that uses particle deposition based on the equations of Ermak (1977). Both annual-average and peak 24-hour average concentrations were calculated. The on-site meteorological data from the train loop station operated by Western Energy was used in the analysis. A full year of readings for the period of January through December, 1980 was sequentially analyzed in this study. Three geographical areas of interest were identified: the area immediately adjacent to the proposed mining operation (hereafter referred to as the mine area), the townsite of Colstrip, and the Northern Cheyenne Indian Reservation (NCIR). The mine area was selected because

impacts will be highest there; the town-site of Colstrip was selected because it is currently classified as not being in compliance with the air quality standards, and the NCIR was selected because it is classified by EPA as a Class I area and as such is accorded special consideration.

The analysis of impacts in the mine area is complicated by the presence of both attainment and nonattainment areas (for TSP). Figure III-14 shows isopleths of annual-average TSP concentration predicted to result from the proposed Area C operations. The isopleths include the contribution from both fugitive and nonfugitive emissions. As the figure shows, the proposed operations would increase TSP concentration in both the attainment and nonattainment areas. However, the mining operation would not be required by current Montana laws to include fugitive dust in the impact analysis. Because the nonfugitive dust emissions would be sufficiently small to escape nonattainment review, the mining operation would not be required to make a demonstration of compliance with the emission offset ruling. Since nonattainment and PSD would not apply to this project, the remaining discussion of the impacts does not reference the distinction between the attainment and nonattainment areas. Also, the remaining discussion addresses all particulate matter including both fugitive and nonfugitive emissions.

Table III-10 summarizes the results of the air quality modeling study. The annual-average TSP concentration predictions for the mine area (11 ug/m^3), when added to existing levels of approximately 25 ug/m^3, total 36 ug/m^3. Increased TSP in emissions from nonproject sources in the Colstrip area (see Table III-9) might result in a further increase in the mine area, on the order of 7 ug/m^3. This estimation is based on approximate calculations. Details of this estimate can be found in the Technical Support Document. Thus, total annual-average TSP concentrations in the mine area would rise to approximately 43 ug/m^3. This value is an arithmetic average and still well below the Montana air quality standard of 75 ug/m^3. Federal annual standards are geometric means and are expressed as both primary (75 ug/m^3) and secondary (60 ug/m^3). Since the arithmetic mean is always greater than the geometric mean, we can conclude that the predicted total TSP concentration in the mine area would not exceed federal annual standards.

The impact of the project on annual-average TSP concentrations in the townsite of Colstrip would be very slight. The predicted increase of 1.2 ug/m^3 would be less than the detection limit for most monitoring equipment and would be essentially equivalent to the cutoff EPA uses in determining if a source has an insignificant impact on a given receptor. The impact of increases in nonproject emission sources on Colstrip would be far greater. These emissions would be expected to worsen the existing air quality problem in Colstrip.

Annual-average TSP concentrations in the NCIR resulting from the project would be extremely low and can be disregarded completely.

Peak and second highest 24-hour TSP concentrations in the mine area would be around 38 ug/m^3. Existing peak 24-hour TSP concentrations would be around 90 to 100 ug/m^3, but the high impacts from the mining

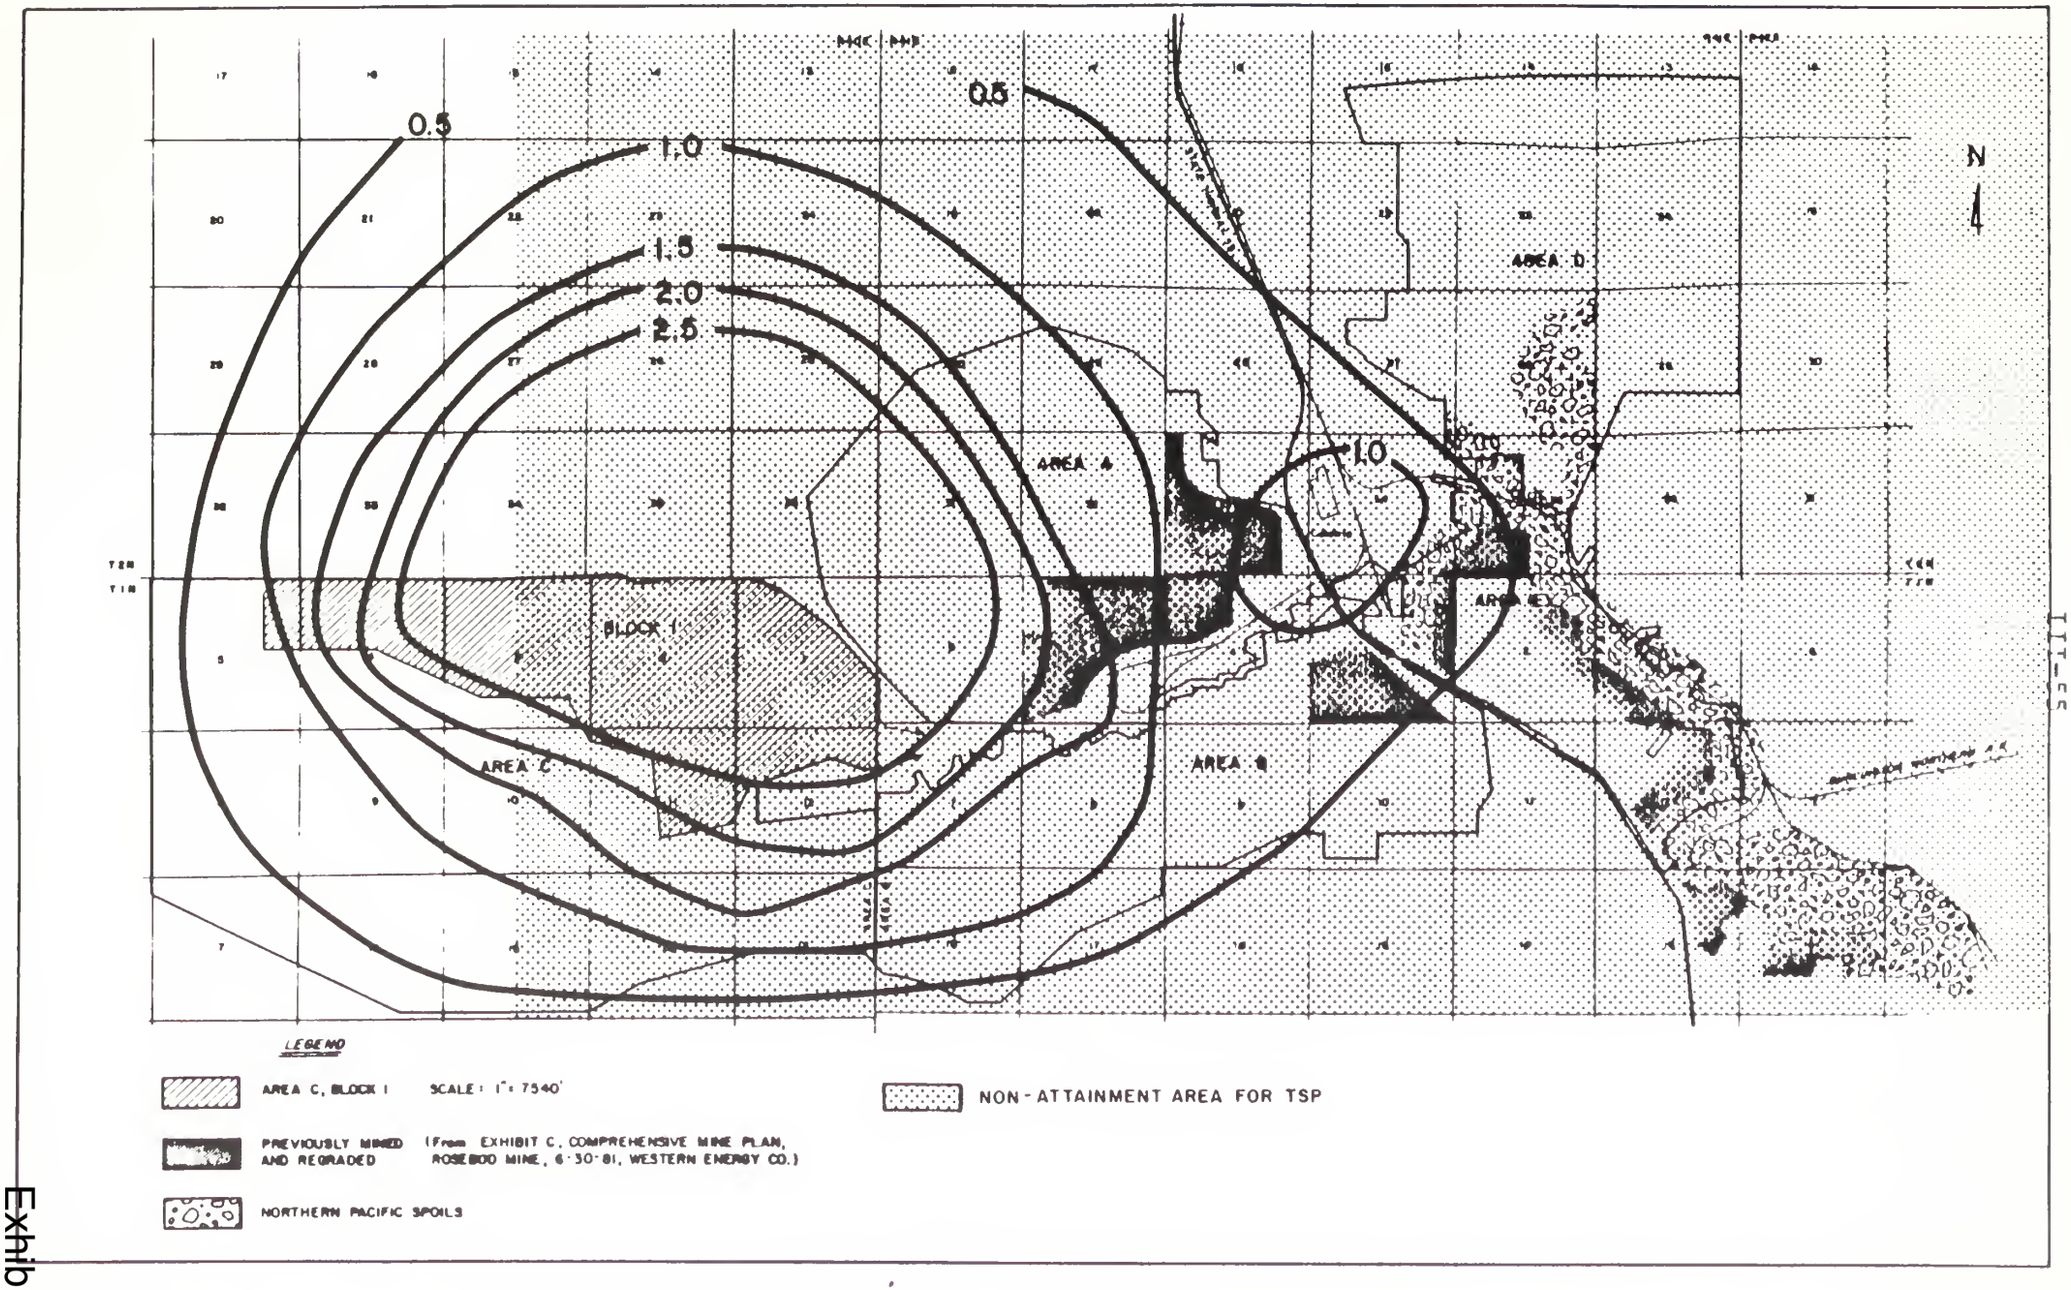

FIGURE III-14 ISOPLETHS OF ANNUAL-AVERAGE TSP CONCENTRATION IN ug/m^3 RESULTING FROM THE AREA C, BLOCK I OPERATIONS ALONE

Exhibit 3

operation may not occur under the same meteorological conditions. Even with the worst-case assumption that these peaks overlap, the total value of 138 ug/m^3 would still be below both primary and secondary air quality standards. Impacts from nonproject sources in the area would not cause excursions of the standards at Area C.

The peak 24-hour impact of the mining operation on the townsite of Colstrip (less than 5 ug/m^3) would be inconsequential when compared to the existing peaks that occur there (during 1974 to 1979 Colstrip had measured peaks every year of over 350 ug/m^3). Therefore, the proposed mining operation would not be expected to have a significant impact on 24-hour concentrations in Colstrip. Nonproject emissions in Colstrip would increase 24-hour concentrations.

Peak impacts in the NCIR would be very low; they are not likely to be measurable.

The impacts caused directly by the project would be far below the primary standards, which are designed to protect human health. The townsite of Colstrip would be expected to continue to exceed the primary standard, due primarily to nonproject sources of emission. The high concentrations have not produced a hazard to health in the past primarily because of the high percentage of large particles, which pose less threat to human health than small particles. It is uncertain whether future particulate levels in Colstrip would constitute a health hazard. It is unlikely, however, that the proposed project would be a significant component to any potential threat to human health.

While producing large TSP concentrations, fugitive dust impacts do not pose as great a hazard to health as equivalent concentrations resulting from other sources. This is because much of the measured TSP in the fugitive dust impact is composed of particles greater than 15 micrometers in mass mean diameter. These large particles are removed by nasal hairs and mucous membranes prior to entering the lungs by inhalation. No adverse health effects have been reported from exposure to annual geometric mean TSP concentrations of 86 ug/m^3 in Colstrip during 1974 through 1979 (Montana Department of Health and Environmental Sciences, 1980).

Deposition of particulates in the project area would increase from existing 30-day average levels of approximately 7.4 grams per square meter on an annual-average basis to levels of approximately 8.6 grams per square meter at points separated from the mining operations by at least 500 meters. The 30-day average value for settled particulates regulated by Montana is currently being exceeded throughout much of the Colstrip area, including the project area. This would be expected to continue, and to increase in the project area. Values could be as high as 60 grams per square meter in the immediate area of the mining operation. However, at distances of 500 meters or more from the mining operation, peak values would be around 10 grams per square meter.

Visibility in the project area would decrease slightly as a result of the project. An increase in concentration from 25 to 42 ug/m^3 would produce a consequent decrease in ambient visibility from 35 to 27 miles. However, because the concentration impact would be very localized to the project area, this degradation is overstated. For lines of sight passing directly over the mining area and close to the ground, the impact will be in the range of 10 to 20 percent. For other vantages, the visibility degradation would be expected to be negligible. In particular, there would be no impact on visibility in the nearest Class I area, the Northern Cheyenne Indian Reservation. Another reason the impact is overstated is that the computation of visual range loss is based on particles of all sizes. Most visibility degradation occurs as a result of very small particles (less than one micrometer in size). Since less the ten percent of the Area C contribution can be attributed to these small particles, it is unlikely that any noticeable impact on visibility would occur.

E. NOISE

1. Construction Impacts

Among the first activities associated with the development of Area C, Block I would be the construction of shop and office facilitites and an overland conveyor from the mining area to the power generating station. This would require earth-moving and other construction equipment that would cause much higher than normal ambient sound levels in the construction vicinity.

The construction phases would generally include excavation, foundation work, erection, and finishing; the excavation phase would usually be the noisest. Typical sound levels produced by equipment used in the excavation phase are presented in Table III-11. A worst-case estimate of construction sound levels is derived by adding all the sources, weighted by the fraction of the work day the equipment is generally in operation. From Table III-4 the $L_{eq}(8)$ (i.e., the equivalent eight-hour sound level) at a distance of 50 feet from a point where all the equipment would be operating would be 92 dBA. However, because all the equipment would not be operating in the exact same location, this represents an upper limit to the construction noise level. Attenuation of this sound level due to distance alone would reduce construction noise levels to 72 dBA at a distance of 500 feet and to 52 dBA at 4,000 feet. The construction of the mine shops and offices would take place at a site more than seven miles from the townsite of Colstrip; due to distance attenuation alone, the $L_{eq}(8)$ construction noise would be reduced to 34 dBA, which would not be audible above to existing in-town sound levels.

2. Operation Impacts

During the operation of the proposed mine, heavy equipment would be used to remove the overburden and coal. Table III-12 lists the types and numbers of mining and reclamation equipment assumed to be in use at Area C. Overburden removal would probably occur full-time; coal removal would occur two shifts per day, five days per week. This equipment is likely to be in operation full-time during working hours. Field observations indicate that sound levels associated with existing overland conveyors are very low; because of these observations the conveyor noise was considered insignificant in comparison with other sources and was not included in the noise calculations.

Another source of noise due to mine operation would be blasting. Explosives are used in the removal of both overburden and coal. Unlike the continuous noise produced by mining equipment, blasting would occur intermittently and would be of very short duration. Approximately 136 overburden blasts and 320 coal blasts are expected each year. The noise produced by blasting depends on a number of variables, including the strength of the explosive charge and the amount of stemming placed behind the charge in the drill hole.

Exhibit 3

Noise regulations designed to protect a community's exposure to ambient noise generally consider time-averaged noise levels. For example, EPA's guidelines use an equivalent sound level averaged over 24 hours. EPA also has a standard that adds a 10 dBA penalty to ambient sound levels measured between 10:00 p.m. and 7:00 a.m. to account for the additional annoyance during sleeping hours. Due to time-averaging, the infrequent and brief blasting noise has very little impact on average community noise levels. The continuous operation of heavy mining equipment would be more likely to affect average noise levels.

To provide a worst-case estimate of noise impacts due to the proposed mining activities at Area C, Block I, an approach similar to that used in estimating construction impacts can be used. Table III-12 lists the major sources of noise due to mine operation and typical sound levels associated with each at a distance of 50 feet. The equipment is subdivided into overburden and coal removal equipment since these take place at different locations. Bulldozers and coal haul trucks were evenly divided between the coal mining activities, which take place in the pit, and overburden removal, which takes place at the perimeter of the pit. Because this equipment is assumed to be co-located, even though in reality the pieces move all over the mine area, the estimate of the combined noise level is conservative.

The wide range in blasting noise levels is indicated in the measurements shown in Table III-13. These observations have been collected from several locations and include a variety of blasting conditions. The maximum sound levels indicated in the table are instantaeous measurements rather than time-averages.

The most important criterion that influences the impact of sound is distance from the source. Sound energy diverges or spreads out, and thereby results in lower sound pressure with increasing distance. This decrease or attenuation of the sound pressure level results in a decrease of 6 dBA each time the distance from the source is doubled; each time the distance increases by a factor of ten, the sound level decreases 20 dBA.

This attenuation due to distance alone would result in a substantial reduction in Area C, Block I noise by the time the sound reached Colstrip. Since the distance from the nearest part of Area C, Block I to the townsite of Colstrip is approximately 19,200 feet, the 98 dBA produced by the mine equipment would be reduced by distance alone approximately 52 dBA to about 46 dBA in town. The last column in Table III-10 shows blasting noise levels normalized to a distance of 19,200 feet.

Other factors also influence sound propagation through the atmosphere. These include the absorption of sound energy by the atmosphere, the refraction of sound waves due to temperature or wind speed gradients, and ground effects. Absorption of the sound energy by the atmosphere is highly variable and depends on relative humidity, the frequency of the sound, and to a lesser extent, on ambient temperature. Between Colstrip and Area C, sound absorption by air with a relative humidity of 20 percent could attenuate noise by 20 to 30 dB at 500 Hertz and 5 to 10 dB at 250 Hertz, but affects the lower frequencies very little.

TABLE III-13

MEASURED SOUND LEVELS DUE TO BLASTING[a]

Type of Blast	Distance to Blast (feet)	Measured Maximum Sound Level (dBA)	Approximate Sound Level at 19,200 feet (dBA)[b]
Coal	1,500	79.0	57
Coal	8,000	66.1	58
Coal	8,000	65.7	58
Coal	5,000	80.4	69
Coal	5,000	83.1	71
Coal	6,500	74.9	65
Coal	6,500	75.0	65
Coal	11,700	55.5	51
Coal	12,500	60.2	56
Coal	20,500	55.4	56
Coal	12,400	66.1	62
Coal	17,000	75.3	74
Coal	23,000	54.5	56
Overburden	8,000	86.2	79
Overburden	16,000	65.2	64
Overburden	16,000	67.8	66
Overburden	18,500	57.2	57

[b]Attenuation due to divergence only; atmospheric absorption and ground cover attenuation are not included.

Exhibit 3

The grass groundcover in the Colstrip area will also attenuate sound from the mining area. Over the distance from the mine to the townsite, this is enough to completely attenuate ground level sound transmission.

Atmospheric stability and winds also affect sound propagation. During stable atmospheric conditions, the temperature of the air and the speed of sound increase with height and cause sound waves radiating from a source to bend toward the ground. Similarly, winds that increase in speed with height reduce upward sound divergence and can cause higher sound levels at a downwind receptor than during calm periods. Either of these can lessen the attenuation of sound due to groundcover and topography by returning sound waves from above back to ground level.

In summary, it is unlikely that the operation of mining equipment would normally be heard in the community of Colstrip. Despite the potentially high sound levels at the mine, distance and other attenuation factors are expected to reduce sound to relatively low levels before it reaches Colstrip. Of equal important is the masking effect provided by the relatively high ambient sound level that currently exists in Colstrip due to the generating plant. Therefore, except under especially adverse meteorological conditions, mine noise is not expected to be discernible in Colstrip, and should certainly not have any effect in terms of hearing damage.

Depending upon the blasting techniques employed and upon meteorological conditions, blasting noise might be audible in Colstrip. Based on the measurements displayed in Table III-13, blasting noise would be not likely to cause hearing damage, but might be an occasional nuisance.

F. SOILS

Western Energy has proposed to replace approximately 27 inches of subsoil and 8 inches of topsoil, a total of 35 inches of replaced soil on the mined area of Area C, Block I. The soils resources of the remainder of Area C are less well defined at this time. The depths of replaced soils in Area C could be less than this in some areas. The soils at the Rosebud Mine in general present few serious limitations for reclamation. The major impacts in Block I that could be expected from mining and the proposed reclamation actions would be alteration of the physical and chemical character of the soils in the disturbed area. These alterations would not be anticipated to prevent revegetation or to seriously alter the character of surface water dynamics in the area; however, the changes would be sufficient to alter the soil moisture regimes and infiltration and runoff conditions, limiting potential plant communities and agricultural uses in the area. Within the proposed conveyor corridor, 95 acres of the 225 acres to be disturbed have previously been disturbed by mining activities. The soils on the remaining 131 acres along the route are relatively similar to the soils in Block I, Area C, and the impacts are anticipated to be similar to those identified for the Block I mining area. Recommendations for possible mitigation for the impacts discussed below are included in Chapter IV.

1. Biological Impacts

Two major soil handling methods would be used in Area C, Block I. In early phases of mining and for all areas to be disturbed by support activities, soil materials would be salvaged as subsoil and topsoil and stored. After the third mining pass, topsoil and subsoil layers would be hauled directly to a scarified, regraded overburden surface whenever possible.

In both methods, soil organic matter, microbial populations, and reproductive plant parts would be disturbed and mixed into the entire topsoil salvage layer, reducing the quality of the soils at the surface and the likelihood of growth from small seeds. In the cases where soil materials are stockpiled and stored, it is probable that populations of soil microorganisms would decline (Miller and Cameron, 1976). Reproductive plant parts such as bulbs, tubers, seeds, and roots might be attacked by an increased population of pathogens during storage, reducing their viability. This will reduce "volunteer" establishment of native forbs, shrubs, and grasses not included in the seed mix, and might suppress establishment of some plants included in the seed mixes due to continued high pathogen levels after stored soils were replaced (Miller, R. M., 1982).

After stored soils have been replaced on the regraded spoil, microbial populations can be anticipated to reach pre-mining levels in one to two years, for all groups of microbes except the blue-green algae, which have not yet been documented as being capable of reestablishment (Miller, R. M., 1982; Mott, 1982), based upon research on spoils up to ten years

old. In addition, for the microbial groups that would become reestablished, different microbial species would generally be involved, which allows for restoration of basic nutrient cycling functions within the soil but might not replace functions that are limited to a few species, such as soil aggregation (Miller, R.M., 1982).

Organic matter would oxidize and decompose during topsoil storage. The result would be a decrease in available nutrients, reduced water and nutrient-holding capacity of the soil, and a reduction in soil structure. From present research data, the time required to restore soil structure is uncertain. Soil organic matter and nutrients would begin to build up once vegetation is reestablished on the replaced soil, as dead plant roots and litter begin to build up in and on the soil and supply nutrients. It might take up to 20 years before vegetation requirements and nutrients available in the soil system reach a balance (Woodmansee et al., 1978).

2. Physical Impacts

Physical alteration of the soils would result from salvaging, handling, and replacing soils in the mine area and from changes in the underlying material or overburden. Soil moisture availability has a strong influence on the present and potential vegetation in the area. Changes in bulk density, infiltration and runoff characteristics, depth to rock or impermeable layers, and soil textural variations would alter existing soil moisture relationships and influence survival and dominance of vegetative types.

a. Bulk Density

Plant root penetration might be limited by high bulk densities in the subsoil or at the regraded overburden contact. Weakly consolidated sandstone in the Colstrip area has been shown to resist root penetration at a bulk density of 1.5 g/cm^3 (Schafer et al., 1979).

Most natural soils of the Colstrip area do not exceed 1.6 g/cm^3 (Schaefer et al., 1977). Measurements on regraded spoil and replaced soils at the Rosebud Mine show a wide range of bulk densities in which bulk densities in excess of 1.7 g/cm^3 are relatively common (Schaefer et al., 1977; Dollhopf et al., 1981; Stark, unpub. data).

As bulk densities become higher, infiltration by water is decreased and accordingly, more soluble salts may become concentrated nearer the surface than would occur in a freely draining system. Plant rooting depths would be decreased, increasing the competitive edge of the shallow-rooted cool-season grasses at the expense of deep-rooted warm-season grasses. Reduced water available for vegetation would result from decreased infiltration and increased runoff, which would also increase the potential for soil erosion. Most of these effects would not be seen until soil bulk densities exceed 1.5 g/cm^3.

Ponderosa pine communities, although they occupy a relatively small proportion of the area to be disturbed (11 percent) are important for wildlife, aesthetics, and for supplying vegetative diveristy. Work by Stark (1982) has shown that bulk densities of 1.3 g/cm^3 or less in near-surface soils are ideal for ponderosa pine survival and regeneration. Therefore, for areas that have been identified as areas to be reestablished to ponderosa pine, bulk densities of 1.3 g/cm^3 in the soils will help insure the survival and regeneration of the trees. Additionally, the trees may take advantage of free water available in much more dense rock material at depth in natural settings (see Chapter II, Section F), therefore areas where overburden bulk densities exceed 1.5 g/cm^3 areas may not be of concern.

The areas in which increased bulk densities are likely to occur are impossible to predict due to high variability in spoil placement and the moisture conditions of spoil and overburden when they are being handled.

b. Soil Textures

The tendency of soils to become compacted during placement is influenced by soil texture. Texture also influences infiltration, runoff, erodibility, and accordingly, soil moisture regimes.

Mining would result in the disruption of large, discrete areas of soils with similar textures that characterize the pre-mined environment, and would produce a landscape in which high horizontal and vertical variability in overburden, subsoil, and topsoil texture would occur. In general, this high variability would be expected to occur in small, random areas, with general homogenization of the soil types over the large area resulting.

Loamy soils, which presently occupy 44 percent of the disturbed land area, would make up an estimated 58 percent (by volume) of the soils placed on the post-mined land area. Sandy soils would decrease from 44 percent to 36 percent of the land area after mining. Clinker soils would decrease from eight percent to four percent after mining, and unbaked shale and siltstone soils would decrease from four to one percent.

Overburden textures tend, overall, to be moderate, however, relatively thick zones exist in topographically high positions with high sand content (greater than 70 percent) (see Geology, Technical Support Document). Also, some thin lenses of clayey textures with clay contents exceeding state suspect levels of 40 percent exist, however, these are generally isolated, thin strata. If the high sand content overburden material was to end up at the surface of the overburden without mixing, it could create a droughty condition for many plants, especially shrubs and trees. If clayey material was to end up on the overburden surface, it could restrict water movement and rooting depth, which could reduce the vigor of some species and increse the survival of other species with no easily generalized impact.

The alteration in soil types would decrease the overall water storage capability of the landscape by decreasing infiltration. Surface

erosion can be expected to increase, especially during the high-intensity rainstorms characteristic of the region.

Shallow-rooted, cool-season grasses could be anticipated to dominate the reclaimed plant community because of their higher adaptability to a wide variety of soil conditions. This would reduce the management options and potential diversity of grazing systems in the post-mined area, especially when compared to the pre-mining potential. Without special management or soil handling, ponderosa pine and skunkbush sumac plant communities may not be able to compete for limited soil moisture to form self-sustaining stands.

3. Chemical Impacts

Soils would be replaced on the reshaped landscape to an average depth of 2.8 feet. Accordingly, the lower part of the rooting profile would be composed of overburden. Presently, approximately half of the soils of Area C, Block I have low soluble salt contents (electrical conductivities of less than 1.0 mmhos/cm) within a five-foot profile, while other soils, especially loamy and clayey soils near drainages, have moderate to high salt contents (electrical conductivities of 6 to 20 mmhos/cm) in the lower portions of their profiles. On the reclaimed landscape, mixed, regraded overburden with moderate salt content can be expected to prevail. This would result in a moderation of the extremes of osmotic stress encountered by vegetation in the area. Shrubs such as sagebrush species and woody plants common to riparian areas, would encounter improved condition within their broad salt tolerance ranges; whereas some salt intolerant species, such as ponderosa pine or skunkbush sumac, may exhibit reduced growth or vigor due to the salt content of the overburden (Stark, 1982).

Although some degree of overburden mixing can generally be assumed, this does not preclude the possibility of unmixed material occurring near the surface in some areas. As indicated in studies by Dollhopf et al. (1981), the intensity of overburden sampling in Area C, Block I (average drill hole spacing 1,600 feet) can be used to predict the character of overburden with only 45 to 60 percent confidence, and gives even less indication of values that may occur at any horizontal or vertical location in the replaced overburden.

All that can be stated with confidence using the overburden data from Area C, Block 1 is that the trace elements exceeding state suspect levels found consistently in the overburden holes do occur in the area to be mined, with no conclusions possible as to their presence or absence in other, unsampled overburden. Trace elements not found in exceedance levels in the overburden sampling are not necessarily absent in the unsampled overburden.

Overburden commonly exceeds DSL suspect levels for nickel, molybdenum, and electrical conductivity. Cadmium and manganese exceedances occur in a limited number of samples. Zinc and lead exceedances have been linked to contamination by pipe joint grease and are unreliable.

Table III-14 shows the relationships of the 27 overburden holes in Area C, Block 1 to the exceedance values identified in sampling.

Although no predictions can be made regarding the location or distribution of exceedance values in replaced spoils, Dollhopf et al. (1981) found that if materials containing exceedances were five percent or less of the total overburden sampled, they were not detectable in the spoil pile. Thus, it is unlikely that cadmium or manganese would be found in the regraded overburden to an exceedance level. Material occupying 5 to 15 percent of the overburden could not be detected half of the time (such as electrical conductivity), and material with exceedance values that occurred more than 15 percent of the time in the overburden would always be found in the spoil pile, generally diluted to some extent from their pre-mine concentration. Therefore, the overburden properties most likely to be found in concentrations exceeding DSL suspect levels in the reclaimed spoils include soluble salts (electrical conductivity), nickel, and molybdenum.

Soluble salt level (electrical conductivity) is of concern in the rooting zone because it can increase moisture stress in plants. Ponderosa pine have been noted as being less vigorous and able to regenerate in soils with moderate to high soluble salts (Stark, 1982). In general, the soluble salt level in a majority of the existing subsoils is higher than the amounts that can be expected in the regraded overburden.

Nickel is of concern in the rooting zone because it may interfere with plant physiological functions, especially iron uptake (Torrey, 1978). This effect may not be apparent because of the 2.8 feet of topsoil in which most plants will have their roots, however if iron chlorosis does appear in the revegetated area, amelioration with supplemental fertilizers would be possible.

Molybdenum is of concern when it occurs in forage and is consumed by ruminants such as cattle and sheep. Little has been quantified about how much molydbenum, as measured by acid-ammonium oxalate extraction in the soil, will occur in forage. It is known that legumes tend to concentrate molybdenum, and that most of the high molybdenum forage found naturally occurs in poorly drained soils (Kubota, 1977). Molybdenum causes copper deficiency reactions if the forage in which it occurs makes up a significant part of an animal's annual diet (Hornick et al., 1977). If excessive amounts of molybdenum were to occur in the near-surface spoils, the limited cover of legumes to be established on the post-mine surface and the likely limited areal extent of such excessive concentrations would probably limit the percentage of molybdenum-rich forage. This would mean that a minor portion of a grazing animal's diet in the area would include these forage sources, and so molybdenum would likely not be a cause for concern. Due to the unpredictability of unsampled overburden and the many unknowns involved in the uptake process (Lindsay, 1979), the only way to quantify this impact would be to measure levels of molybdenum in forage growing on the reclaimed surface and compare that to molybdenum concentrations in the pre-mine vegetation, pre- and post-mine soils, and root zones.

TABLE III-14

OCCURRENCE OF LEVELS OF EXCEEDANCES IN OVERBURDEN

AREA C, BLOCK I

	Electrical Conductivity	Nickel	Molybdenum	Cadmium	Manganese
Number of Holes with Exceedances	12/27	19/27	21/27	4/27	--
Percentage of Sampled 5' Intervals Containing Exceedances	10%	30%	29%	4%	5%
Suspect Level	4-6 mmhos/cm	1.0 ppm	0.3 ppm	0.1-1.0 ppm	60 ppm
Exceedance Values:					
Mean	6.8 mmhos/cm	1.9 ppm	0.46 ppm	0.88 ppm	80.5 ppm
Range	4.03-11.4 mmhos/cm	1.01-7.6 ppm	0.3-3.6 ppm	0.1-3.9 ppm	61.4-124.0 ppm

Exhibit 3

4. Agricultural Potential

Although loamy soil acreage would be increased over the whole area, sandy and loamy soils would be placed indiscriminately on the landscape. Sandy soils would not be placed in drainages or on slopes exceeding ten percent, as required by DSL. Previous cropping success has been limited to large areas of loamy and clayey soils that could be managed in a similar fashion. Cropping success has been sporadic on sandy soils due to low water availability. The patchy intermingling of loamy and sandy soils on the post-mined landscape would reduce the potential for crop production.

5. Area C, Block II

In the life of mine area, Block II, the proportion of loamy and clayey alluvial soils is greater, compared to other soil types, than in Block I. This soil group has the highest potential for subsoil layers containing excessive soluble salts, which might limit salvage depths. There is a possibility, therefore, that the overall depth of soils suitable for replacement on regraded surfaces may be less than in Block I. The overall higher clay contents in the soils of Block II could also result in a greater tendency for compaction during replacement.

G. VEGETATION

Existing vegetation on approximately 1,627 acres of land in Area C, Block I would be destroyed, beginning with construction of facilitites and continuing as mining progresses. For all of Area C, the amount of vegetation destroyed would be about 7,900 acres.

Through reclamation procedures planned for Block I by Western Energy, vegetation would be restored to the entire disturbed area. The revegetation effort should result in plant communities consisting primarily of native species. The seed mixtures that Western Energy plans to use are made up of native plants (Appendix G, Table 2) with the exception of four species, cicer milkvetch (Astragalus cicer), sanfoin (Onobrychis viciaefolia), Kentucky bluegrass, and Canada bluegrass (Poa compressa). Woody species would be included in the seed mixtures, and in addition, trees and some shrubs would be planted as tubeling transplants. A tree spade would be used to transplant approximately 50 larger trees. Stocking rates for ponderosa pine (Pinus ponderosa) and Rocky Mountain juniper (Juniperus scopulorum) are to be equivalent to pre-mine conditions with an allowance for expected mortality.

The success of revegetation efforts takes several years to judge because of the many factors that enter into the dynamics of community establishment. Most of the revegetation efforts of sufficient age at the Rosebud Mine for analysis used mixtures of introduced and native and introduced species. In these areas, forage production has been almost double that of the pre-mine vegetation; however introduced cool-season grasses have dominated the community to the exclusion of many warm-season grasses, perennial forbs, or shrubs (DePuit et al., 1980). No areas have been completed using the two-phase seeding approach proposed for Area C, Block 1. One study area for native plant establishment techniques was established in 1977, and has shown positive results for both broadcast and drill seeding techniques and several levels of seed application and species mixes (DePuit et al., 1980). It is probable that a protective cover of vegetation can be established on the post-mine area with forage productivity higher than pre-mine levels. It is not certain whether all of the criteria for bond release, however, would be met, as this has yet to occur in Montana.

While overall success of the revegetation plan would be expected, post-mining vegetation would vary considerably from the pre-mining plant communities. These impacts are as follows:

- Rangeland forage production is likely to exceed pre-mining production as forage grass species become dominant providing weather is favorable and proper management is applied to the area. This would not happen immediately, but is expected to occur within five to ten years after final seeding, following an initial flourishing of annual grasses and weedy species.

- Increase in forage production should be in the range of 25 to 50 percent. This assumes that Western Energy would follow a deferred rotation grazing system and proper grazing use after

vegetation is well established and that root-inhibiting compacted layers are not created during overburden grading or soil replacement operations. (See discussion, Section F.)

- The amount of land in rangeland vegetation would be greater than in the pre-mining state because the disturbed hayland and pasture acreage would be revegetated with native species. Tame pasture and hayland would be reduced from 334 acres to 104 acres after mining. This would result in a reduction of about 250 tons of hay annually, and the loss of some early spring grazing. These losses would be partially offset by increased acreages of range for forage production.

- Post-mining sites would probably have less vegetative diversity than pre-mining sites, particularly on areas reclaimed with stockpiled soils. Lack of commercial seed sources for some species, particularly forbs, may prevent their initial establishment on reclaimed areas. Diversity should increase with age in the reclaimed area due to infilling from adjacent natural seed sources. The rate of increase in plant diversity by invasion from undisturbed plant communities will be a function of the reclaimed area's proximity to the undisturbed areas and the natural plant species propagule dispersal mechanisms, and the availability of suitable micro sites.

- The frequency of some of the grasses and shrubs species dominant before mining would be reduced under the proposed reclamation plan. This would be especially true for increaser species that had assumed dominant positions due to historical use patterns. The impact would be generally favorable in that the reduced occurrence of these species would more nearly reflect the potential climax community.

  Grasses - Prairie junegrass, found in pre-mining communities with frequencies of 30 to 70 percent, would be significantly reduced. This species is not included in any of the proposed seed mixes due to the unavailability of commercial seed, so its occurrence on the reclaimed surface would depend upon natural regenerative processes.

  Needle-and-thread grass occurs with a 70 percent frequency in the pre-mined grassland and skunkbush sumac communities. Seed for this species is included in the suplemental seed mix and so it is anticipated to be present in all reclaimed areas, but with a lesser frequency than in the pre-mined sites.

  Shrubs - The overall acreage of shrub cover will be reduced by about 33 percent. Within these acreages, it would be likely that the frequency of shrubs would be reduced to less than in the pre-mine shrub acreages because of increased competition from reseeded grasses. Table III-15 compares the acreage of pre-mine vegetative communities with acreage proposed for reestablishment in reclaimed areas. As the table shows, the major decrease in shrub species will occur in the

TABLE III-15

CHANGE IN VEGETATIVE COMMUNITIES
BEFORE AND AFTER MINING
AREA C, BLOCK I

General Vegetation Type	Acreage to be Disturbed	Post-Mining Acreage After Reclamation
Grassland	631 acres	1,345 acres
Big Sagebrush/Grassland	87	78
Silver Sagebrush/Grassland	77	19
Skunkbush Sumac/Grassland	72	60
Rubber Rabbitbrush/Grassland	4	2
Ponderosa Pine/Grassland	135	60
Cropland	376	60
Hayfield and Pasture	230	0
Areas Generally Devoid[a] of Vegetation	15	3

[a] In pre-mined areas this includes clinker pits, rock outcrops, and ranch yards. In post-mined areas this includes recreated sandstone "knobs."

silver sagebrush and skunkbush sumac types. All of the acreages presented in Table III-15 assume successful revegetation and do not include natural invasion of shrubs into post-mined areas. This is not meant to imply that invasion of shrub species may not occur, rather that it is not known to what degree this may happen.

- The area and distribution of ponderosa pine communities would be reduced: 180 acres of this vegetative type will be disturbed by mining, and only 60 acres are proposed to be planted with ponderosa pine. With complete revegetation success, only 55 percent of the disturbed ponderosa pine type would be replaced. To date, the establishment of conifers on scraper-hauled and regraded spoils at Colstrip has not been successful to the point that would indicate that stands of trees equivalent to pre-mine density could be established by the reclamation methods proposed by Western Energy. Researchers working at Colstrip (Richardson, 1981; Stark, 1980) have generally agreed that competition for soil moisture between trees and grass is the chief factor affecting survival of ponderosa pine seedlings and transplants, as well as other woody species. The reconstructed soils, due to their loamy and bulk densities, favor moisture uptake through the extensive shallow fibrous root systems of grasses, giving these plants the competitive advantage over the deeper root systems of woody species (see Soils, Section F).

- Discrete range sites presently existing in Area C, Block I would not be restored in the reclamation process due to mixing of soils. This would constitute the loss of potential for separate and distinct plant communities inherent in the existing range sites, and the spatial, seasonal, and species diversity presently found in the area.

Western Energy has not submitted specific reclamation plans beyond Block I for Area C but, it is assumed that revegetation efforts would be subject to similar influencing factors described in Block I. Future reclamation plans would incorporate results from revegetation experience and studies on earlier reclaimed mined areas. Post-mining revegetation conditions would probably approximate Block I, but would reflect the specific reclamation plans and climatic and soils conditions under which the plans are implemented (see Sections F and G, Chapter III).

H. WILDLIFE

In general, the significant areas of concern for impacts pertain to disturbance to especially valuable habitats or features. Most notably, these include: the prominent sandstone outcrops/cliffs that have historically served as nesting habitat for several raptor species, including the golden eagle and prairie falcon; the wooded and shrubland habitats, which provide nesting sites, and forage and shelter; and perennial and seasonal sources of surface water available to wildlife. Two specific sites of special concern exist in Area C, Block I: a golden eagle nest site and a sharp-tailed grouse dancing ground. The U.S. Fish and Wildlife Service has recommended that the sandstone outcrop on which the golden eagle and prairie falcon nests are located not be destroyed (U.S.F.W.S., 1981). Also, DSL has requested a 100-meter buffer zone be left between the outcrop and the mine. Western Energy is continuing its sponsorship of mitigation investigations on sharp-tailed grouse, particularly dancing ground reestablishment. The anticipated mining pattern for the Area C, Block II life of mine would eliminate the sandstone cliff nesting sites as well as two sharp-tailed grouse dancing grounds. These nesting sites and dancing grounds may have regional importance to the raptor and sharp tail grouse populations.

Legal and illegal hunting, wildlife vehicle collision mortality, and other human-wildlife interactions could be expected to increase with new and expanded development. Thus, a somewhat greater disturbance from human presence, including vehicle collisions with wildlife, could be expected in the immediate Area C vicinity as mining begins. No impacts to wildlife are expected as a result of the location and operation of the conveyor. Except for one mile, the conveyor corridor is located in areas already disturbed by mining.

Nearly all of the area to be disturbed by the Area C mining operation currently serves as habitat for a variety of wildlife. The reclamation plan would alter the proportions and composition of habitat types somewhat. Some of these changes would be neutral to beneficial if realized, but others, especially the reduction of ponderosa pine and shrublands by more than 50 percent, would represent long-term negative change. A reduction in the overall diversity of available habitats can generally be expected to be reflected in reduced wildlife diversity. Pre- and post- mining vegetation types are compared in Section G, Vegetation. The following sections discuss the noteworthy mining impacts to wildlife groups in the vicinity of Area C.

1. Big Game

During the years of active mining, active mine areas may be less suitable for big game. However, the relatively low big game populations in the area in recent years and availability of alternative habitat in adjacent, undisturbed areas suggest that this impact may not be a significant limiting factor.

Because of the importance of ponderosa pine and shrub habitats to mule deer, the unknown efficacy of efforts to reestablish these habitats

after mining, and the proposed reduction of the ponderosa pine type on the area, suitability of the area for mule deer use is expected to be somewhat decreased by the proposed action. Reduction of sagebrush-grassland may make the area less suitable as pronghorn habitat.

Finally, habitat surrounding Area C is comparable to Area C, and may serve as alternative habitat. No evidence is available suggesting that deer or antelope populations in the area are presently limited by available habitat or food sources, so Area C does not appear to be critical to the welfare of deer and pronghorn in the study area.

2. Other Mammals

Although Area C mining activities would temporarily eliminate small mammal populations in the disturbed area, there is no indication that any especially sensitive species of small mammals would be affected by the mining operations. To the extent that the general small mammal population is important as a prey base for raptors, this prey base would be reduced until a diverse, stable vegetative community, adequate to support the kinds and numbers of small mammals present now, is re-established. Limited studies in various Colstrip area habitats, including reclamation sites, suggest that small mammal populations may be larger, though less diverse, at least in the early years of reclamation. However, the alteration of the proportions of various habitats could affect the relative attractiveness of the area to the different small mammal species. This is particularly true of species such as porcupine and chipmunks, which are associated with wooded and shrubby habitats; and rabbits and marmots, associated with rocky microhabitats.

3. Mammalian Predators

Mining in Area C, Block I would temporarily render disturbed areas unsuitable for mammalian predators because of the lack of prey and proximity to human activity. It is not certain how successful the plans for revegetation will be in supporting a prey base similar in numbers and diversity to that now on the site. Therefore, it is not known which predators will return to the area.

The coyote is the most common mammalian predator in the area, but since the coyote doesn't appear to be habitat- or food-limited in the area, the habitat loss asociated with disturbance of Area C development should not significantly affect local coyote populations.

4. Upland Game Birds

One sharp-tailed grouse dancing ground may be disturbed by haul road construction and use. Feeding and nesting habitat near this dancing ground would also be reduced. It is uncertain what effect the reduction in feeding and nesting habitat and the disturbance to the dancing ground will have on sharp-tailed grouse in this local area. Western Energy will attempt to replace the dancing ground in Area C if it is abandoned during the mining operations.

Other upland game birds, such as ring-necked pheasant, Hungarian partridge, Merriams' turkey, and sage grouse are infrequent in Area C and are thus not likely to be significantly affected by the Area C mining operation.

5. Waterfowl

Waterfowl nesting and feeding habitat in Area C would be reduced during active mining. Reclaimed areas should replace this loss. Mining would not be expected to have appreciable impact on waterfowl species.

6. Songbirds

The revegetation program would alter the relative proportions of songbird habitats in the disturbed area. A reduction of shrub and woodland bird species would be expected. For example the impact to cavity-nesters would be long-term.

7. Raptors

One golden eagle nest, which was active in 1978, has been documented in Area C. Golden eagles are regularly sighted, especially in the spring, in and near Area C (ECON, 1975, 1976, 1977, 1978, 1979; Western Energy, 1980). Eagles are protected by the Bald Eagle Protection Act of 1940 as amended in 1962 (16 USC 668a), which prohibits "taking" of eagles or their nests, active or inactive. "Take" is further defined as "pursue, shoot, shoot at, poison, wound, kill, capture, trap, collect, or molest or disturb" (16 USC 668a). The Block I mining plan does not propose to physically disturb the nest site itself. The U.S. Fish and Wildlife Service has not yet determined whether or not the proximity of proposed mining activities to the nest site would constitute a disturbance within the definition of the law.

No specific studies have been conducted on hunting territories and food habitats of the golden eagles in the Colstrip area. Studies by Tyus and Lockhart (1979) suggested that breeding territories range from about 10 to over 20 square miles. Important food sources for golden eagles include rabbits, marmots, grouse and other species.

In addition to the possible reduction of hunting territory, the more direct threat of nest abandonment from direct disturbance exists. The sensitivity of raptors to disturbance varies tremendously between species and between individual pairs of the same species. Golden eagles and prairie falcons are both considered sensitive to human disturbance (Call, 1978).

Block I mining would also destroy some nesting and hunting habitat for other raptors, including a localized long-term reduction in mature ponderosa pine nest sites. Several of the raptors observed in Area C are

of both state and federal concern (Flath, 1981; Spear, 1980). Although present evidence is not adequate to assure revegetation would produce a raptor prey base comparable to present conditions, the area disturbed by Block I mining would be relatively small compared to the normal hunting range of most raptors in the area. It is not known whether a displacement of hunting territory out of the mine area will affect nest success.

8. Reptiles and Amphibians

Few reptiles and amphibians would be affected by mining in Area C. Hognose snakes (Heterodon sp.), of special concern in Montana (Flath, 1981), may be present, but this is not certain, as no special reptile surveys have been conducted. Rattlesnakes and other predatory reptiles would return to the area as reclamation progressed and prey populations began to recover in revegetated areas. Microhabitat changes, particularly reduced availability of rock habitats and winter denning areas after mining, may inhibit repopulation of reptiles.

9. Threatened and Endangered Species

No threatened or endangered species have been identified for Area C, Block I. If threatened or endangered species are found in or adjacent to Area C, consultation with the U.S. Fish and Wildlife Service would be undertaken and mitigation taken as necessary in compliance with the Endangered Species Act.

I. SOCIOLOGY AND ECONOMICS

1. Economic Condition

a. Employment and Population

Annual impact employment projections for Rosebud County and Colstrip are presented in Table 19 (Appendix I). Similar quarterly data is exhibited in Table 20 (Appendix I). As indicated by these tables, the impact employment in Rosebud County and Colstrip associated with the Area C work force addition peaks during the second quarter of 1983. However, when this additional work force is added to the baseline forecast, shown in Tables 10 and 11 (Appendix I), total employment in Rosebud County and Colstrip peaks the fourth quarter of 1982. Annual baseline and impact employment peaks in 1983 at 8,168 in Rosebud County. Projected county employment declines to 5,940 in 1985, stabilizing through 1995, and then rises to 6,596 in 2010. Area C increases the baseline county employment projections by 4.8 percent in 1983, 6.0 percent in 1990, and 5.8 percent in 2000.

In comparing 1982 and 1983 annual and quarterly peaks, it is important to note the differences between quarterly peaks and annual peaks. Annual data indicate that the peak baseline and impact population occurs in 1983 rather than 1982. When analyzed quarterly, peak baseline plus impact employment and population occurs during the fourth quarter of 1982, stabilizes through the second quarter of 1983, and then declines sharply during the third quarter of 1983. Although dependent on current construction schedules and nonlogged responses, the available data indicates that peak populations will begin during the last half of 1982 and extend through the first half of 1983.

The Area C addition is expected to result in about 210 new basic jobs between 1985 and 2010. These new jobs are projected to result in about 130 nonbasic, or derivative jobs for a total employment gain in Rosebud County of about 340 positions, or approximately six percent of projected baseline employment. The employment (basic/nonbasic) multiplier for the impact scenario is about 0.6, lower than that projected for the baseline conditions. This is because the basic impact employment includes nonlocal miners and construction workers and government services were not expected to expand much as a result of the Area C expansion.

The impacts of permanent mining and temporary heavy construction employment were treated separately in this analysis. Temporary heavy construction employment related to the proposed mining activities in Area C, Block I was assumed to have no effect on derivative employment in Rosebud County. The existing work force in trade and services was assumed to assimilate the additional temporary impact. Mining employment, on the other hand, was assumed to have an effect on support sector employment. Retail and service employers in the area were assumed to regard mining employment as long-term and to expand or build new facilities to accommodate the enlarged economic base.

Colstrip's annual impact and baseline population is expected to peak in 1983 at 7,259 persons. This figure, when compared with the 1982 fourth quarter peak of 8,205, emphasizes the importance of quarterly analysis. Annual peak 1983 employment and population for Rosebud County, including both baseline and impact forecasts, are 8,168 and 16,419 persons, respectively compared to the 1982 fourth quarter peak figures of 8,770 and 17,570 persons.

Population impacts for the temporary heavy construction work force in Area C, Block I were also assumed to be different from those for the more permanent mining work force. The projected impact work forces were residency-adjusted before the population impacts were computed to account for out-of-Rosebud County and out-of-Colstrip commuting. It was assumed that 30 percent of the construction work force and 37 percent of the mining work force would commute into Colstrip. Ten percent of the mining work force and 15 percent of the construction work force were assumed to commute into Rosebud County (Edwards, Reardon, Spiegel, Tomasik, 1982).

Population projections for Rosebud County and Colstrip are shown in Tables 19, 20, and 21 (Appendix I). Baseline and impact projections parallel those for employment, mentioned above. Rosebud County population is projected to peak during the fourth quarter of 1982 at 17,570. Annual population is expected to peak at 16,415 during 1983. It is projected to decline to 12,191 in 1985, and stabilize through the year 2000. Area C expansion will add between 5.5 and 5.8 percent to the projected county baseline population after 1985.

The population of Colstrip would be expected to peak at 8,205 residents the fourth quarter of 1982. About 60 percent of these residents would be temporary. Of the peak 1982 population, approximately 540 (about seven percent) would be attributable to the Area C expansion. The Colstrip population would remain at a relatively high level (8,096 residents) until the second quarter of 1983, when it would begin to decline. The maximum population attributable to Area C would occur at this time and would comprise about 816 persons (about ten percent of the total population). The latter population contribution would occur as the construction crews for generating Units 3 and 4 are declining and would slightly reduce the rate and prolong the period of population decline in Colstrip. The Area C operations would contribute approximately 250 permanent residents to the Colstrip population by late 1983. The total population of Colstrip is expected to stabilize at about 3,700 residents by 1985 or 1986, when all planned construction has ceased. At this time, the population attributable to the proposed operations at Area C, Block I would be about 12 percent of the total resident population.

b. Personal Income

Table 22 (Appendix I) presents mining and construction income, Montana personal income tax payments, and the Area C, Block I, work force for the forecast period 1982 to 2018. Total labor and proprietors' income in Rosebud County would increase as a result of the Area C expansion. In 1980 dollars, Area C would increase Rosebud County labor and

proprietors' earnings from a low of about 2.6 percent in 1982 to a high of about 11.2 percent in 2010. The continued industrialization of Rosebud County is not expected to significantly increase labor costs to local businesses. Also, the 1970-1979 trend in wages is consistent with local persons filling many of the new jobs (Polzin, 1981).

2. Social Life

The social impact of the population increase attributable to the Area C, Block I mine operations would be small in the context of the sizes of the total and transient populations induced by all development in Colstrip. Additional burdens would be placed upon some already overextended social and community service programs (e.g., formal recreation programs, shopping); these additional burdens will reduce the availability of such services and reduce the quality of social life to some unmeasured degree. The proposed project also would slightly prolong the period in which transient residents comprise a significant proportion of Colstrip's population. According to area informants, the presence of large numbers of transients within the Colstrip population inhibits the development of a community identity. The persons brought to Colstrip by the proposed project would be very similar to the present residents of Colstrip. As such, they are likely to share similar values, patterns of social interaction, and recreational habits. Their occupations and pay scales would also be identical to those of many present residents of Colstrip. Given this similarity, the impact of the proposed project upon the social life of Colstrip is expected to be minimal. The determination of minimal impact is based upon the similarity of newcomers and with consideration of the context of existing social life in Colstrip. That context is of an unstable social life for many, with relatively few of the social amenities many people have come to expect, a large proportion of people considered to be (and who consider themselves to be) transient, and widespread feelings of powerlessness, rootlessness and anonymity.

3. Social and Community Services

a. Law Enforcement

The Rosebud County Sheriff has indicated that anticipated population growth induced by the construction of Colstrip Units 3 and 4 and the Area C, Block I mine might require the addition of one deputy and one secretary to his Colstrip staff (Ash, 1982).

b. Fire Protection

The additional Colstrip population attributable to the proposed project would not be expected to have a significant impact upon the provision of fire protection services.

c. Sanitary Sewer

The additional Colstrip population attributable to the proposed project would not be expected to have a significant impact upon the local sanitary sewer system.

d. Water Supply

The additional Colstrip population attributable to the proposed project would not be expected to have a significant impact upon the local public water supply.

e. Solid Waste

The solid waste load is projected to increase about seven percent as a result of Area C. Solid waste collection capacity in Colstrip is adequate to serve projected peak populations. The capacity of the area waste disposal site is adequate for present and projected populations.

f. Social Welfare

The increase in population attributable to the proposed project would not be expected to have a significant effect on the provision of social welfare services in Colstrip.

g. Medical Services

Existing medical services and resources are inadequate to meet the present Colstrip residents' needs as well as the added population brought in by the proposed project according to the Montana Health Systems Agency. Mental health services are considered to be overextended at present; therefore, additional population growth would further aggravate this situation. Many rural communities in Montana also are similarly underserved and are apt to remain so because of their small populations and distance from major medical facilities. No specific estimates of the type of medical or other health manpower are available for Colstrip's projected peak populations. The difficulty of recruiting health manpower and the expense of health/medical facilities make it unlikely that the problem will be resolved in the near future, and certainly within the projected peak population period.

h. Housing

Table 23 (Appendix I) contains projections of housing demand in Colstrip as a result of the proposed project. The proposed project would create a 12 to 14 percent increase in Colstrip housing demand through 2010. Although the maximum housing demand of 295 units would be projected to occur in the third quarter of 1983, when reviewed in combination with the baseline projections, the maximum total housing demand of 2,943 units would be projected to occur in the fourth quarter of 1982. Peak housing demand would be projected to exceed the proposed housing unit supply by 60 units. This would not be considered problematic because of the possibility that more "doubling up" may take place

than is anticipated, or the schedule may lag, causing the projected fourth quarter housing impact to be delayed until early 1983, when the baseline housing demand would be smaller.

i. Education

Table 24 (Appendix I) shows the current and projected elementary (kindergarten through eighth grade) and high school (grades nine through twelve) enrollment in Colstrip School District #19 by year through 1985 and in five-year intervals thereafter to the year 2000. The increase in enrollment attributable to the proposed project is also identified in the table. During the next two years, elementary and high school student enrollment would be expected to increase substantially, with the addition of 496 new elementary and 192 high school pupils, primarily due to the anticipated increase in the size of the Colstrip Units 3 and 4 work force. Thereafter, school enrollment would decline and then stabilize in 1985; with a total of approximately 1,100 students, of whom about 30 percent will be in high school and the remainder in grades kindergarten through eight.

The increase in enrollment attributable to the proposed project would be small. Starting in 1982 with 56 students, the enrollment increment would increase to 143 students by 1985 and then stabilize at that general level thereafter.

With the completion of the new Pine Butte Elementary School by September 1982, the Colstrip school district would have sufficient capacity to educate all students attrbutable to Area C expansion and projected to reside in the area. Through 1984, there will be a continuing need for the modular, wood-frame classrooms that currently serve as the Pine Butte School. Thereafter, the new Pine Butte and Isabelle Bill Schools would have sufficient capacity for all elementary students. Also, the current high school facility can accommodate the projected enrollment increase. Given the small size of the existing high school classes there appears to be little need to add teaching staff at the high school level. Additional space for secondary students would be available in the fall of 1983 with the completion of the proposed new Colstrip High School.

4. Public Finance

The proposed project would add significantly to the taxable value for the county and both school districts.

The forecasted impacts of the proposed project on the fiscal condition of Rosebud County are presented in Table 25 (Appendix I). It should be noted that property taxes on non-Area C, Block I property are expected to decrease as the total taxable value of the county is increased by the Area C, Block I coal production and ancillary equipment. The net effect on taxable value in the county due to the two primary taxable components of the mine expansion, capital investment and gross proceeds,

is shown in Table 26 (Appendix I). The peak increase in taxable value due to Area C occurs in 1990. However, Table 27 (Appendix I) indicates that Area C constitutes an increasingly greater percentage of county taxable value through 2015 as the baseline taxable value diminishes. The increase in a given year in total taxable value under the balanced budget scenario forces mill levies down below those projected under the baseline scenario.

The net effects of the Area C expansion on Rosebud County local revenues and operating expenditures are shown in Table 28, Appendix I. At most the proposed expansion would result in an increase of approximately six percent in either operating expenditures or local revenues.

The projected impacts on the two school districts are shown in Tables 29 and 30 (Appendix I). Revenue and expenditure patterns similar to those occurring in the baseline projections are expected. However, revenues and expenditures are somewhat higher for the reasons discussed above. Mill levies in the balanced budget scenarios are somewhat lower, due to the effects of the Area C expansion on taxable value in the school districts.

The forecasted impacts of the proposed project on the Colstrip townsite finances are presented in Table 31, Appendix I. The net effects of the Area C expansion on local revenues and operating expenditures in the Colstrip townsite, as presented in Table 32 indicate that at most the proposed expansion would result in an increase of approximately 13 percent in either local revenues or operating expenditures. The influx of workers into the townsite would not be expected to significantly affect the level of services required, or the overall fiscal condition.

In addition to creating additional revenues for the local taxing jurisdictions, the Area C expansion would result in the payment of approximately $189 million (1980 dollars) in federal royalties, roughly half of which would be returned to the state, and payment of approximately $318 million in Montana coal severance taxes (Table 33, Appendix I).

J. LAND USE

1. Direct Impacts

The major direct impact on land use in Area C, Block I would be the addition of 1,627 acres of mining disturbance at the Rosebud Mine, which represents an increase of about 59 percent over the current disturbance at the Rosebud Mine complex. The change in land use patterns in Area C, Block I is presented in Table III-16.

Livestock grazing would be precluded on 1,006 acres (less than 0.04 percent of available rangeland in Rosebud County) during active mining and intial reclamation. After vegetation is reestablished (about three years after seeding, providing natural conditions warrant), limited grazing under the planned pattern can begin (see Section G, Vegetation). The planned deferred grazing pattern would continue until bond release (a minimum of ten years), after which normal ranching operations could resume.

Vegetative productivity would fluctuate during intial vegetation establishment due to such factors as early rapid growth from seeding operations and subsequent natural changes in species composition as the vegetative cover stablizes. Actual post-mining productivity under proper management would probably be higher than pre-mining levels (see Vegetation, Section G).

The amount of cropland that would be displaced by the proposed plan (about 606 acres) amounts to about 0.5 percent of the total cropland in Rosebud County. Since the cropland in Area C, Block I would be reclaimed as rangeland, (with the exception of about 60 acres disturbed by facilities, topsoil stockpiles, and haul roads that would be returned to cropland), this acreage would be unavailable for use as cropland until after bond release, at which time surface owners could put the reclaimed land to other uses. The suitability of irrigating cropland in the vicinity of Area C, namely along Stocker Creek and East Fork Armells Creek, could be diminished by mining activities if water quality were adversely affected (see Section B, Hydrology). This could affect about 1,825 acres of land in Area C that is potentially irrigable (Hydrometrics, 1981), although most of this acreage is not irrigated at present due to insufficient flow during the majority of years.

All projected mining and power generation in Rosebud County would displace livestock grazing on about 24,000 acres (less than one percent of the available grazing land in Rosebud County (Montana Department of State Lands, 1981). Mining activity in Area C, Block I would contribute to less than four percent of the total displacement. Similarly, the total projected acreage of consumed cropland due to mining and power generation in Rosebud County is about 800 acres (0.6 percent of the available cropland in Rosebud County) (Montana Department of State Lands, 1980). Mining activity in Area C, Block I would contribute to about 75 percent of the total consumption.

TABLE III-16

SUMMARY OF LAND USE IMPACTS
IN AREA C, BLOCK I

Land Use Category	Present Use	Use During Active Mining (1982-1987)	Post-Mining Land Use (After Reclamation)
Rangeland			
Grassland and Shrubland	1,724	853[a]	2,360
Ponderosa Pine	180	45	105
Cropland			
Grain Fields	436	60[a]	120
Hay Fields	334	104[a]	104
Mining Disturbance	0	709	0
Mine Facilities and Associated Disturbance	0	918	0
Other Land (Sandstone outcrops, clinker pits, and abandoned ranch yard)	19	4	4
	2,693 acres	2,693 acres	2,693 acres

Most of the county-wide displacement of rangeland would be temporary, except for about 890 acres that would be permanently converted to urban and industrial uses (Montana Department of State Lands, 1981). The proposed project in Area C, Block I would not be expected to contribute significantly to the increased urban and industrial land use, the bulk of which is due to the construction and operation of Colstrip generating Units 3 and 4.

Long-range changes in land use could occur with additional mining activity subsequent to the development of Area C, Block I. (See Sections F, G, and H, Chapter III.)

The conveyor corridor would cut through the cropped lands located inside the Area A loadout facility railroad loop. Approximately 70 acres are currently irrigated and produce approximately 2.0 tons of hay per acre annually. The corridor would occupy only 6.5 acres, but could prclude the irrigation on all or a portion of the remaining 63.5 acres for the life of the conveyor facility.

2. Indirect Impacts

The Colstrip Townsite Expansion Master Plan calls for increased housing, facilities, streets, and parks to meet the demands of power plant construction (Units 3 and 4) and coal mine expansion (Rosebud County Planning Board, 1980). This land use plan is expected to adequately incorporate population increases that could result from the development of Area C (see Section I, Sociology and Economics).

No adverse impacts are anticipated to federal planning as it pertains to the BLM's management Framework Plan.

K. TRANSPORATION

Development of Area C would bring in a maximum of about 302 workers during the construction phase, and a maximum of about 228 workers during the operation phase (see Section I, Sociology and Economics). Of these workers, approximately 30 percent would be expected to live outside Colstrip and commute into the area. During the construction phase, approximately 100 workers would be commuting into Colstrip, with about 40 workers living outside Rosebud County. Assuming that 50 percent of the workers would car pool, and 25 percent of those workers living in Billings or Miles City would use commercial bus service to Colstrip, the resulting traffic increase would be about 65 additional vehicles per day using FAP 37 and/or FAP 39 (or 33 additional vehicles along any given segment) distributed over three shift changes (Table III-17). Similarly, estimated traffic increase during the operation phase would be about 57 vehicles per day (or 28 additional vehicles along any given segment). These increases are less than five percent of current daily traffic levels, and should not have any significant impact, particularly with the completion of the proposed highway reconstruction (Rice, 1982). With the completion of Colstrip generating Units 3 and 4, traffic levels should decrease substantially.

Rail capacity would not be affected because all coal recovered in Area C would be transported to the Colstrip generating units by conveyor. The coal conveyor would undercross the county road, thereby causing no traffic interference.

The proposed plan would necessitate the permanent relocation of about four miles of the East Fork Castle Rock County Road (R140) to about 0.5 mile north of its present location, and about two miles of the East Fork Armells Creek County Road (R141) to about 0.50 mile south of its present location (Figure II-22). In their present location, these roads would be disrupted by mining activities. The Rosebud County Commissioners in Forsyth have determined that the proposed relocation would not adversely affect the public or the surrounding land owners (letter of November 13, 1981 to Western Energy Company). During mining years 21 through 34, County Road 141 would have to be relocated or closed because the road would be displaced by mining. The rebuilt road would comply with the standards set forth by the county commissioners in their letter of November 13, 1981.

TABLE III-17

POTENTIAL INCREASED DAILY TRAFFIC LEVELS

	Construction Phase (1982-83)		Operation Phase (1984-2010)	
	Workers	Vehicles[d]	Workers	Vehicles[d]
Living in Colstrip[a]	202	--	144	--
Communting Solo	40	40	36	36
Car Pooling[b]	50	25	42	21
Commercial Bus Service[c]	10	--	6	--
	302	65	228	57

[a] Assumes that workers living in Colstrip would not be commuting along major highways and may use Western Energy Company's shuttle bus service to the mine.

[b] Assumes 50 percent of commuting workers would carpool in groups of two.

[c] Assumes 25 percent of workers commuting from outside of Rosebud County would use commercial bus lines from Billings or Miles City.

[d] This represents total additional commuting vehicles. If half commute via northern routes to Colstrip and half via southern routes, increased vehicular traffic along any given segment would only be 50 percent of the represented number.

L. RECREATION

1. Urban Recreational Resources

All Colstrip Area Recreation and Parks Association (CARPA) recreational resources and facilities are used to capacity at present population levels and are considered inadequate to serve the existing population (see Chapter II, Section I). To date, CARPA reportedly has been unable to use school facilities for recreational purposes, due to scheduling conflicts. Colstrip is in need of additional multi-purpose recreation space, indoors and outdoors. The existing needs for space will not be met, even with the completion of the Stillwater Park in the fall of 1982 (Noyd, 1982). The project would sustain these use pressures by maintaining high population for an extended period; however, the long-term recreational needs would decline in direct proportion to the 45 percent decline in projected population between 1982 and 1983 with the completion of Units 3 and 4.

2. Impact on Nonurban Recreational Resources

Additional population growth attributable to the proposed Area C, Block I mine operation would impose no significant negative impact to the area's nonurban recreation resources.

M. CULTURAL RESOURCES

1. Area C, Block I

A summary of project impact to the nine cultural resources in Area C, Block I is presented in Table III-18. The mining would partially or totally destroy seven of these sites: Lynn's Square, Gene's Vision Quest, Cooley Site, Fadhl Kill Site, Fadhl Homestead, Tripoint, and Medicine Root sites. The Three Ring and the Farley Lookout sites are located adjacent to the mining areas and may be affected by erosion, vandalism, or off-road vehicle use.

Of the seven sites that would be destroyed, three (Lynn's Square, Gene's Vision Quest, and the Tripoint Sites) appear to be ineligible; and three (the Cooley, Fadhl Kill, and Fadhl Homestead Sites) appear to be eligible for nomination to the National Register of Historic Places. One site (the Medicine Root Site) needs additional testing before a National Register recommendation can be made. Of the two sites located adjacent to direct mining or construction activity areas, one (the Farley Lookout Site) appears to be eligible for nomination to the National Register. The other (the Three Ring Site) does not.

Mitigation, in the form of intensive data collection and recording or other approved methods, is required prior to the disturbance of those sites determined eligible for the National Register. Those sites determined ineligible have been fully recorded and the information placed on file.

2. One-Mile Buffer Zone

The purpose of the buffer zone survey was to locate and identify cultural resources that could be affected by blasting. Most prehistoric sites would not be affected with the exception of rock and rock shelters. Likewise, only historic sites with standing structures would be affected. However, all sites in the buffer zone may sustain increased deterioration through vandalism.

A summary of project impact to the 25 sites within the one-mile buffer zone around Area C, Block I is presented in Table III-19. Eleven of the 25 cultural resources have rock art or standing structures and could be affected by blasting. Of these, two (Doc Taylor Place and Muskrat Homestead) have been determined to be eligible for the National Register; one (Cooley Place Site) appears to be eligible for the National Register; seven appear ineligible for the National Register (Dusty Shelter, Castle Rock Post Office and Homestead, Caskey 310, Lovelace Memorial, Petro City, P.E. Davis Rock Art, and Connie's Gallery); and one (Forsite) needs testing before a National Register recommendation can be made.

The Sly Bison Site, which has been determined eligible for the National Register, and Insite sites, identified in Chapter II as potentially eligible, are prehistoric and neither contains rock art or

TABLE III-18

SUMMARY OF IMPACT TO CULTURAL RESOURCES
AREA C, BLOCK I

National Register Eligibility	Impact Assessment
Sites Considered Ineligible	
1. Three Ring Site (24 RB 1060)	1. Site may be impacted. Site is located between the boxcut and spoils reduction area, a road construction area, and a scoria pit. Impact assessment unnecessary if site is ineligible for National Register.
2. Lynn's Square (24 RB 1071)	2. Site would be destroyed. It is located within the highwall reduction area. Impact assessment unnecessary if site is ineligible for National Register.
3. Gene's Vision Quest (24 RB 1072)	3. Site would be destroyed. It is located partially within a topsoil stockpile area Impact assessment unnecessary if site is ineligible for National Register.
4. Tripoint Site (24 RB 873)	4. Site would be destroyed. It is located within the mining pit area. Impact assessment unnecessary if site is ineligible for National Register.
Sites Considered Eligible	
5. Cooley Site (24 RB 1059)	5. Site would be at least partially destroyed. The northern portion of the site is located within a road construction area, and a pit power feeder transmission line passes through the center of the site. Impact would be considered significant if site is determined eligible for National Register.

TABLE III-18 (Continued)

National Register Eligibility	Impact Assessment
6. Fadhl Kill Site (24 RB 299)	6. Site would be destroyed. It is located within a boxcut spoils reduction and road construction area. Impact would be considered significant if site is determined eligible for National Register.
7. Farley Lookout Site (24 RB 1058)	7. Site may be impacted. It is located adjacent to the highwall reduction area. Impact would be considered significant if site is determined eligible for National Register.
8. Fadhl Homestead Site (24 RB 884)	8. Site would be destroyed. It is located within the mining pit area and a road construction area. Impact would be considered significant if site is determined eligible for the National Register.
Sites Requiring Additional Work Before National Register Recommendation Can be Made	
9. Medicine Root Site (24 RB 879)	9. Site would be destroyed. It is located within the highwall reduction area. Impact assessment cannot be made without eligibility recommendations.

Exhibit 3

TABLE III-19

SUMMARY OF IMPACT TO CULTURAL RESOURCES

BUFFER ZONE

Sites	National Register Eligibility
Potential Impact from Blasting and Vandalism:	
1. Doc Taylor's Place Site (24 RB 1065)	Has been determined.
2. Muskrat Homestead Site (24 RB 313)	Has been determined.
3. Cooley Place Site (24 RB 1064)	Appears eligible.
4. Dusty Shelter Site (24 RB 1069)	Does not appear eligible.
5. Castle Rock Post Office and Homestead Site (24 RB 335)	Does not appear to be eligible.
6. Caskey 310 Site (24 RB 1076)	Does not appear to be eligible.
7. Lovelace Memorial Site (24 RB 301)	Does not appear to be eligible.
8. Petro City Site (24 RB 302)	Does not appear to be eligible.
9. P.E. Davis Rock Art Site (24 RB 875)	Does not appear to be eligible.
10. Connie's Gallery Site (24 RB 877)	Does not appear to be eligible.
11. Forsite Site (24 RB 878)	Requires additional work before eligibility recommendation can be made.
Potential Impact from Vandalism Only:	
12. Sly Bison Site (24 RB 267)	Has been determined.
13. Insite Site (24 RB 874)	Appears eligible.

TABLE III-19 (Continued)

SUMMARY OF IMPACT TO CULTURAL RESOURCES

BUFFER ZONE

Sites	National Register Eligibility
14. McDonald Quarry Site (24 RB 303)	Does not appear to be eligible.
15. Rabbit Ridge Site (24 RB 310)	Does not appear to be eligible.
16. Rocky Top Site (24 RB 1061)	Does not appear to be eligible.
17. Wheatfield Vista Site (24 RB 876)	Does not appear to be eligible.
18. Pottery Site (245 RB 1062)	Does not appear to be eligible.
19. Sunburn Out Site (24 RB 881)	Does not appear to be eligible.
20. Normand Estates Site (24 RB 883)	Does not appear to be eligible.
21. Pigeon Site (24 RB 880)	Does not appear to be eligible.
22. East Fork Site (24 RB 886)	Requires additional work before eligibility recommendation can be made.
23. How Dry I Am Site (24 RB 252)	Has been determined ineligible.
24. MAL 1401	Requires additional work to determine if this warrants a site description before National Register recommendation would be made.
Potential Impact from Road Relocation:	
25. Albino Deer Site (24 RB 885)	Requires additional work before eligibility recommendation can be made.

Exhibit 3

standing structures. Thus, they would not be affected by blasting. Similarly, the East Fork and Albino Deer sites and MAL 1401, which need testing would not be affected. The Albino Deer Site will, however, be affected by road location.

The remaining nine sites would not be affected by blasting as they do not contain rock art or standing structures and do not appear eligible for the National Register.

If those sites needing additional testing and/or determined eligible for the National Register are to be disturbed by future mining, further cultural resource work would be required. Mitigation, through recording or other approved method, is required for the sites with rock art and standing structures prior to disturbance. If the company locates previously unrecorded cultural resources, they must notify the appropriate agencies and take steps to assure that valuable information on the sites is not lost.

Similarly, the portions of Area C life of mine plan outside of the proposal Block I mine site would be surveyed and mitigation requirements met in accordance with the National Historic Preservation Act prior to permitting.

N. AESTHETICS

Mining in Area C, Block I, would change all of the aesthetic values in the area to some degree, and would change them most appreciably during the life of the mine. Colors, textures, contrast, and relief would all be significantly altered during mining and after reclamation. Overall relief would be approximately the same in the reclaimed spoils, but topographic breaks in the mined areas that previously existed due to sandstone and clinker outcrops would be gone. Ponderosa pines in the mine area would be lost, perhaps permanently, thus altering texture, color, and contrast in the post-mine landscape. The revegetated slopes would have a generally uniform color and texture over the entire mined area and a noticeable contrast at the disturbed/undisturbed interface.

For the life of the mine, the noise levels in the area would increase due to heavy truck traffic, dragline operation, periodic blasting, and the conveyor system operation. Post-mine noise levels would remain high until all of the Area C (beyond Block I) mining activity is completed. Post-mine noise levels would eventually revert to pre-mine levels.

CHAPTER IV
ALTERNATIVES TO APPROVING THE PERMIT AS PROPOSED

This chapter presents alternatives to approval of Western Energy Company's proposed mine plan. Both administrative and technical alternatives are considered.

Administrative alternatives available to the Department of State Lands and OSM include taking no action, denial of the permit, selective denial of portions of the permit, and approval of the permit, subject to stipulations. Possible stipulations that would reduce environmental impacts identified in Chapter III are discussed in this chapter as technical alternatives. Any of these alternatives could be implemented if necessary to reduce the environmental impacts of the proposed project.

This chapter also discusses technical alternatives to the proposed action, including alternative mining methods and alternative energy sources; however, the Department is not empowered to require Western Energy to adopt any of the technical alternatives presented herein.

A. ADMINISTRATIVE ALTERNATIVES

1. No Action

Policy dictates that the Department must either approve or deny an application for a mining and reclamation permit within 240 days after receipt of a complete application. OSM has no legally required deadline for approval.

Montana does not have a formal administrative alternative to "defer action" following the receipt of a complete application for a mining and reclamation permit; however, the state may deem an application incomplete if the mine plan fails to meet state requirements. This action would lead to a postponement of the action, which has the effect of deferral. However, the Secretary of Interior has authority to defer approval of a mine plan for appropriate reasons.

2. Denial of the Permit

If the Department and OSM find the mine plan does not conform to the requirements of Montana's permanent regulatory program (ARM 26.4.301 et seq.), or the Federal Lands Program, then the agencies are obligated to deny the permit application. In the case of denial, it is likely that Western Energy would propose an alternative mine plan within Area C.

No mining would occur in Area C until a revised mine plan was submitted and approved; until that time, the land would continue to be subject to the effects of natural processes and to further discretionary modifications by surface owners.

Denial of the permit would almost certainly delay Western Energy's scheduled October 1983 coal delivery commitment to Colstrip Unit 3. Inasmuch as the boilers for Units 3 and 4 are being manufactured to conform with the characteristics of the Rosebud coal proposed to be mined from Area C, permit denial would require Western Energy to either reapply for an Area C permit or find another source of Rosebud coal to meet their contractual commitment to supply coal to Colstrip Units 3 and 4.

In the event that the Area C, Block I permit application was denied, Western Energy would still have the option of applying for mining permits on other undeveloped leaseholds, which could eventually replace the volume of coal proposed to be mined from Area C, Block I. However, plans and approvals for a new mine would take several years at this point, and there is no evidence that mining activities in other undeveloped portions of Western Energy's leasehold would have any less impact than the mining proposed for Area C, Block I.

3. Selective Denial

The Department and OSM have the option of denying Western Energy permission to mine in specified areas within the proposed permit boundary because of special, exceptional, critical, or unique characteristics, or where mining would affect the use, enjoyment, or fundamental character of adjacent land exhibiting any of the aforementioned characteristics. The impact analysis presented in this EIS has not identified any such lands in or adjacent to Area C, Block I, but that does not preclude the disclosure of such lands during the review of this EIS or subsequent review by the DSL technical staff. Additional permit application review is ongoing.

4. Permit Approval with Additional Stipulations

Possible stipulations that would reduce adverse environmental impacts identified in Chapter III are discussed in subsection B.3 of this chapter (Alternative Measures to Mitigate Adverse Impacts). Conceivably, any of these measures could become stipulations to the permit, if approved.

B. TECHNICAL ALTERNATIVES.

Three technical alternatives have been considered: alternative energy sources, alternative mining methods, and alternative measures to mitigate adverse impacts.

1. Alternative Energy Sources

The need to mine in Area C, Block I is based on the continued demand for coal and a specific contract to supply Rosebud coal to Colstrip Unit 3. Inasmuch as the boilers for Units 3 and 4 are being designed to

accommodate the characteristics of the Rosebud coal, it does not appear likely that other sources of energy will replace Western Energy's market for Area C, Block I coal.

Alternative sources of energy, including oil and gas, nuclear, hydroelectic, solar, and geothermal, may replace or reduce the need for new coal-fired power plants in the future, but are not expected to replace coal-fired plants now in operation or under construction.

Fossil fuels such as natural gas and oil are being replaced by coal-fired units in response to the national move toward energy independence. Conversion of coal-fired boilers to oil or gas has been discouraged under federal policy. Electric generation from nuclear power has not increased as rapidly as once predicted because of high capital costs and a level of uncertainty concerning the safety of nuclear power plants. New sites for hydroelectric power generation are limited. Solar power (including direct conversion, wind, energy, and biomass utilization) is still in the developmental stage and is not likely to replace coal-fired generating units in the near future. Geothermal source areas are localized and it is unlikely that geothermal power will be able to provide electric power at the same scale as coal-fired generators.

Nationwide energy conservation programs have been demonstrated to reduce electric energy usage and slow the consumption of energy fuels, but it is unlikely that energy conservation measures alone would eliminate the need for additional power generation in the Pacific Northwest in the foreseeable future. Energy loads (from all energy resources) in the Northwest regional area have been projected to be insufficient to meet the area's needs through the year 1992 (Pacific Northwest Utilities Conference Committee, 1981).

2. Alternative Mining Methods

Several alternative methods to mine coal were suggested and subsequently discounted as being impractical in the Area B (Montana Department of State Lands, 1976) and Area B Expansion EISs (Montana Department of State Lands, 1980), including underground mining, auger mining, contour mining, and in situ mining. These methods have not been reintroduced as alternatives to the proposed mine plan for Area C, Block I because of the proximity of Area C to Area B and the similarity of conditions. The reader is refered to the discussion in the two referenced EISs if any further elaboration is needed regarding the rationale for eliminating these methods as viable alternatives to the proposed project.

In this section, two reasonable alternatives will be discussed: mining of the McKay coal seam and a realignment of the pits proposed at Area C, Block I.

a. Mining of the McKay Coal Seam

The Department could require Western Energy to mine the McKay coal, underlying the Rosebud seam, if the McKay coal proved to be marketable.

Exhibit 3

Currently it is not. Western Energy has been unable to find a suitable market for the McKay coal due to its inferior quality. The McKay has an average sulfur content of about 1.31 percent (by weight), which is half again as high as the Rosebud (at 0.87 percent). Additionally, there are other "problem" constituents in the ash, namely iron (Fe) and sodium (Na), whose percentages are greater than the Rosebud. Increased iron content promotes boiler slagging at normal operating temperatures and increased sodium content tends to promote boiler tube deterioration (Western Energy, 1981).

In recognition of these problems, the Montana Board of Natural Resources and Conservation has prohibited the use of McKay coal in Colstrip Units 3 and 4, both as an exclusive fuel source and in combination with Rosebud coal (Western Energy, 1981).

The possibility still exists that Western Energy could find a buyer for McKay coal or blended McKay-Rosebud coal, and the Department continues to encourage Western Energy to find such a market. If McKay coal was mined in Area C, Block I, special handling, new equipment, and a revised mine plan would be required to provide separate handling of the McKay coal. The current contract calls for the sale of Rosebud coal only from Area C, Block I, and the equipment that would be used to extract coal from Area C, Block I is contractually dedicated to the fulfillment of that contract. Under the terms of the contract, Western Energy cannot divert any dedicated production equipment to uses other than fulfillment of the contract. In effect, this restriction tends to eliminate the possibility of producing small quantities of McKay coal in response to intermittent market demand. Thus, Western Energy would need to purchase and dedicate additional mining equipment to mining the McKay seam, and make necessary modifications to the proposed mine plan, which is currently designed to recover the Rosebud seam alone.

The McKay seam averages about eight feet in thickness throughout the proposed mining area, and represents about ten million tons of coal. The interburden between the McKay and the overlying Rosebud seam averages about 23 feet in thickness. Western Energy contends that, given a market, only a large-scale contract (1.5 to 2 million tons per year) would prove to be economically feasible at this time. Mining of the McKay would cause an increase in the depth of the pit by about 31 feet, which would require a permanent adjustment to the proposed mining plan. Decreased sidewall angles would be required to accommodate a deepened pit, resulting in escalated costs to remove the overburden and a larger disturbance area.

Mining both the McKay and Rosebud seams in Area C, Block I would recover approximately one-third more coal per acre disturbed, resulting in a commensurate increase in severance tax royalties to the state and possibly slow the rate at which new acreage is disturbed at Colstrip. On balance, noneconomic environmental impacts would increase slightly as a result of taking both seams, especially as a result of increased surface disturbance and the mixing of interburden with overburden materials. Higher concentrations of total dissolved solids (TDS) would probably occur in the spoils groundwater (refer to the Technical Support Document).

Exhibit 3

b. Pit Realignment

On April 28, 1982 the BLM received bids on federal coal leases throughout the Powder River Basin, including tracts located within Western Energy's Area C mine boundary totaling 892.56 acres. Western Energy was the only bidder. The USGS and BLM are currently analyzing these bids. A legal challenge to the sale has been filed by the National Wildlife Federation in U.S. District Court.

In the event that these tracts are obtained, Western Energy has developed an alternative mining sequence in Area C, Block I (Figure IV-1) to accommodate these lease tracts. The revised mining sequence depicted in Figure IV-1 is considered to be a viable alternative to the proposed project, and as such, it has been assessed and compared with the impact from the proposed project.

1) Geology

Western Energy engineers indicated that the mining method would be somewhat altered in Block I if the pit realignment alternative was implemented (personal communication during the October 1981 mine visit). Specific overburden handling information was not available from Western Energy; however, the engineers did indicate that overburden in excess of 100 feet would be removed by scrapers and stacked prior to the dragline moving in to strip the remaining overburden.

Since the upper sections of deeper overburden are predominantly sandstone in Area C, Block I, the placement of this overburden during reclamation has a significant bearing on the replaced overburden geochemistry. If this high percentage sand material is not mixed with the dragline spoils, then the bulk geochemistry of the spoils would not be that of the composited hole geochemistry shown in Chapter II, Table II-2. Not mixing the sand and dragline spoils would result in relatively higher average trace metals content in the dragline spoils than that shown in Table II-1 for some of the interior holes in Area C. Also, placement of the high sand spoils over the dragline spoils during reclamation could result in near-surface spoils with sand contents in excess of DSL suspect levels (i.e., greater than 70 percent sand).

This alternative would involve removal of all the sandstone ridge in Area C, Block I, and would result in a greater alteration of the visual appearance of the reclaimed area. In addition, this alternative would leave essentially no undisturbed rock in the permit area, whereas the Block I plan leaves an undisturbed sandstone ridge in part of the southern permit area. Other impacts would be the same as those for the Block I mine plan.

The reorientation of the pits would result in an overall increase in coal recovery from the Area C, Block I permit area. The pit realignment alternative would add approximately 400 minable acres to the Block I permit area with in situ coal reserves of approximately 16.3 million tons in the Rosebud seam. The amount of this additional resource that Western Energy would recover in the first five years of mining with the revised pit orientation is not known, but it is likely that production would be approximately the same for either pit orientation for the first year.

Exhibit 3

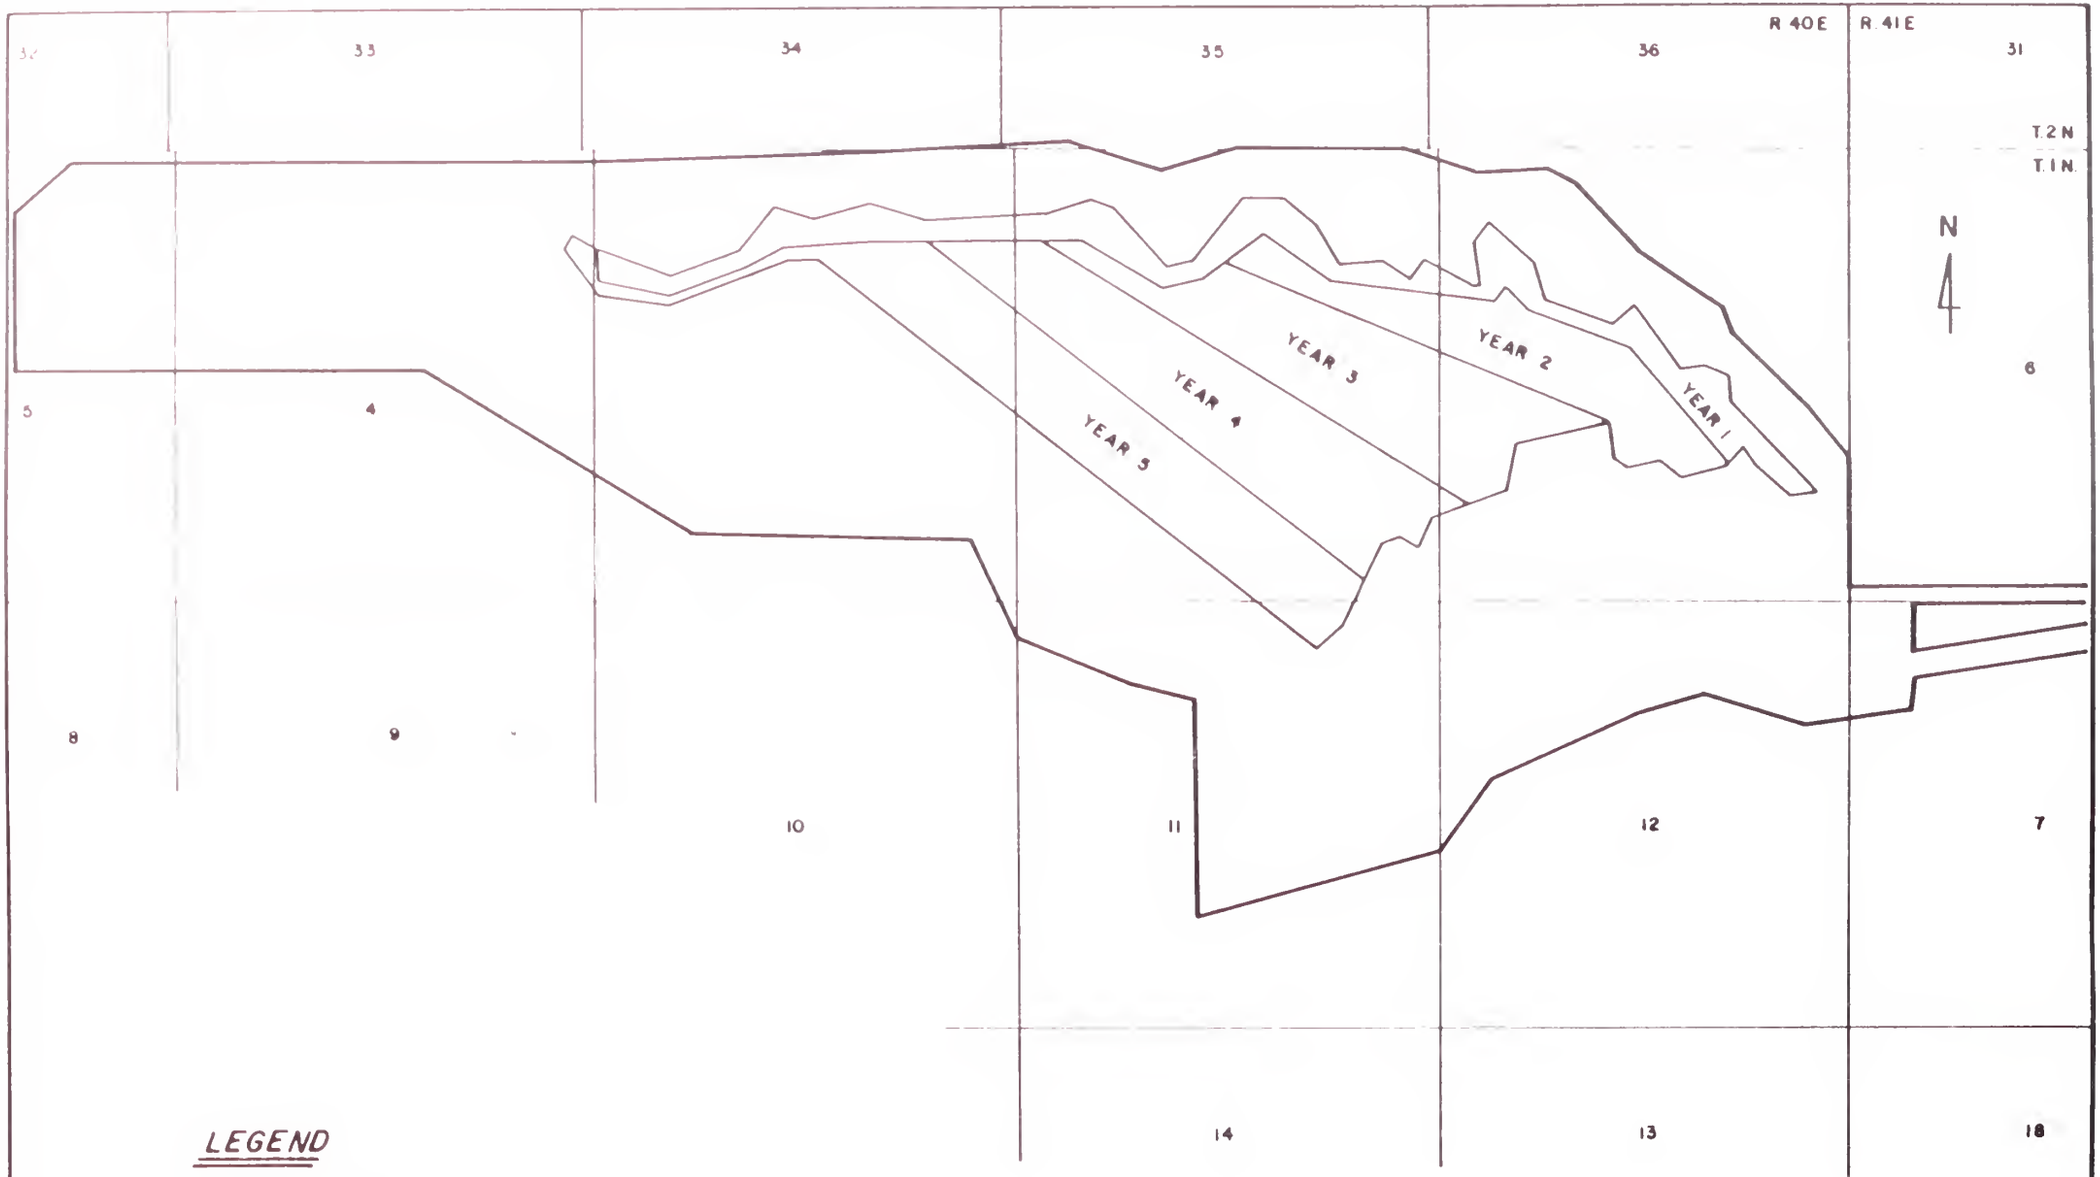

FIGURE IV-1 TECHNICAL ALTERNATIVE: REVISED MINING SEQUENCE AT AREA C, BLOCK I

Exhibit 3

2) Hydrology

The revised mining sequence would have no significant impact on groundwater flow. The nature of drawdown around the pit, the shape of a cone of depression in the Rosebud potentiometric surface and the extent of drawdown with time would remain effectively the same as they would be subject to the original mining sequence.

Since the revised mining sequence would disturb more area and would remove much of the sandy overburden prior to use of a dragline, some minor effects may result. First, the placement of sandy overburden at the surface unmixed with lower, finer spoil may slightly increase groundwater recharge potential. Second, if finer-grained spoils containing more leachable salts are mixed with sandy overburden, higher TDS values for groundwater may occur. Although this increase is not expected to be large, the exact increase in TDS concentrations cannot be accurately predicted with the existing data base.

3) Climate

No impact.

4) Air Quality

If the leases are acquired and the proposed mine plan is changed to reflect the alternative pit progression shown in Figure IV-1, the location of the sources of air emissions will change. However, because the coal and overburden removal rates do not change, the rates of emission would not change significantly. The alteration in pit location was examined in detail and the air quality model layout was revised to account for the different pit and spoil area locations. Trial calculations were performed and it was concluded that differences in air quality, deposition, and visibility impacts from those predicted in Chapter III would be very small and confined to the immediate area surrounding the mine. Therefore, the impacts predicted in Chapter III are assumed to apply to this alternative as well.

5) Noise

The impacts would be essentially the same as those for the proposed project, as discussed in Chapter III.

6) Soils

The reorientation of mining passes would result in the disturbance of more land by mining. Of the land to be disturbed, more undeveloped

rangeland supporting ponderosa pines and junipers would be disturbed. Suitable soils may not be available for successful reestablishment of even a portion of these vegetative types.

If excessively sandy overburden materials were placed near the surface (see Geology, Section A), the droughty condition of these materials as substrata would limit reestablishment and long-term vigor of some plant communities. Placement of excessively sandy overburden in areas that may experience gully development or the migration of headcutting would increase the potential of deep gully development.

The placement of sandy overburden material in the lower portions of mined-out pits would avoid this additional impact for the reoriented mine pits.

7) Vegetation

The reorientation of pits would result in the disturbance of additional conifer-shrubland and sagebrush shrubland areas. It is not certain whether ponderosa pine or skunkbush sumac, important species in the conifer-shrubland areas, can be reestablished on the regraded spoils (Section III-G). This alternative would result in an increase of good condition grassland for grazing and a decrease in vegetatively diverse types, especially ponderosa pine stands.

8) Wildlife

Wildlife effects of pit realignment would not be appreciably different. This alternative would disturb slightly more woodland, but as with the proposed action, would not disturb the golden eagle nest site. Of greater concern is the implied long-term commitment of the Block II alternative to a pattern of mining through the raised topography, which includes the sandstone cliff features of value as raptor nesting sites.

9) Sociology and Economics

Socioeconomic impacts would be identical to those described for the Block I plan, discussed in Chapter III.

10) Land Use

Most of the disturbance to cropland and rangeland under the pit realignment alternative would be similar to that identified under the proposed project. A portion of the cultivated field in the northwest section of the permit area that would be disturbed under the Block 1

mining plan would not be disturbed as a result of pit realignment. This amounts to about 80 acres of cropland that could remain in production for five additional years; however, the presence of mining activity on the northern portion of the field may make cultivation of the southern portion impractical. The extent of rangeland disturbance will be similar to that of the proposed plan, with a decrease in disturbed acreage in the northwest section of the permit area, and an increase in the disturbed acreage in the center of the permit area.

11) Transportation

Transportation impacts would be identical to those described for the Block I mining plan, discussed in Chapter III.

12) Recreation

Recreation impacts would be identical to those described for the Block I plan, discussed in Chapter III.

13) Cultural Resources

The impacts of the pit realignment alternative on the cultural resources located within Area C, Block I and its one-mile buffer zone cannot be made until the final archaeological report on the sites and the final mine plan have been released, reviewed by the Montana SHPO, and a determination of National Register eligibility has been made.

14) Aesthetics

The effect of pit realignment would not significantly differ from the impacts discussed for the proposed project, except that more forested acreage and more topographic diversity would be eliminated by mining through the sandstone ridge, instead of around its perimeter.

3. Alternative Measures to Mitigate Adverse Impacts

The following alternatives are presented as measures designed to mitigate the adverse impacts discussed in Chapter III.

a. Geology

Because of the significant increase in trace metal content in the five to ten feet of shale lying directly above the Rosebud coal, some method of selective removal of that zone in stripping overburden might be considered. A method that would prevent mixing that zone with other spoils and keep it below the top ten feet of reclaimed spoils would be very effective in minimizing, and in many cases eliminating, anomalous nickel, cadmium, and molybdenum values in the near-surface spoils. Possible methods include loading and hauling this material for later selective placement in the spoils or selective dumping of this material with the dragline to insure it does not end up on top of the spoils pile. The latter method would be more economical and probably easily achievable.

Field mapping could determine if significant faulting exists where it is inferred in portions of Block I. If present, then such faulting should be incorporated into Western Energy's surficial geology map and into the mine engineering plan for the pit realignment alternative mine plan. Engineering planning that recognizes any significant faulting could mitigate its effect on coal recovery in Area C.

Settlement problems can be mitigated with nominal bulldozer grading. It is expected that future subsidence problems will be small (under four feet of differential vertical displacement), can be mitigated by back-filling and regrading, and will occur soon after initial spoil grading. Subsidence problems are expected to be evident well before the end of the ten-year bonding period.

b. Hydrology

Western Energy's Rosebud Mine, Area C will affect the existing environment. Mitigation techniques proposed or recommended to alleviate long-term environmental degradation are presented in the following sections.

a) Groundwater

There are very few mining or engineering practices of a practical nature that can be used to mitigate potential groundwater impacts. However, one of the few possible means of mitigating groundwater flow changes is by employing truck-and-shovel mining methods instead of using a dragline. The nature of spoils (as replaced by truck-and-shovel) can be hydraulically different than spoils replaced by a dragline. A truck-and-shovel operation could create and replace spoils that more closely approximate the vertical permeabilities and porosities of undisturbed

coal and overburden. A truck-and-shovel operation tends to break up overburden less than a dragline, and can also recompact the spoils once they are replaced.

Greater compaction causes lower porosities in the spoils, which could allow for a quicker recovery of groundwater levels. Given a constant rate of inflow to spoils from any source, it would take, for example, half as long to fill up a given volume of spoils with 10 percent porosity as opposed to the same volume of spoils with 20 percent porosity. However in Area C, for example, the predominant source of groundwater recovery in reclaimed spoils would come from infiltration of precipitation. In this situation, the greater compaction of spoils by truck-and-shovel as opposed to a dragline operation would inhibit groundwater recovery because the extra compaction would limit vertical permeability, and hence infiltration. Since recharge from infiltration in Area C and most of the other mine areas is an important contribution to the regional flow system, it is important that recharge capacity be maintained. It appears that, all things considered, a dragline operation would create spoils more conducive to recharge and groundwater recovery than would a truck-and shovel operation.

b) Surface Water

The major impacts to the surface water regime from mining that can be mitigated are geomorphic instability and accelerated erosion. Geomorphic stability is largely determined by regional landscape units. In reclaimed areas, the stability of geomorphic landscape units is strongly influenced by reclamation techniques. Two of the primary factors that affect sediment yields from reclaimed landscape units are the nature of surficial materials and the topography, both of which should be the focus of design and management efforts. The following strategies were recommended by Ertec, Inc. to prevent instability and accelerated erosion.

o Alternative Reclamation Practices and Engineering Techniques

Studies on currently reclaimed areas suggest that infiltration rates and sediment yields from reclaimed sites are strongly correlated with the methods of topsoil placement and machine handling of the spoils. Dollhopf et al. (1977) determined that reclamation treatments (in this case, the use of bulldozers) that compact the spoils result in greater runoff and erosion rates. To avoid such problems, alternative reclamation practices, such as the use of chisel plowing techniques, could be employed.

o Soil Handling Mitigation Measures

Many of the soils in the Colstrip area are fairly erodible due to the high proportion of fine sands, which may result in high sediment yields from reclaimed areas. A range of measures (discussed in detail in Soils, Section F) could be applied to mitigate this effect. These measures could include mixing the salvaged topsoil or using surface stabilization techniques to minimize erosion prior to the successful establishment of vegetation.

o Topography Changes to Minimize Instability

Another factor that could be considered in large-scale landscape design is the post-mine topography. The current mine plan follows DSL regulations as to the gradient of reclaimed hill slopes. Slope length and shape also significantly affect erosion rates and must be considered in the landscape design. Experience gained during the early stages of reclamation could lead to the modification of the designed post-mine topography to minimize areas of potential instability.

o Subsidence and Soil Piping Mitigation

Geomorphic instability due to subsidence in the spoils materials may take three forms: area-wide settling, localized subsidence or collapse, and piping.

As discussed in Chapter III, area-wide settlement is likely to be less significant than in many other reclamation sites in Montana. However, the equipment used in handling the spoils is also a critical factor, and settlement is likely to be minimized if the reclaimed areas are contoured by scrapers rather than bulldozers, particularly if contouring is accomplished in winter (Groenweld and Rehm, 1980).

Localized subsidence, which may continue for a longer period following contouring, is also strongly affected by handling techniques and equipment. Groenweld and Rehm (1980) suggest that this type of subsidence can also be avoided if bulldozer contouring is restricted during winter months.

Mitigation measures to control piping and other types of settlement could include a range of controls on stability, such as: selective placement of spoils away from the geochemically active surface zone to mitigate surface cracking; selection of appropriate handling equipment; using techniques to avoid differential compaction, and an awareness of the importance of environmental factors, notably the potential freezing of spoils during contouring and reclamation.

o Gully Control

At the scale of the drainage basin within the mined area, stability can best be achieved by integrating the smooth upward-concave profiles of the reclaimed stream channels with the hill slopes within the basin, as well as with the upstream and downstream drainages. The reclaimed basins described in Western Energy's mine plan achieve this by approximating the original slope of the stream channels, and by grading the tributaries into the main channels so that no knickpoints are created. However, because of the inherently unstable nature of ephemeral drainage systems and the engineering considerations of reclamation, some instability problems may occur that require further mitigation measures. One of these problems is the development of gullies.

The relevant scales of operation for dealing with gully erosion include both the drainage basin, where runoff must be controlled, and the channel, where a stable form must exist. To be effective, attempts to control gullying must be comprehensive and the problems must be correctly identified. Gullies may develop from surface erosion when

runoff is concentrated by small depressions and knicks on a hill slope, or from subsurface erosion (piping) and the collapse of pipes. Measures to deal with the first type of gully development may not help and may even aggravate the problem of subsurface erosion. A further difficulty is in identifying the main source of sediment, which may be the adjacent hill slopes, the gully head, or the channel bed and banks further downstream.

Measures to control gullying should concentrate on reducing runoff. To control surface runoff, the stream channels, gullies, and surrounding headwaters can be mulched or vegetated to increase roughness, decrease flow velocity, and induce infiltration. The treatment can be supported by building temporary dams in each channel to trap sediment and thereby reduce channel depth and slope.

For subsurface erosion, a more uniform pattern of infiltration and soil water movement must be achieved. Mechanical measures such as diversion ditches and terraces often used to control surface runoff are inappropriate. By causing ponding, they provide a concentrated supply of water that may open a new piping system or increase erosion in an existing one. Control of subsurface erosion is best achieved by establishing a healthy grass cover, or where conditions are marginal for improved pasture, a mixture of shrubs, grasses, and trees. If tunneling has reached an advanced stage, the tunnels must be broken up by ripping prior to establishing the vegetative cover.

Conservation measures in the channel may include reshaping gullies to a more stable design. If such land-forming operations are impractical, simple mechanical controls can be employed such as earth and brush dams, boulders, or planks to form barriers across the channel. These induce sedimentation and change the slope in both the main gully and the tributaries. Such temporary dams have a high risk of failure. Therefore, they must be carefully constructed, anchored, and regularly maintained.

A range of stability problems can be associated with the mine highwall and its reclamation. These include gully incision on the highwall reduction slope, differential erosion between the coherent bedrock and the spoils, piping, and mass wasting at the highwall.

Many gullying and piping problems at the highwall may be managed using the techniques described above and the careful design of the highwall reduction slope to minimize instability. At a broader scale, an alternative approach to mitigating the problems of stream instability at the highwall may be by bluff extension. Using this approach, a step within the stream longitudinal profile may be left within the more resistant bedrock at the highwall. At the base of the bluff, an armored plunge pool can be constructed to dissipate the energy of the stream. Downstream from the plunge pool the stream flows at a gentler gradient over the more erodible reclaimed spoils, reducing the potential for incision and accelerated erosion. However, highwall stability problems may result using bluff extension methods, in the form of slumps and rockfalls. These concerns can be addressed throughout mining and reclamation and the appropriate actions taken to solve them.

o Roadway Sediment Mitigation

Within post-mine landscapes, which are stable at the large scale, problem areas may exist where erosion rates are extremely high and these areas are major sources of sediment. A problem that may be managed using agronomic or engineering techniques is that of increased erosion associated with roadways and other developments.

The main problems associated with roads are excess runoff, and the stability of the road cuts and fills. In erodible areas, roads may be placed on ridges to minimize the catchment area from which runoff originates. Even so, excess runoff cannot be entirely mitigated because whenever the ridge slopes into saddles or along spurs, erosion by overland flow and gullying can occur. Grass-lined side ditches, with regularly spaced culverts, could provide an effective method of runoff control. Various techniques to improve road cut and fill stability include: benching, which is used to reduce the overall slope angle of the bank, establishment of herbaceous plants, construction of diversion ditches and spillways to dispose of runoff, and use of erosion nets.

c. Climate

No recommendations.

d. Air Quality

A number of alternative stipulations were investigated. These include:

- Application of alternate dust palliatives to calcium chloride on the haul roads
- Addition of foaming agents to the coal to reduce dust production during handling
- Installation of water injection systems on the drilling units
- Enclosing the emergency stockpile

However, if all of the above measures were taken, dust emissions would be reduced by less than one percent. Therefore, these stipulations would not result in a significant change to the analysis of impacts.

e. Noise

Although ambient sound levels from Area C mining are not expected to be a significant nuisance in Colstrip, mine construction and operation activities may noticeably increase sound levels at locations closer to

the mine or at locations where ambient sound levels are now very low. Measures can be taken to reduce potential impacts due to equipment and blasting noise.

Noise produced by mining equipment is best minimized by using equipment designed to operate quietly. Proper muffling and maintenance of equipment during its operational lifetime is also effective.

Specific techniques are available for minimizing blasting noise. Special attention to overcharged blast holes, adequate stemming, covering the detonating cord, and using adequate burdens is important in minimizing noise production.

The special effect certain meteorological conditions can have on sound propagation through the atmosphere should also be considered. One rule of thumb for minimizing blasting impacts is to postpone the blast if a temperature inversion exists at less than 5,000 feet and the affected community is downwind of the blast. Since low temperature inversions are frequently observed at night and during the first several hours after sunrise, special care should be taken during these hours. Another rule of thumb is postponing blasting when the affected community is downwind and the wind speed is greater than 15 mph.

f. Soils

1) Selective handling of soil by textural types would mitigate against the elimination of diverse soil types and the related impacts of reduced vegetative diversity. This is presently being done to a limited degree in other areas at the Rosebud Mine for sandy soils (see discussion in Chapter III). Soils that must be stockpiled from haul roads, clinker pits, facility areas, the boxcut reduction zone, and the first three mining passes could be stored separately for placement in specific areas, increasing the long-term survival potential of some vegetative types.

The boxcut reduction zone and first three mining passes comprise 438 acres, including 86 acres of clinker soils. If salvaged to the depths shown in Appendix F, the clinker material from this area is sufficient to reclaim the entire 60-acre area projected for ponderosa pine plantings with total depth of 30 inches of mixed clinker soil material, or to reclaim a larger area with 10 to 12 inches of clinker material over a 15 to 20 inch loosened subsoil layer. Ponderosa pine have a higher tolerance for rock fragment content in soils, thus allowing salvaging to greater depths of this material than proposed. This would further maximize the use of this resource. This alternative would increase the likelihood of tree survival, and due to the location of ponderosa types on hill slopes, it would reduce the potential for erosion in these areas.

2) In the long term, cropping patterns after mining can be expected to follow the same pattern as on the pre-mine landscape, which is that only loamy and clayey soils can be cropped, because yields on these soils are consistent enough to allow economical cropping.

Therefore, areas in which cropland will be the post-mined land use should be respread with loamy or clayey soil materials. The isolated location of projected cropland areas (mine shop and topsoil stockpiles, see Figure I-8) will be helpful, in that the loamy and clayey soils salvaged from each area can be stored nearby for replacement. The only additional impact that will result will be a reduction in organic matter and soil microorganisms during storage and potential soil compaction during soil replacement (see following mitigations).

3) Topsoil degradation during storage is due in large part to oxidation of organic matter and the establishment of increased populations of pathogenic microbial species, which attack viable plant parts in stored soil (see Chapter III, Section F). A way to decrease both of these processes is to store dry soil, allow compaction of the pile as lifts are placed, and to leave as little surface area as possible within limits of the erosion criteria for stockpiles after the final stockpile configuration is completed.

4) The reduction of organic matter in the soil after storage, or to a lesser extent, after direct hauling, can be tempered by incorporating mulch on all reclaimed surfaces immediately after the first phase of seeding, or by using a cover crop as discussed in Section g. This will improve the moisture and nutrient holding capacities of the surface soil, reduce the tendency of the surface to crust, and improve infiltration. It will also provide a base for the reestablishment of important soil microorganisms.

5) Increased bulk density in applied soil layers can be mitigated by using the bulldozer-mounted ripper bars to scarify replaced soil. Spot-checking of subsoil bulk densities prior to the placement of the next lift would aid in identifying the areas where bulk densities exceed 1.5 g/cm^3. If ponderosa pine plantings are to be located on non-selecting handled topsoil, it may be necessary to achieve bulk densities of 1.3 g/cm^3 (Chapter III, Soils) or less.

g. Vegetation

1) Seeding Method

Although the two-phased revegetation method is expected to produce satisfactory results as stated in Chapter III, no data could be found recommending this method over more conventional seeding methods. While it was developed in an attempt to increase species diversity in reclaimed areas that had otherwise demonstrated limited diversity, it has two apparent drawbacks. One is the waiting period of up to three years between seeding sequences, which considerably delays the establishment of effective grass cover. The other is the possibility that aggressive annual weedy species may be equally or more competitive to the first planting sequence than the second seeding sequence would be. Weedy plants may also hinder establishment of the second phase.

A suggested alternative is one that has become standard for seeding native grasses in the Great Plains. This method entails growing an

adapted annual cover crop on a prepared seedbed to produce a standing stubble, and then direct seeding the desired mixture into the standing stubble. This method improves soil moisture, reduces soil temperatures, and has been shown to give a ten percent greater population of native grasses as opposed to using a protective cover of straw mulch (Schuman et al., 1980). Seeding could be done either in late fall or early spring and would require the use of a double-disk grass drill capable of seeding in untilled stubble and capable of handling the diverse seed mixture.

This method has the advantages of a firm seedbed, which is essential for warm-season grasses, good contact between seed and moist soil, greater soil moisture from trapped snow, reduced surface evaporation, and reduced soil temperature fluctuations. Erosion and weed infestation would also be minimized.

2) Establishing Conifers

The reclaimed soils at Colstrip are essentially grassland soils rather than woodland soils. Extensive experience with conifers as windbreak plantings (Ferber, 1974) and in forest plantings (Larson and Schubert, 1969) strongly suggests that young trees cannot compete with weeds and grass for moisture on grassland soils. To achieve success in reestablishing a conifer vegetative community, special measures to enhance the storage and availability of soil moisture must be employed.

(a) One alternative is to place rocky or coarse sandy soil having rapid infiltration and percolation at the surface to a zone below the reach of most grass roots (12 to 16 inches, Larson and Schubert, 1969). The porcelanite or clinker beds would provide a good source for materials to build this special soil.

(b) Another alternative entails regular maintenance practices to eliminate competing grasses and weedy forbs. Methods to accomplish this include cultivation, application of herbicides, mulching, or supplemental irrigation. One or more of these methods must be used to control competitive plants until root systems of the trees are well established.

Revegetated conifer zones would require an extended period of protection from grazing and trampling by livestock or wildlife. Fencing of these areas should be considered when the adjacent revegetated range site is ready for grazing use.

3) Reestablishment of Range Sites

Sandy and silty soil material should be identified, segregated, and reapplied on the graded spoils to reestablish areas of sandy and silty range sites in large enough areas to establish discrete plant communities. This would allow vegetative seed mixtures to be tailored to the adapted climax community for each soil. The proposed deferred-rotation-grazing system could then be applied to the reclaimed area in recognition of the specific growth habits of the key species on each site. This would allow for increased spatial and species diversity, and possibly lengthen the period of optimum grazing use on the reclaimed areas.

h. Wildlife

Where impact to important habitat components is unavoidable, it may be possible to mitigate or compensate for such impacts via the following activities:

- Continue sponsorship of investigations into restoration of conifer habitats with a long-term goal of establishing the extent and composition of habitat comparable to the existing conifer habitat. Because of the long recovery time for these woodlands, additional attention should be directed to establishing shrub communities to supply improved diversity, cover, and forage in the near term.

- Examine feasibility of creating cliff habitats where mining abuts steep and precipitous terrain.

- Evaluate design considerations for post-mining topography and anticipated post-mining hydrologic characteristics to provide comparable surface water supplies for wildlife and enhancement of these areas for wildlife use. These design features may include retention of sediment ponds, creation of small stock-pond type impoundments, or water-well aquifer pumping to stock ponds or tanks.

- Evaluate feasibility of incorporating plans to replace particular microhabitat features such as rock areas or brush piles.

i. Sociology and Economics

During the period of peak construction-induced population, 1982 to 1985, the Rosebud County Sheriff's Department should ensure that adequate coverage is available during the evening shift in the Colstrip area. If necessary, the department should hire an additional deputy for the area.

Solid waste collection should be limited to one day per week pickup, which normally is sufficient for residential purposes.

The Colstrip Mental Health Center may have to add part-time professional or paraprofessional staff.

The Sunlight Development Company should carefully monitor the housing supply/demand situation in late 1982. If more doubling up does not occur, or the construction schedules do not lag, a housing supply deficiency of about 60 units may occur. Adequate housing should be provided for all construction employees.

j. Land Use

Presently cultivated land could be reclaimed as cropland instead of as rangeland. The treatment of the land during reclamation would

not be much different under this scenario. Avoiding over-compaction of the overburden and avoiding pockets of high electrical conductivity would increase the crop potential of the reclaimed land (see Section F, Soils). Planting the reclaimed land to rangeland and allowing establishment of vegetation and nutrient cycling during the period prior to bond release would increase the potential for productive cropland after bond release. If the cultivated land was reclaimed to cropland instead of rangeland immediately after disturbance by mining activity, there would be an increase in erosion potential on that land due to a lack of vegetative cover during part of the year. Therefore, although immediate reclamation to cropland would result in harvestable crops at an earlier date, the long-range productivity of the cropland would be increased by allowing the land to return to rangeland prior to any post-mining cropping.

k. Transportation

No recommendations.

l. Recreation

The Stillwater Park Complex should be completed as soon as possible. CARPA and the school district should continue to explore means for cooperating on the availability and use of school facilities.

m. Cultural Resources

No mitigation plan is yet available for review.

n. Aesthetics

Mitigating measures to lessen the impact on aesthetic values include the construction of complex slopes on reclaimed spoils; leaving parts of the highwall as topographic breaks, especially where highwall reduction would necessitate timber removal; using neutral-colored paint on buildings, the coal conveyor, mining equipment, etc., appropriately colored to blend with the existing environment; controlling fugitive dust via the methods recommended in Section D (Air Quality); and eventual revegetation using plant species similar to adjacent undisturbed acreage. Such measures would tend to lessen the unnatural contrasts that occur during mining operations and would also enhance the natural contrast, color, and texture in the post-mine environment.

Exhibit 3

CHAPTER V
CONSULTATION AND COORDINATION

A. DEVELOPMENT OF DRAFT ENVIRONMENTAL IMPACT STATEMENT

Information used in the preparation of this Draft Environmental Impact Statement was obtained from the following agencies and companies:

Federal Agencies

U.S. Department of Agriculture
- Agricultural Research Service
- Forest Service
- Soil Conservation Service

U.S. Department of Interior
- U.S. Geological Survey
- Bureau of Land Management

State Agencies

Montana Department of Health and Environmental Sciences
Montana Department of Highways
Montana Historical Society - State Historic Preservation Office
Montana Department of State Lands
Montana Department of Natural Resources and Conservation
Wyoming Department of Environmental Quality

Companies

Bison Engineering (Subconsultant - Air Quality)
Western Analysis, Inc. (Subconsultant - Socioeconomics)

The following individuals contributed to the preparation of this Draft EIS. Ertec's subconsultants included S. Larson (Pappadopolis & Associates), J. Gelhaus and M. Roach (Bison Engineering); D. Bourke, L. Rovig, S. Holtzmann, T. Klack, L. Priest (Western Analysis, Inc.); and A. Fricke and D. Nielsen. Other contributors are Ertec personnel.

B. REVIEW OF THIS STATEMENT

In accordance with DSL's and OSM's regulations governing environmental impact statements (EISs), copies of this draft EIS will be made available to the public for comments and suggestions. All comments received will be carefully considered in the preparation of a final EIS. Written comments should be sent to Commissioner Gareth Moon, Department of State Lands, Capitol Station, Helena, Montana 59620.

The draft EIS is available for review in the following places:

- Montana Department of State Lands, 1625 11th Avenue, Helena, Montana
- Big Horn County Public Library, 419 North Custer Avenue, Hardin, Montana
- Miles City Public Library, 1 South 10th, Miles City, Montana
- The Rosebud County Library, 201 North 9th Avenue, Forsyth, Montana
- Bicentennial Library of Colstrip, 320 Water Avenue, Colstrip, Montana
- Parmley Billings Public Library, 510 North Broadway, Billings, Montana
- Sheridan County Fulmer Public Library, 320 North Brooks, Sheridan, Wyoming
- Montana State Library, 930 East Lyndale Avenue, Helena, Montana
- Office of Surface Mining, 1020 15th Street, Denver, Colorado
- Office of Surface Mining Area Office, 935 Pendell Blvd., Mills, Wyoming

A limited number of copies are available on request from the Department of State Lands, Capitol Station, Helena, Montana 59620.

Technical Support Documentation is on file with the following entities:

- Montana Department of State Lands Reclamation Division, 1625 11th Avenue, Helena, Montana
- Montana Department of State Lands EIS Team, 1539 11th Avenue, Helena, Montana
- Office of Surface Mining, Department of Interior, 1020 15th Street, Denver, Colorado

CHAPTER VII

APPENDICES

Exhibit 3

APPENDIX A

TABLE A-1

MONTANA DEPARTMENT OF STATE LANDS
SUSPECT LEVELS IN OVERBURDEN AND TOPSOIL MATERIAL

Analysis	Suspect Level
Electrical Conductivity	>4-6 mmhos/cm
Sodium adsorption ratio	>12 $(meq/liter)^{1/2}$
Mechanical analysis	Clay >40% Loamy sand and sand
Saturation %	none
pH	>8.8-9.0
PO_4-P	none
NO_3-N	variable
NH_4-N	unknown
Cd	>0.1-1.0 ppm
Cu	>40 ppm
Fe	unknown
Pb	pH < 6, >10-15 ppm pH > 6, >15-20 ppm
Mn	>60 ppm
Hg	>0.4-0.6 ppm
Se	>2.0 ppm
Mo	>0.3 ppm
B	>8.0 ppm
Zn	>30-40 ppm
Ni	DTPA extraction: >1.0 ppm

mmhos/cm = millimhos per centimeter (EC x 10^3 @ 25°C)
meq/liter = milliequivalents per liter
ppm = parts per million
DTPA = Diethylenetriaminpentacetic Acid

Exhibit 3

APPENDIX B

TABLE 1

SUMMARY OF QUALITY OF WATER FROM THE SEVERAL AQUIFERS IN
AREA C AND THE ENTIRE ROSEBUD MINE AREA
(Concentrations Expressed in Milligrams per Liter Unless Otherwise Noted)

Aquifer	Number Wells	Specific Conductance Micromhos/cm	Total Dissolved Solids	Total Hardness	Calcium	Magnesium	Sodium	Bicarbonate	Sulfate	Chloride
Rosebud Spoils										
Average Rosebud Mine	35	3,639	3,298	2,354	336	363	166	700	2,015	23
Range	35	1,576-10,825	1,044-10-619	548-6,251	64-580	84-939	20-1,648	205-3,750	417-1,587	0.0-177
Valley Fill Material										
Average Area C	8	2,660	2,460	1,530	169	264	157	538	1,350	16
Average Rosebud Mine	40	2,982	2,767	1,778	257	268	177	536	1,629	20
Range Area C	8	1,670-4,040	1,350-4,680	837-2,430	114-287	135-417	46-279	486-581	584-2,500	2-45

[c] Source: SCS-Montana Technical Guide, Section II-E-8, current figures (3/82) for Miles City field office.

Initial stocking rates are intended to be used as a guide for grazing management. Actual stocking rates will vary depending upon the class of livestock, season of use, and characteristics of the site.

Exhibit 3

APPENDIX G

TABLE 2

PROPOSED REVEGETATION APPROACH
AREA C, BLOCK I

PHASE I - SUPPLEMENTAL GRASS, FORBS, AND SHRUB MIXTURE

This seed mixture will be broadcast onto prepared seedbeds in all reclaimed areas during the first optimal seeding period following soil placement.

Common Name/Scientific Name	Percent of Mix (PLS)
Side-oats grama/*Bouteloua curtipendula*	28
Needle-and-Thread/*Stipa comata*	15
Indian ricegrass/*Oryzopsis hymenoides*	10
Fourwing saltbush/*Atriplex canescens*	5
Winterfat/*Ceratoides lanata*	10
Blue grama/*Bouteloua gracilis*	10
Lewis flax/*Linum lewisii*	5
Prairie coneflower/*Ratibida columnifera*	5
Western yarrow/*Achillea millefoluim lanulosa*	5
Purple prairie clover/*Petalostemon purpureum*	2.5
White prairie clover/*Petalostemon candidum*	2.5
Cicer milkvetch (Lutana)/*Astragalus cicer*	1
Sainfoin (ESKE)/*Onobrychis viciaefolia*	1

Seeding rates 13 lbs./acre of pure live seed (PLS), with an additional 5 lbs. PLS/acre of sterile wintergraze.

Exhibit 3

APPENDIX G

TABLE 2 (Continued)

PHASE II - REVEGETATION AREA SEED MIXTURES

These mixtures will be drill seeded one to three years after the first phase supplemental mixture is planted. Seeding rates will be 20 pounds of pure live seed (PLS) per acre, with an additional five pounds (PLS) of the sterile hydrid wintergraze included to increase cover. Areas have been delineated based upon topographic position on the post-mined topography.

Lowland/Drainage Seed Mixture - 84 acres

Common Name/Scientific Name	Percent of Mix (PLS)
Rosana Western Wheatgrass/*Agropyron smithii*	30
Slender Wheatgrass/*A. trachycaulum*	20
Thickspike Wheatgrass/*A. dasystachyum*	10
Mountain brome/*Bromus marginatus*	10
Kentucky bluegrass/*Poa pratensis*	10
Canada bluegrass/*P. compressa*	10
Canada wildrye/*Elymus canadensis*	10

Uplands Grass Mixture - 821 acres

Common Name/Scientific Name	Percent of Mix (PLS)
Rosana Western wheatgrass/*Agropyron smithii*	40
Critana thickspike wheatgrass/*A. dasystachyum*	25
Slender wheatgrass/*A. trachycaulum*	5
Green needlegrass/*Stipa viridula*	30

Of the areas planted with this mix, tubeling shrubs grown in a greenhouse from locally collected seed will be planted on the following acreages:

21 acres - Big sagebrush/*Artemisia tridentata*

18 acres - Silver sagebrush/*Artemisia cana*

11 acres - Skunkbush sumac/*Rhus trilobata*

1 acre - Rubber rabbitbush/*Chrysothamnus nauseous*

1 acre - Skunkbush sumac and Rubber rabbitbrush

Exhibit 3

APPENDIX G

TABLE 2 (Continued)

Steep Uplands Grass Mixture - 600 acres

Common Name/Scientific Name	Percent of Mix (PLS)
Green needlegrass/*Stipa viridula*	50
Rosana western wheatgrass/*Agropyron smithii*	15
Critana thickspike wheatgrass/*A. dasystachyum*	30
Slender wheatgrass/*A. trachycaulum*	5

Of the areas planted with the mix, tubeling shrubs will be planted on the following acreages:

63 acres - Big Sagebrush

41 acres - Skunkbush sumac

2 acres - Rubber rabbitbrush

Conifer Zone Grass Mixture - 61 acres

Common Name/Scientific Name	Percent of Mix (PLS)
Green needlegrass/*Stipa viridula*	40
Side-oats grama/*Bouteloua curtipendula*	40
Indian ricegrass/*Oryzopsis hymenoides*	10
Rosana western wheatgrass/*Agropyron smithii*	5
Critana thickspike wheatgrass/*A. dasystachyum*	5

Of the areas planted with the mix, nine acres will be planted with tubelings of skunkbush sumac.

In any of the areas in which sandy soils may occur, e.g., the Uplands, Steep Uplands, and Conifer Zone, an additional "patch seeding" approach will be used. Sandy soil materials of one acre or less in size will be seeded with the following mixture of warm season grasses at a rate of 40 lbs./acre PLS:

Big bluestem/*Andropogon gerardii*

Sand bluestem/*A. hallii*

Little bluesteam/*Schizachyrium scoparium*

Prairie sandreed/*Calamovilfa longifolia*

Exhibit 3

APPENDIX G

TABLE 2 (Continued)

Additional shrubs and trees will be transplanted by utilizing a tree spade and transplanting mature stock from potentially disturbed areas onto regraded areas. Any of the numerous shrub and tree species occurring in Area C, Block I may be handled in this way.

APPENDIX H

TABLE 3

MAMMALS EXPECTED IN SOUTHEASTERN MONTANA*

Common Name (Scientific Name)	Colstrip[1]	Special Concern[2]	Thompson[3]
Insectivora:			
Masked shrew (Sorex cinereus)	X		
Hayden shrew (Sorex haydeni)			X
Preble's shrew (Sorex preblei)			X
Merriam's shrew (Sorex merriami)		X	
Chiroptera:			
Little brown myotis (Myotis lucifugus)	X		
Long-eared myotis (Myotis evotis)			X
Small-footed myotis (Myotis leibii)	X		X
Long-legged myotis (Myotis volans)			
Silver-haired bat (Lasionycteris noctivagans)			
Big brown bat (Eptesicus fuscus)	X		X
Hoary bat (Lasiurus cinereus)			X
Townsend's big-eared bat (Plecotus townsendii)		X	X
Lagomorpha:			
Nuttall's cottontail (Sylvilagus nuttallii)	X		
Desert cottontail (Sylvilagus audubonii)	X		X
Snowshoe hare (Lepus americanus)			
White-tailed jackrabbit (Lepus townsendii)	X		X
Rodentia:			
Least chipmunk (Eutamias minimus)	X		X
Yellow-bellied marmot (Marmota flaviventris)	X		X
Richardson's ground squirrel (Spermophilus richardsonii)	X		
Thirteen-lined ground squirrel (Spermophilus tridecemlineatus)	X		X

* Nomenclature follows Jones, et al, 1979; distribution information from Hall, 1981; Burt and Grossenheider, 1964; Flath, 1981; and Thompson, 1982.

1 Denotes species seen during the Rosebud Mine Wildlife Studies (Ecological Consulting Service, 1972, 1973, 1974, 1975; ECON, 1976a, 1977a, 1978, 1979; Western Energy, 1980).

2 Denotes species listed by Flath, 1981.

3 Denotes species listed as known from latilongs 33 or 43 by Thompson (1982).

Exhibit 3

TABLE 3 (Continued)

Common Name (Scientific Name)	Colstrip[1]	Special Concern[2]	Thompson[3]
Black-tailed prairie dog (Cynomys ludovicianus)	X	X	X
Fox squirrel (Sciurus niger)			X
Red squirrel (Tamiasciurus hudsonicus)			X
Northern pocket gopher (Thomomys talpoides)	X		X
Olive-backed pocket mouse (Perognathus fasciatus)			X
Ord's kangaroo rat (Dipodomys ordii)	X		X
Beaver (Castor canadensis)	X		X
Western harvest mouse (Reithrodontomys megalotis)	X		X
Deer mouse (Peromyscus maniculatus)	X		X
White-footed mouse (Peromyscus leucopus)	X		X
Northern grasshopper mouse (Onchomys leucogaster)	X		X
Bushy-tailed wood rat (Neotoma cinerea)			X
Meadow vole (Microtus pennsylvanicus)	X		X
Long-tailed vole (Microtus longicaudus)			X
Prairie vole (Microtus ochrogaster)	X		X
Sagebrush vole (Lagurus curtatus)			
Muskrat (Ondatra zibethicus)	X		X
House mouse (Mus musculus)	X		X
Meadow-jumping mouse (Zapus hudsonius)	X		X
Western jumping mouse (Zapus princeps)			
Porcupine (Erethizon dorsatum)	X		X
Carnivora:			
Coyote (Canis latrans)	X		X
Red fox (Vulpes vulpes)	X		X
Swift fox (Vulpes velox)		X	X
Black bear (Ursus americanus)			X
Raccoon (Procyon lotor)	X		X
Ermine (Mustela erminea)			X
Long-tailed weasel (Mustela frenata)	X		X
Black-footed ferret (Mustela nigripes)**		X	
Mink (Mustela vison)			X
Badger (Taxidea taxus)	X		X

** Endangered species (Federal Register, 1980)

Common Name (Scientific Name)	Colstrip[1]	Special Concern[2]	Thompson[3]
Striped skunk (Mephitis mephitis)	X		X
River otter (Lutra canadensis)			X
Mountain lion (Felis concolor)			X
Bobcat (Felis rufus)	X		X
Artiodactyla:			
Elk (Cervus elaphus)	X		X
Mule deer (Odocoileus hemionus)	X		X
White-tailed deer (Odocoileus virginianus)	X		X
Pronghorn (Antilocapra americana)	X		X
Mountain sheep (Ovis canadensis)			X

APPENDIX H

TABLE 4

BIRDS EXPECTED IN SOUTHEASTERN MONTANA*

Common Name (Scientific Name)	Colstrip[1]	Special Concern[2]	Skaar[3]
Gaviiformes:			
Common loon (Gavia immer)	X		X
Podicipediformes:			
Horned grebe (Podiceps auritus)	X		X
Eared grebe (Podiceps caspicus)	X		X
Western grebe (Aechmophorus occidentalis)	X		X
Pied-billed grebe (Podilymbus podiceps)	X		X
Pelecaniformes:			
White pelican (Pelecanus erythrorhynchos)	X		X
Double-crested cormorant (Phalacrocorax auritus)			X
Anseriformes:			
Whistling swan (Olor columbianus)			
Canada goose (Branta canadensis)	X		X
Snow goose (Chen hyperborea)			
Mallard (Anas platyrhynchos)	X		X
Black duck (Anas rubripes)			X
Gadwall (Anas strepera)	X		X
Pintail (Anas acuta)	X		X
Green-winged teal (Anas carolinensis)	X		X
Blue-winged teal (Anas discors)	X		X
Cinnamon teal (Anas cyanoptera)	X		X
American widgeon (Mareca americana)	X		X
Shoveler (Spatula clypeata)	X		X
Wood duck (Aix sponsa)			X
Redhead (Aythya americana)	X		X
Ring-necked duck (Aythya collaris)	X		X
Canvasback (Aythya valisineria)	X		X
Lesser scaup (Aythya affinis)	X		X
Common goldeneye (Bucephala clangula)	X		X
Bufflehead (Bucephala albeola)	X		
Ruddy duck (Oxyura jamaicensis)	X		X
Common merganser (Mergus merganser)			X

* Distribution information from Robbins et al., 1966.

1 Denotes species seen during Rosebud Mine Wildlife Studies.

2 Denotes species listed by Flath, 1981.

3 Denotes species listed by Skaar, 1975, as present in latilongs 34 or 43.

Exhibit 3

TABLE 4 (Continued)

Common Name (Scientific Name)	Colstrip	Special Concern	Skaar
Falconiformes:			
Turkey vulture (Cathartes aura)			X
Goshawk (Accipiter gentilis)		X	
Sharp-shinned hawk (Accipiter striatus)			X
Cooper's hawk (Accipiter cooperii)	X	X	X
Red-tailed hawk (Buteo jamaicensis)	X		X
Swainson's hawk (Buteo swainsoni)	X		X
Rough-legged hawk (Buteo lagopus)	X		X
Ferruginous hawk (Buteo regalis)	X	X	X
Golden eagle (Aquila chrysaetos)	X	X	X
Bald eagle (Haliaeetus leucocephalus)**	X	X	X
Northern harrier (Circus cyaneus)	X		X
Osprey (Pandion haliaetus)		X	X
Prairie falcon (Falco mexicanus)	X	X	X
Peregrine falcon (Falco peregrinus)**		X	
Merlin (Falco columbarius)	X	X	
American kestrel (Falco sparverius)	X		X
Galliformes:			
Ruffed grouse (Bonasa umbellus)			X
Sharp-tailed grouse (Pedioecetes phasianellus)	X		X
Sage grouse (Centrocercus urophasianus)	X		X
Ring-necked pheasant (Phasianus colchicus)	X		X
Chukar (Alectoris graeca)			X
Hungarian (Gray) Partridge (Perdix perdix)	X		X
Turkey (Meleagris gallopavo)	X		X
Ciconiformes:			
Great blue heron (Ardea herodias)	X		X
American bittern (Botaurus lentiginosus)			X
Gruiformes:			
Whooping crane (Grus americana)**			X
Sandhill crane (Grus canadensis)			X
Virginia rail (Rallus limicola)			
Sora (Porzana carolina)			X
American coot (Fulica americana)	X		X
Charadriiformes:			
Killdeer (Charadrius vociferus)	X		X
Mountain plover (Eupoda montana)		X	X
Black-bellied plover (Squatarola squatarola)			
Common snipe (Capella gallinago)	X		X

** Endangered species (Federal Register, 1980)

Common Name (Scientific Name)	Colstrip	Special Concern	Skaar
Long-billed curlew (Numenius americanus)		X	X
Upland plover (Bartramia longicauda)	X		X
Spotted sandpiper (Actitis macularia)	X		X
Solitary sandpiper (Tringa solitaria)	X		X
Willet (Catoptrophorus semipalmatus)	X		X
Greater yellowlegs (Totanus melanoleucus)	X		X
Lesser yellowlegs (Totanus flavipes)			X
Least sandpiper (Erolia minutilla)			X
Long-billed dowitcher (Limnodromus scolopaceus)	X		X
Semipalmated sandpiper (Calidris pusilla)			X
Western sandpiper (Erunetes mauri)			X
Marbled godwit (Limosa fedoa)			
American avocet (Recurvirostra americana)			X
Wilson's phalarope (Steganopus tricolor)	X		X
Northern phalarope (Lobipes lobatus)			X
Herring gull (Larus argentatus)			X
California gull (Larus californicus)			X
Ring-billed gull (Larus delawarensis)	X		X
Franklin's gull (Larus pipixcan)			X
Common tern (Sterna hirundo)	X		
Black tern (Chlidonias niger)	X		
Columbiformes:			
Rock dove (Columba livia)			X
Mourning dove (Zenaida macroura)	X		X
Cuculiformes:			
Yellow-billed cuckoo (Coccyzus americanus)			X
Black-billed cuckoo (Coccyzus erythropthalmus)	X		X
Strigiformes:			
Barn owl (Tyto alba)			X
Screech owl (Otus asio)			
Great horned owl (Bubo virginianus)	X		X
Pygmy owl (Glaucidium gnoma)		X	
Burrowing owl (Athene cunicularia)	X	X	
Barred owl (Strix varia)		X	
Long-eared owl (Asio otus)	X	X	
Short-eared owl (Asio flammeus)	X		X
Saw-whet owl (Aegolius acadicus)		X	X

Letter No. 1

UNITED STATES
DEPARTMENT OF THE INTERIOR
FISH AND WILDLIFE SERVICE
Billings Area Office
Federal Building, Room 3035
316 North 26th Street
Billings, Montana 59101-1396

IN REPLY REFER TO

ES

June 18, 1982

RECEIVED
JUN 22 1982
STATE LANDS

Mr. Gareth Moon
Commissioner
Department of State Lands
Capitol Station
Helena, MT 59620

ATTN: Mr. Kit Walther

Dear Mr. Moon:

We have reviewed the DEIS for Western Energy Company's Rosebud Mine, Area C, Block 1, Colstrip, Montana. We found that the DEIS adequately describes impacts on fish and wildlife resources that would be expected to occur from the proposed five-year life of the mine development.

The following comments refer to specific sections of the DEIS.

Page III-57; 7. Raptors - This section of the DEIS describes protection provided eagles by the Bald Eagle Protection Act of 1940, as amended in 1962 (16 U.S.C. 668a). The section further states that the U.S. Fish and Wildlife Service has not yet determined whether or not the proximity of proposed mining activities to the existing nest site would constitute a disturbance within the definition of the law. It is our opinion that because the nest site has not been active since 1978, and because a 100-meter buffer zone between the outcrop containing the nest and the mine has been established (DEIS III-55), that "disturbance" within the definition of law will not occur as a result of implementation of the five-year permit to mine. If the nest should become "active" prior to or after the commencement of mining, then a re-evaluation of disturbance conditions would be required. } A

Page IV-2 ;3. Selective Denial - This section discusses the selective denial option available to the Department and OSM for denying mining in specified areas within the proposed permit boundary. Identification of lands for selective denial during the EIS review process is solicited. The U.S. Fish and Wildlife Service has previously recommended to the Department that the sandstone outcrop which provides valuable raptor } B

Exhibit 3

VIII-1

John C. Wood

A. Your comment is noted. Western Energy will if permitted report annually the atatus of nest activity. Should the nest become active, a reevaluation of "disturbance" condition will be requested of FWS.

B. Your comment is noted. At such time Western Energy submits its Block II mine plan the apecial, exceptional, critical or unique characteriatica of the referenced sandstone outcrop in Section 11 will be evaluated in detail.

nesting habitat and is located in Section 11 immediately adjacent to Area C, Block 1, not be permitted for mining. This outcrop would appear to meet the special, exceptional, critical or unique requirements and should be considered for selective denial during the Area C, Block II permit review.

We appreciate the opportunity to review and comment on this DEIS.

Sincerely,

John G. Wood
Acting Area Manager

cc: Director, Montana Department of Fish, Wildlife, and Parks, Helena, MT
Regional Director, USFWS, Denver, CO (ENV)

Letter No. 2

United States Department of the Interior

GEOLOGICAL SURVEY
Water Resources Division
Federal Building, Drawer 10076
Helena, Montana 59626

June 22, 1982

Mr. Kit Walther
EIS Team Leader
Montana Department of State Lands
1539 11th Avenue
Helena, MT 59620

Dear Mr. Walther:

We appreciated the opportunity to review the Draft Environmental Impact Statement for Western Energy Company's Rosebud Mine Area C, Block 1. Our review was limited to the hydrologic sections of the EIS and the Technical Support Document. Our comments are listed on the attached enclosure.

In general we feel that the documents adequately address the major hydrologic concerns. Most of our comments are of an editorial nature and are intended to clarify wording. The few technical issues raised should be easily rectified.

Feel free to call if our comments are unclear. We will be happy to expand or clarify the brief statements listed on the enclosure.

Sincerely yours,

Joe A. Moreland

Joe A. Moreland
Acting District Chief

Enclosures

Joe A. Moreland

Thank you for your review and comments on the Area C, Block 1 EIS. Responses to your comments are presented in the order submitted.

Exhibit 3

Comments pertaining to the draft EIS

p. II-1 ¶1 It is the Tongue River Member of the Paleocene Fort Union Formation. The current wording makes it sould like three formations.

p. II-5 ¶2 Explain the significance of exceeding DSL suspect levels (There is no level for sand in Appendix A).

p. II-7 Show number of samples on which these percentages in the table are based.

p. II-13 ¶4 linear porosity is not an appropriate term. The sediments may exhibit anisotropy with the direction of higher permeability being parallel to dragline movement.

Also reference this statement on the anisotropy of spoils material unless ERTEC determined it themselves.

Mention the number of spoils aquifer tests that the mean is based on.

Why no standard deviations, too, when a mean has been calculated?

p .II-16 ¶1 Transmissivity values don't decrease. The rate of recovery changes, which indicates a boundary.

¶2 Aquifer tests in clinker will not confirm areas of recharge. They will only tell you about the hydraulic characteristics of the aquifer.

p. II-18 ¶2 Being confined by a coal seam is not a reason for lower T's. In fact, you would have a fully saturated interval, which for similar K's, would lead to the opposite conclusion.

p. II-19 ¶9 Velocities don't "have" conductivity. Needs clarifying.

p. II-21 fig Averaging 8 years of water levels for a dynamic system is questionable. The lack of uniformity in the spoils may be due to this averaging.

p. II-22 ¶5 Precipitation is lowest from Nov, to March. Delete "precipitation is higher and."

p. II-24 fig Areas where the Rosebud Coal has been removed need to be delineated, and contours removed if present.

Exhibit 3

Joe A. Moreland

Page II-1, Paragraph 1
The wording has been clarified to read the Tongue River Member of the Paleocene Fort Union Formation.

Page II-5, Paragraph 2
The information is given in Section A of the Technical Support Document.

Page II-7
The information is given on page 1 of Section A of the Technical Support Document.

Page II-13, Paragraph 4
The term linear porosity has been deleted and changed to permeability. The statement was made based on personnel communication with Peabody Coal Company personnel.

Table II-3 shows the number of aquifer tests conducted in the spoils that the mean and median values are based on. More important than standard deviations are statements regarding the high variability of transmissivities which are made on II-13, II-14, II-16, and II-18. We have included an addition to the technical support document which lists standard deviations.

Page II-16, Paragraph 1
The statement is not necessarily true. Transmissivity is a measure of the rate at which fluid of a certain viscosity will move through a unit width of an aquifer under a unit hydraulic gradient. It is based on the saturated thickness which all other things being equal decreases at a boundary as water is withdrawn because of more rapid drawdown in those areas. In any case the authors have identified the cause of the decrease as a low permeability boundary.

Page II-16, Paragraph 2
Wording in the EIS has been changed accordingly.

Page II-18, Paragraph 2
The statement has been removed from the EIS.

Page II-19, Paragraph 9
The statement has been clarified to indicate that the coals are the better aquifers in the area.

Page II-21, Figure
The values were not averaged. The most representative value or the value that occurred most often was used in the development of the potentiometric map.

Page II-22, Paragraph 5
The phrase precipitation is higher has been deleted.

Page II-24, Figure
The areas where Rosebud coal has been removed have not been included on this figure because it overly complicates the figure. The intent of this figure is to define regional flow patterns within the Rosebud coal.

p. II-25 ¶2 The diagram, fig. II-9, shows <u>two</u> normal faults. Another discrepancy is the delineation of only one fault on fig. II-13.

¶2 Faulting is the underlying reason for the coal seam being exposed.

¶2 Because transmissivities are as great or greater than those in the coal, isn't horizontal flow across the fault just as likely as vertical flow?

¶2 Do you know the coal is offset? Without your control shown on fig. II-9, there appears to be many questionable inferences.

p. II-25 ¶3 You have indicted on pg. II-18 ¶2 that the interburden is confined (saturated) by the Rosebud coal seam.

Water may be leaking into the interburden from either coal seam, but not both in the same place.

p. II-25 ¶4 & 5 "Controlled" is a poor choice of words; perhaps "similar."

p. II-25 ¶6 The first mode of communication should include all major water-bearing strata, not just the McKay.

p. II-26 fig Should show control points.

Water levels of the Rosebud and McKay should be similar at the fault if there is enhanced vertical connection along it.

p. II-28 ¶2 Prior to the removal of the Rosebud coal, vertical leakage would have been downward to McKay according to the hydraulic gradient illustrated on fig. II-9. When the Rosebud is removed, the unconfined water level in the spoils will probably be lower than the McKay water level (at least initially), thereby reversing the gradient and causing upward leakage from the McKay.

p. II-29 fig Rosebud outcrop is really a subcrop under valley fill. The terms "gaining" and "losing" stream refers to a stream-valley fill interaction, not a bedrock-valley fill interaction.

Exhibit 3

Joe A. Moreland (Cont.)

Page II-25, Paragraph 2
The appropriate wording change has been made.

Page II-25, Paragraph 2
Structural contour maps generated from data supplied by Western Energy Company indicate that in some areas there is up to 160 feet of displacement within a 5000 foot distance. Visual inspection of mining in Area B, which is south of the proposed fault, shows only a 12-20 foot flexure in the coal. It is the author's opinion that there is at least one offset feature within the faulted zone. Whether it is a normal or reverse fault is speculative based on a map prepared by the Geological Survey. Based on flow modeling, potentiometric map development and well test data, it is Ertec's opinion that the zones where flexure and faulting are present represent areas of increased vertical permeabilities. This is not to say all flow is vertical in these areas.

Page II-25, Paragraph 3
The paragraph has been modified to indicate that the source of recharge is variable depending on location.

Page II-25, Paragraphs 4 and 5
The wording has been modified.

Page II-25, Paragraph 6
The appropriate change has been made.

Page II-26, Figure
The results of the three-dimensional flow modeling indicate that there is approximate 0.5-2 feet of difference in water levels along the fault zone. Figure II-13 shows the location of the cross-section. Figure II-13 is a regional map showing general trends in recharge and discharge. Scale is too large to display data points.

Page II-28, Paragraph 2
As a result of modeling we agree with your conclusion.

Page II-29, Figure
The terminology is used loosely in this figure to indicate areas where water is either entering the valley fill system or leaving the system. Since there is no sustained flow in East Fork Armells Creek above Colstrip there cannot be gaining or losing streams.

VIII-5

p. II-28 ¶7 Ground water contours don't need to come to the surface for discharge to occur e.g. pumpage from wells; discharge due to a vertical hydraulic gradient.

p. II-30 ¶2 How did you determine that valley fill recharges bedrock in the vicinity of the surge pond? Fig. II-11 shows insufficient data for analysis in this area. Also, upstream and downstream of this area, fig. II-11 shows discharge from the bedrock system and discharge from the ground water system, respectively.

p. II-30 ¶1 Fig. II-11 shows recharge <u>from</u> bedrock above Colstrip, not recharge <u>to</u> bedrock as stated here.

p. II-37 ¶4 Why is an agricultural economy viable if the ground water quality is poor for irrigation?

p. II-38 ¶2 Please discuss "natural causes."

¶2 What geochemical and hydrologic processes were responsible for the impacts shown in some of the wells?

p. II-39 ¶1 Why not show a standard deviation for TDS in Area B also?

p. II-39 ¶4 What is a "predominant" range if the range is 684 to 3,500? Is it one standard deviation, or some percentage of samples about a mean, etc?

p. II-39 ¶5 Delete "TDS" in second to last line on page.

p. II-40 ¶1 What about ion exchange from the clays in the interburden to account for sodium?

¶2 How do you know that sodium sulfate waters predominate when at the bottom of the page you have data for 2 wells in the sub-McKay in Area C and one is magnesium sulfate?

Exhibit 3

Joe A. Moreland (Cont.)

Page -28, Paragraph 7
The discussion refers to natural discharge. If discharge occurs then the gradient will become vertical upward at the discharge but the water table surface will also intersect the groundwater surface.

Page II-30, Paragraph 2
The determination was made as discussed in the referenced paragraph. Figure II-11 shows insufficient data to draw conclusions about whether alluvium s recharging bedrock or not upstream from the surge pond.

Page II-30, Paragraph 1
The sentence has been modified.

Page II-37, Paragraph 4
The major agricultural economy in Area C is livestock. Although groundwater quality is poor for irrigation, it is considered "fair to good" for stockwater. Therefore, groundwater quality has not been a limiting factor to livestock production in the area.

Page II-38, Paragraph 2
The natural causes of high salt concentrations would include leaching of excessive salts from areas more rich in clay and, hence in captured salts of various kinds, and concentration caused by evapotranspiration losses. The authors have not speculated on causes for higher levels in some of these wells except to say that spoils leaching is apparently responsible for many of these elevations. However it is recognized that alluvial TDS levels in the headwaters of Cow Creek may tend to be naturally high relative to alluvial TDS values in adjacent drainages.

Page II-39, Paragraph 1
See response page II-13, paragraph 4 regarding standard deviations.

Page II-39, Paragraph 4
The range given was an eye approximation made by recognizing that values of TDS over 50,000 mg/l and less that 10 mg/l were unrealistic.

Page II-39, Paragraph 5
The wording has been changed.

Page II-40, Paragraphs 1 and 2
The ion exchange in the interburden could add to the sodium concentrations. It was the author's opinion based on the location of wells and water quality that the faulting was the avenue for contamination.

The statement is based on data for the entire study area and not just on Area C.

p. II-40 #5 Alternately, if you are basing predominant sodium-sulfate water in sub-McKay on what is in the McKay coal, you've neglected the magnesium-sulfate water in areas B, E, D, etc. In this paragraph, you're implying downward movement along faults. In #2, it was upward movement along faults.

p. II-41 #2 Thirty-six percent does not constitute "most of the wells" but the highest percentage in any single aquifer.

p. II-54 sec. f The section on ground-water recharge deals solely with valley fill. Shouldn't something be said about bedrock aquifers too or indicate that they were dealt with in previous section?

p. II-54 general Where are the recharge and discharge numbers for the bedrock aquifers in Area C?

p. III-6 #4 Reference some of these conclusions.

P. III-7 #5 Disrupting the Rosebud overburden which is the source of water for 30% of wells seems to be significant, although this impact could be mitigated.

#8 What drawdown criteria was used to determine the maximum radius of significant influence?

p. III-10 #1 Due to the change in Table III-9 on Errata sheet, can you explain the +47% change in discharge on East Fork Armells?

Joe A. Moreland (Cont.)

Page II-40, Paragraph 5
The discussion did not indicate the location of areas where faulting and direction of movement is thought to play a role in water quality.

Page II-41, Paragraph 2
The appropriate change in the text has been made.

Page II-54
The text has been modified to indicate that bedrock discharge/recharge relationships were discussed on page I-28, section 3.

Page II-54, General
Recharge and discharge values for bedrock have been determined as a result of modeling (calibration). They have not been included in the EIS because the numbers, out of a particular context, are misleading. In order to make sure of these values a complete regional water balance would have to be conducted, which is beyond the scope of the project. The recharge and discharge values have been included in the TSD.

Page II-6, Paragraph 4
The references have been added.

Page II-7, Paragraph 5
Western Energy has committed to replacing overburden wells with deeper wells. The increased cost of pumping is discussed in the Hydrology impacts section in the EIS.

Page II-7, Paragraph 8
Because of the overall accuracy of the model it was decided that a drawdown of one foot would be considered as a significant change.

Page III-10, Paragraph 1
The errata sheet was in error. A technical problem in the model with spoiling areas along streams was encountered. The error was corrected and a new table compiled (see response to letter #17, J.R. Lee).

Re: Western Energy Company's Rosebud Mine
Area C, Block I
Rosebud County, Montana
Draft Environmental Impact Statement (DEIS)

Dear Mr. Walther:

We wish to thank you for this opportunity to review the Draft Environmental Impact Statement (DEIS) for Western Energy Company's proposed Area C coal mine near Colstrip, Montana. Personnel of the Western Field Operations Center have reviewed the DEIS primarily from the standpoint of potential impacts of the project on other mineral resources.

Known mineral resources in the project area include three coal seams, oil, gas, uranium, sand and gravel, and clay. The resources that would be directly effected by the project are coal and oil and gas. Only the Rosebud coal seam will be mined, leaving the McKay and Stocker seams in place because they are considered to be subeconomic at this time. Unfortunately, the latter two seams will never be more nearly economic to mine than at the same time as mining proceeds on the Rosebud seam. This loss (possibly irretrievable) is adequately pointed out in the text. Oil and gas are not currently being produced in the immediate project area. Should oil or gas be discovered in the area at a later date, mining of the coal would not preclude oil and gas production.

Thus, we anticipate no significant adverse impacts on mineral resources, other than the coal loss described in the text, and have no objection to the DEIS as written.

Sincerely,

G. A. Kingston, Chief

G. A. Kingston

Thank you for reviewing the Area C, Block I Draft EIS. Your comments have been noted.

In reply refer to: SJ

June 25, 1982

Gareth Moon, Commissioner
Montana Dept. of State Lands
1625 Eleventh Avenue
Helena, MT 59601

Dear Mr. Moon:

We have reviewed the draft environmental impact statement (EIS) on Western Energy Company's Rosebud Mine Area C, Block 1, and offer the following comments:

1. The EIS does not address the purpose and need for the electricity that will be produced from the additional mining area, and } A

2. The discussion of technical alternatives on pages IV-2 and IV-3 does not adequately reflect the latest load forecasting data. A copy of Bonneville Power Administration's load forecast is attached for updating page IV-3. } B

Nicholas J. Stas
Acting Environmental Manager

Attachment

Nicholas J. Stas

A. Refer to page IV-3 of the DEIS for explanation.

The fuel to be burned at Colstrip Unit 3 is to be supplied completely from Area C. In a recent injunction hearing, Montana Power testified that it is important for Unit 3 to come on line as scheduled for several reasons (Rose, 1982):

- Delay in bringing Unit 3 on line will add to an existing potential electric power deficit supply problem in Montana and the Pacific Northwest.
- Replacement power for Unit 3 is estimated to cost $29 million per month, and would be oil- or gas-fired electric generation.
- If oil or gas cannot be purchased, or if other sufficient oil- or gas-fired generation capacity cannot be found in the northwest power grid, then replacement power for Unit 3 would not be available and it is likely that curtailment of electric power to consumers in Montana and the Pacific Northwest might become necessary.
- The projected energy deficits might result in brown-outs and black-outs in the region.

B. The referenced publication cites a high load growth projection of 2.5 percent annually from 1980-2000, and a low-growth projection of 0.8 percent per year. However, coal mined from Area C is not subject to the vagaries of a changing market. Area C coal is under contract to Montana Power Company.

Re: Draft EIS-WECo.
Area C: Block 1

JUN 30 1982

Dear Sir:

The subject statement bears little resemblence to the treatise we were promised, a cumulative study of the impacts of mining the Rosebud coal vein and aquifer at and near Colstrip. The references cited at the back of the volume show the only "input" into the creation of the text came from the files or oracles for the Mining Company, or some out of state Consultants here to make Big Bucks!

At the meeting called by the Dept. of State Lands for the purpose, presumably, of obtaining our cooperation in the writing of a Cumulative Impact Statement relating to the affects of mining the Rosebud coal vein, last fall, we were happy to oblige the request. Evidently, it wasn't needed, because we were never called upon to offer suggestions, or provide any kind of input. It was strictly, apparently, a public relations stunt. We were deceived!

On who'se shoulders lies the blame for this deception?

To address this manuscript briefly:

The map, p. II-21, Fig. II6 is reported to indicate the direction of flow of the "spoils aquifer." What it really indicates is the direction the aluminum tubes were and are laid from the active mine site to the tributaries draining the area.

Because there is not one shred of evidence, to date, to show any "spoils aquifer" has originated, the reference to a "spoils aquifer" must be eliminated from the text, unless DSL can show a log; a location in the mine spoils of each area which has any kind of aquifer characteristics. Can you?

The spoils wells are shown on the map to be immediately down syncline from the waste water discharge points. Those drilled to the alluvium are simply picking up the quantity of water discharged during the mine operation. They are not showing water is making it's way through the spoils, but that the mine affluent discharged as "waste water" is degrading the alluvial waters, and very probably, lower aquifers as the McKay and Sub McKay, whatever it is?

It was a clever devise when one of the staff of DSL told the N.F.R.C. not to protest the issue of the Extension for Area E. Even the final Statement relative to Area E contained such dire information, no Permit should have been granted, but, because the State had little opposition, it was granted.

Exhibit 3

Patty Kluver

A. During preparation of the plans of study (POSs) for the Area C and Comprehensive EISs a public participation meeting was held in Colstrip. In addition, written public comments to the draft plans were solicited. Additional public participation was invited subsequent to issuing the draft EIS. As a result of public comment on the draft, the cumulative hydrologic assessment has been expanded to clarify the impact analyses and address specific public concerns.

B. Figure II-6, page II-21 only shows potentiometric surface of spoils groundwater and the direction of groundwater flow through the mine spoils. It does not indicate the direction pit water is being pumped to sediment ponds or tributary drainage of the area for retention.

C. There are a number of spoils wells in Area A and E and in the Northern Pacific spoils that have water in them, indicating that groundwater flow is being reestablished in the spoils.

D. The spoils wells referred to are actually alluvial monitoring wells in Cow Creek and its tributaries. The waste water discharge points are sediment ponds that receive waters pumped out of the mine pits. These waters are either groundwater discharged from the Rosebud Coal into the pits or surface runoff. They are waste waters only in the sense that they are not used within the mine area for dust suppression or other purposes. The quality of these waters is as good as waters normally discharged to the Cow Creek alluvial system by the coal seams, and in some cases during high surface runoff, ma be of much better quality.

E. Your comment is noted. The Department of State Lands and Office of Surface Mining believe that cumulative hydrologic assessment presented in the Final EIS adequately address the NEPA and MEPA requirements for a cumulative impact assessment. See also response to comment A above.

That same staff member from DSL advised those who might protest the Area E Extension permit, Rather than protest at Area E, wait for the Big One, Area C.

No reason was ever given for this clever conclusion, so we can only presume we know why the former staff member of DSL advised in that manner, ...but, we waited for the Big One!

What did we get? Well, it is another little pithy replica of the EIS publications by the Mining Company, containing a few facts; some probables, some innuendos, and a lot of trash.

Rembmber when it was announced in the paper, DSL says no more permits will be issued until a cumulative impact statement is written? This Impact Statement was supposed to be produced for Area C, and evidently Ertec came up with something, but they must not be very proud of it! There are only five copies, two for DSL; two for the WECo. parimeter, and one for the lowly Office of Surface Mining. We, who's lives and livelihoods are at stake did not receive a copy of this Epic. Small wonder! We weren't asked for input into it, either. . . . . and that is the fallacy in allowing the applicant Company to pay for its own Environmental Impact Statement.. Not only do they pay for it, but they write it according to their own interests, and according to their own time schedule.

SO WHAT IF THERE IS NEED TO HURRY SO THAT THE APPLICANT COMPANY CAN MEET IT'S CONTRACTS AND COMMITMENTS IN OCTOBER, '83?

Maybe they should have started planning the EIS a little earlier! The Company demand for a permit places the Dept. of State Lands in a demeaning and compromising position. It also makes those of us in the out-back region surrounding Colstrip feel the Dept. of State Lands is little but a "tool" of the applicant Company.

E

This EIS would lead one to believe there was little Iron to be found in the waters of the spoils around Colstrip. The statistics quoted refer only to TDS measurements. To counter this erroneous claim, enclosed is a snapshot (Ex. 1) taken at a culvert which drains mine water from a sediment pond in Area E. To what does the EIS team attribute the color of the water, in this picture taken by this writer in July, 1979?

F

Ex. 2 is a copy of the U.S.G.S. data for Rosebud near Colstrip which shows two methods for measurement of Iron. Total Recoverable is one, and the less accurate is Total Dissolved. Obviously, Ertec had access to both measurements, but, since Total Dissolved doesn't pick up an ingredient that is practically insoluble, the Iron measured within E.P.A. criteria. How devious can one become?

G

Patty Kluver (Cont.)

F. Such a determination cannot be made from a polaroid snapshot. There are a number of things that could be responsible for such coloration and without a surface water sample the responsible constituents cannot be positively identified.

G. The measurements for Total Dissolved Iron and Total Recoverable Iron are equally accurate. Total Recoverable Iron measurements will include all iron in the water sample including suspended insoluble iron and iron sediment. The authors did have the data that you mention.

Exhibit 3

I.)
Draft EIS
WECo. Area C: Block 1

Had ERTEC kept the word it gave us at the meeting requested by Dept. of State Lands, we would have told them of some off-site-specific problems they should be aware of.

An example is Ex. 3, a copy of a U.S.G.S. map of the area East-so. east Colstrip. On the map we submit are circles drawn around Domestic wells which have become contaminated by Iron. Having read the criteria published by E.P.A. relating to Iron, even without the learned hand of science, one can be quite assured the trouble-maker is the intrusion of too much Iron.

By adding Exhibits 1, 2, and 3 together, and by reading Ex. 4, a copy of the Iron criteria appearing in the bulletin, Quality Criteria for Water, published by the Environmental Protection Agency, even an ignorant layman as this writer can come to a conclusion.

What is the conclusion drawn by the Dept. of State Lands?

The above mentioned map does not show, by any inference, the extent of wells that have been damaged by Iron in the past ten years. It only shows those located on the map that this writer knows about in this immediate vicinity. A few miles north, a new well struck Iron laden water at 500 ft., just north of the mouth of Cow Creek incidently! And on down Rosebud creek, there are more. } H

In the oral testimony presented at Colstrip, June 14th, I mentioned the primary faults in Area C. Their destruction can lead to total disaster for those depending on shallow wells with windmills, as most of us in the vicinity of the Western Energy and Peabody mine digs do. Yet, on page III-11 is another of those charts of illusion. Groundwater provides the source for all of our pasture wells and springs, with the wells served by windmills. Can you imagine the cost of running an electric line to well locations scattered throughout a 20 section pasture? In addition, there would be the cost of drilling a new well, at $9.50 per foot, plus motor, etc. } I

It is apparent that no one who wrote the estimate appearing on page III-11 has ever had to "pull" a well in 20 below zero weather, or even break trail to it through the snow, to get the equipment in to "pull" it. } J

Following the Public Hearing regarding the Montco mine, the Dept. of State Lands people were quoted as saying, "There is no way we can deny a coal stripmine permit," according to our staff Attorney!"

Obviously, there is need of the opinion of a second Attorney. } K

Exhibit 3

Patty Kluver (Cont.)

H. The wells mentioned here are not within the hydrologic study area (see Figure II-3 in DEIS). Unless DSL and OSM have additional information on the depth of these wells, the aquifers they are completed in, water quality analyses at the time of completion and over time, the type of well, and other pertinent data, we cannot make any conclusion regarding possible contamination of such wells.

I. Coal companies are required by law to replace water supplied that are affected by contamination or loss of quantity due to mining. The coal company would bear the expense of replacement.

J. Your comment is noted.

K. The comment may have been taken out of context. This is true if the coal company's application is determined complete and the mining and reclamation plans proposed by the company meet the standards of Montana's Strip and Underground Mine Reclamation Act and Rules as well as other environmental regulations of the state (i.e., air and water quality acts).

The Dept. of State Lands does not have to rely on the "toughest stripmine and reclamation laws in the nation." There are laws regarding surface and groundwater which apply very well.

From a publication titled Family Legal Guide comes the following quote: p. 779.

> "Underground and percolating water: Three different rules relate to the use of underground, or percolating waters. The common law rule regards water beneath the surface as the property of the landowner. His exclusive ownership is modified, however, in states that (1) require the water to be used for a beneficial purpose, (2) do not protect a use motivated solely by malice toward neighboring landowners, or (3) have a statute prohibiting the waste of underground water.
> The reasonable use rule permits only uses that are reasonable in the light of the circumstances, particularly when the uses affect neighboring landowners.
> The prior appropriation doctrine recognizes state ownership of percolating waters and protects appropriators (private property owners) in order of their seniority."

Is the discharge of groundwater, contaminated by mine spoils, onto the property of others considered putting it to beneficial use?

Is the discharge of mine "waste water" so that it finds its way into, under and onto the property of a neighbor putting it to reasonable use?

} L

The Dept. of State Lands is charged with the duty to protect the interests of all the landowners in Montana. If it continues the policy of granting permits to mine it has in the past, there can be only one comparison.

To grant a permit for Area C: Block 1 could be compared to the British government if they had sold the Falklands to Argentina for some royalties and Argentine severence pesos.

} M

Sincerely,

Patty Kluver
for Genie Land Co.

L. Under Montana law, a discharge of groundwater or "wastewater" is not considered a reasonable or beneficial use. "Beneficial use" in the Montana Water Law means "a use of water for the benefit of the appropriator..." In some instances, water rights are filed on wastewaters and groundwater discharges that are put to beneficial use by the appropriator (i.e., irrigation). There is no drainage law in Montana that gives the landowner a relief from damages incurred by drainage from adjacent lands. The only relief is through case law and the courts. However, the Montana Strip Mine Law provides authority to the State to deny an operating permit if a proposed mine operation would cause adverse hydrologic impacts which would impair present and future land and water uses.

M. Your comment is noted.

MONTANA STATE UNIVERSITY BOZEMAN 59717

June 29, 1982

Mr. Kit Walther
EIS Team Leader
Montana Dep't. of State Lands
1539 11th Ave.
Helena, MT 59620

Dear Mr. Walther:

Having reviewed the draft EIS for Western Energy's Rosebud Mine Area C, Block 1, I have the following comments:

- Vegetation Section (p. II78-II82) is well done. } A
- Alternative (a) p. IV-17 is more desirable than alternative (b) for establishing conifers because of the reduction in long term fuel and labor commitment and the increased potential for seedling establishment and survival. } B
- Appendix G, Table II - Kentucky Bluegrass (Poa pratensis) is an undesirable increaser whose current existence in the proposed mining area is probably due to the overgrazing of the 1880's and 1890's. The establishment of the other usable livestock and wildlife forage species would be greatly enhanced if this species was eliminated from the proposed mixture. } C

I would be happy to explain any of my comments further should you need me to do so. My phone number is 994-3721.

Yours truly,

Clayton B. Marlow
Assistant Professor

CBM:gmb

Clayton B. Marlow

A. Thank you. Your comment is noted.

B. Your comment is noted.

C. The Montana Department of State Lands does not believe that Kentucky bluegrass (Poa pratensis) is an undesirable species in the Lowland/Drainage Seed Mixtrue as proposed by the Western Energy Company. Kentucky bluegrass is an efficient sod-forming species and for this reason has been included in the mix to be used on easily eroded drainage areas. Kentucky bluegrass is also a good forage grass for both livestock and wildlife and has not proven to be a problem increaser in the Colstrip area. It should be noted that the grass in question makes up only 10 percent of the seed mix to be planted in about 5 percent of the total reclaimed area.

RE: Comments - Area C, Block I DEIS

Dear Mr. Walther:

Western Energy Company's technical staff has reviewed the draft environmental impact statement recently published for Area C, Block I. In general, we see no major problems with the DEIS. However, we do wish to submit the following comments in hopes of clarifying a few points which were made in the hydrology section of the document.

Western Energy Company disagrees with the statement (see page II-20 and Figures II-8 and II-10) that, "A major recharge area appears to be located in the vicinity of Area C". Based on Western Energy's hydrological investigations, there appears to be recharge to Area C from the west from alluvium, bedrock, and vertical infiltration. As stated by Ertec, the amount of vertical infiltration is very small. The configuration of the potentiometric surfaces shown in Figures II-8 and II-10 result from kriging data which is averaged from 1973 and 1981. Western Energy feels that the potentiometric maps supplied with the Area C, Block I application SMA00105 (Exhibits R-1 and R-2) are accurate site specific representations of the potentiometric surfaces of the Rosebud coal and the McKay coal. A

On page II-22, the statement, "Where Rosebud spoils become part of the valley fill groundwater flow system, spoils water migrates laterally into valley fills", cannot be substantianted by Western Energy's data or by data presented in the draft EIS. Examination of figures II-6 (page II-21) and figure II-7 (page II-23) show that alluvial water levels are higher than water levels in the spoils. Therefore, interchange of water between these two units would have to be from the alluvium to the spoils. Data presented by Dolhopf (1977, page II, figure 5, attached) suggest that East Fork Armell's Crek alluvium is not in contact with Area B spoils. Recent drilling by Western Energy Company in the railroad loop (holes EX 158-165) and the log for Well P-06 indicate a substantial volume of undisturbed bedrock between East Fork Armell's Creek and alluvium and spoils. The northeast quarter of the northeast quarter of Section 4, T1N., R1E, was not mined and there are not areas where Area A spoils are in direct contact with East Fork Armell's Creek gravel aquifer. B

Exhibit 3

VIII-16

Chris Cull

A. The FEIS reflects wording changes to indicate that the area in question is not a major recharge area for the aquifers in question. There is probably some recharge throughout the entire area. The potentiometric maps have insignificant variations from the referenced exhibits.

B. After discussions with Western Energy concerning well locations and review of the monitored logs it is clear that the Area A spoils are not in direct contact with Armells Creek alluvium. The question concerning Area B cannot be resolved with present data. Detail of future mining plans was not sufficient to acurately determine potential areas where spoils and alluvial material will be in contact. Since mining in Area C will proceed across East Fork Armells Creek, eventually spoils and alluvium will be in contact.

The inferred fault or faults shown on Figure II-9 and discussed in the text cannot be substantiated by Western Energy's drilling redords. The attached cross sections, through Areas A and F (Figure 1) at approximately the location of the cross section on page II-26 and through Area C (Figure 3) across the inferred fault show minor folding but no displacement. These cross sections were drawn using holes drilled for outcrop delineation (locations shown on Figures 2 and 4). } C

Thank you for the opportunity to comment on the Area C draft environmental impact statement.

Cordially,

CHRIS CULL
Manager, Operational Permitting

CC:kk

C. The structural contour maps prepared from Western Energy core hole data show over 100 feet of displacement in a 3,800 feet distance in the Rosebud coal. This is an anomolous dip for the study area. The U.S.G.S. has indicated that a possible fault exists in the area. It is the opinion of the authors that there is fraturing and displacement associated with the structural feature described.

Exhibit 3

Letter No. 9

United States Department of the Interior

MINERALS MANAGEMENT SERVICE
RESTON VA 22091

In Reply Refer To:
MMS-Mail Stop 650

Mr. Kit Walther
EIS Team Leader
Montana Department of State Lands
1539 11th Avenue
Helena, Montana 59620

Dear Mr. Walther:

The Minerals Management Service, U.S. Department of the Interior, has reviewed the Draft Environmental Impact Statement (DEIS) for Western Energy Company's Proposed Rosebud Mine, Area C, Block 1, and we offer the following comments for your consideration.

The DEIS is well written and includes up-to-date literature sources, a realistic assessment of the reclamation potential of the mine, impacts to the biological community, and the agricultural utility of the land. The sections on hydrology appear to be well done, and the assessment of potential impacts on surface and ground water quality are, in general, realistic. } A

Specific Comments

Page 1, paragraph 6, line 6. This line should read ". . . a slight increase in electrical conductivity . . . ." } B

Page ii, paragraph 7. It is suggested that this sentence be changed to read, "These changes would reduce the postmining potential for crop production and . . . ." } C

Page iv, paragraph 3, last sentence. Some further explanation is required to overcome an apparent contradiction here. "Compared to the premining (1978) conditions, productivity for livestock grazing would increase; however, the potential productivity (total biomass production) of the postmined area would be lower . . . ." } D

Page II-22. The statement is made that there are places in the vicinity of the proposed mine where Rosebud spoils are located adjacent to the valley fill material and occasionally become incorporated into the valley fill ground water system. The description of these areas in the EIS would suggest that some weathering occurs. } E

JUL 06 1982

Andrew V. Bailey

A. Comment noted.

B. DSL and OSM believe that the present wording is correct.

C. Comment noted. While that potential exists it is not certain.

D. Productivity for livestock grazing and total biomass production are not perfectly correlated. The components of biomass contribute to productivity for grazing.

E. Comment noted. Where spoils are exposed to the atmosphere they are exposed to weathering.

Exhibit 3

Page II-48, paragraph 3. This paragraph discusses the concentrations of trace metals, noting that mercury was high at several sampling points. However, the potential for increased concentrations of trace metals, such as mercury, as a result of mining and associated oxidized spoils was not addressed, nor was further discussion of this point made except to note that some of the high results were believed to be a result of laboratory error. Since mercury is an important trace metal associated with coal and tends to increase where coal or spoils have had an opportunity to weather, these findings warrant a more complete discussion in the EIS. We recommend that the final EIS include additional discussion of the sampling sites where high mercury concentrations occur. The discussion should state whether or not such sites are in the areas potentially impacted by existing Rosebud spoils and provide some insight as to the source of the mercury. If the sites are found in areas influenced by the Rosebud spoils, then the projected water quality impacts should be amended accordingly. F

Page III-55, H. Wildlife, paragraph 1. We note that Western Energy Company states that seasonal sources of surface water which are now available to wildlife will be impacted by proposed mining activities. We also noted this observation in section B, Hydrology on pages III-6 through 25. The draft document did not provide an assessment on the value of surface water bodies (springs and stock ponds) for wildlife nor the anticipated impact of wildlife if these water sources are removed or rendered unuseable by proposed mining activities. G

Within the same paragraph, Western Energy Company states that the U.S. Fish and Wildlife Service recommended the sandstone outcrop on which golden eagle and prairie falcon nests are located be protected. Also, the Montana Department of State Lands recommended a 100-meter buffer zone be established between the mine and the outcrop. Western Energy Company states further in this paragraph that preliminary life of mine for Area C, Block II, would eliminate the outcrop. No other discussion is made as to whether or not Western Energy Company is or is not going to protect the sandstone outcrop. We recommend that the Office of Surface Mining require the applicant to make a decision on whether it will or will not protect the golden eagle nest outcrop and provide the rationale for its decision. H

Thank you for the opportunity to comment on this DEIS.

Sincerely,

Andrew V. Bailey

Andrew V. Bailey
Acting Associate Director,
Onshore Minerals Operations

F. It is very likely that field sampling techniques or laboratory error are responsible for these values, and it is not felt that further discussion is warranted without reliable data. Discussions with personnel at the National Water Quality Laboratory of the USGS corroborate this conclusion. Two factors support this contention.

1. 0.03 to 0.04 mg/l are equal to 3 to 4 mg/l, which are values that are very unlikely in nature. These occur alongside data taken from the same locations at different sampling times that show no detectable evidence of mercury.

2. Mercury is commonly encountered as a contaminant in field and laboratory settings. Contamination can come from a number of sources, most notably mercury contained within the manometer type stream flow gauges (commonly used at the same time a sample is collected) and mercuric chloride, commonly used to preserve nutrient samples, being incompletely removed from glassware in the laboratory.

G. The impact of mining in Area C, Block I upon surface water bodies was determined to be minimal and hence the corresponding impact to wildlife using such areas would also be insignificant.

H. Please see comment A and DSL's response to comment A in the letter from the Fish and Wildlife Service. The Western Energy Company as agreed to establish a 100 meter buffer zone around the subject sandstone outcrop area. In addition, the company has committed to identifying the buffer zone boundary with a one-wire fence and with signs indicating the area as a disturbance limit to mining related activities. To the extent reasonably possible, the company has also agreed in their mining and reclamation plan to minimize other types of activity in this area.

Letter No. 10

July 4, 1982 JUL 8 1982

Mr. Brace Hayden, Administrator
Reclamation Division
Dept. of State Lands
Capital Station
Helena, Montana 59601

Re: WECo, Area C: Block 1

Dear Brace:

Enclosed is a "supplement" to the critique I mailed you prior to July 2nd. In the ones sent to Kit Walther and to Gareth Moon, there was a copy of the testimony I presented at the May 12th Water Quality Bureau Hearing relative to the renewal of a discharge permit. Since I had already mailed you a copy of the testimony, it is left out of this enclosure. I hope you haven't filed it in the "deep six drawer."

It isn't that I consider myself a talented writer, in submitting EIS critique after EIS critique to DSL. On the contrary, it is real work for me, something which must be done between other jobs, like trying to run this outfit with as little money spent as possible. The repair bill on the machinery and wells alone is perfectly appalling. If DSL thinks they have it rough, they ought to try ranching for a while.

Thought I'd report some words of encouragement to you. It seems the quest for more funds for enforcement and investigation for DSL, etc. is really in the works. It probably won't get anywhere, because M.P.C sure doesn't want any close scrutiny, but, working on the Republican side, maybe a bit of negotiation could be done. I'm planning to work on the other side, too, because it is that important to me, and I'm more D than R, but neither, really. There doesn't seem to be much to vote for either way, or against.

You can't imagine the frustration and hopelessness I feel re: Area C: Block 1. The "mitigating measures" so clearly point out that WECo. will get their way, and to heck with those who stand in their way.

I hope the hail didn't damage you or your property too much. It must have been terrible, but it is a part of living in Montana, and I wouldn't want to live anywhere else. I like the challenge.

My very best to you personally, Brace.

Sincerely,

Patty Kluver

Patty Kluver

The Montana Department of State Lands and the Office of Surface Mining believe that in reviewing the Area C, Block 1 application, they have treated the concerns of the public and the Western Energy Company equally. We appreciate the comments you have offered both written and oral, and have tried our best to address each of them adequately. We have expanded the areas of concern to you in the cumulative hydrologic sections in Chapter III of the FEIS.

RECEIVED
JUL 7 1982
STATE LANDS

Dear Sir:

On Page one, (1) of the written testimony sent to your office prior to July 2nd, paragraph seven (7) evidently needs clarification!

The paragraph does not explain that the spoils wells are recharged by the use of aluminum tubes extending from the active mine pit, on the surface of the spoils, to sediment ponds in the older mine area of Area C. The drainage from those sediment ponds is what is influencing the quality and quantity of the spoils wells, located where no coal strip-mining has ever been accomplished because the area where they are located is the site of "burn." A

Enclosed for your consideration is a copy of this writer's testimony pertaining to a renewal of Waste Water Discharge Permit, before the Water Quality Bureau, May 12, 1982. It is pertinent to the proposed coal stripmine permit for Area C: Block 1 because the discharge points will be used if the permit is granted, along with others yet to be applied for, one suspects.

Enclosed, also is a copy of an article from Focus, published by the Dept. of Agriculture, Mont. State University, at Bozeman, Montana.

While the article projects the accomplishments of the reclamation team of M.S.U., they admit they have not solved the question of reclamation of mined lands to date. In spite of the high cost, they will continue to apply and improve on the scientific studies they have made thus far.

The contents of the paragraphs in sub-title More Questions, 4th page of the enclosure, are particularly pertinent, because they put the lie to the claims for reclamation projected by the WECo., Draft EIS, Area C; Block 1. B

The last page of this enclosure points to the degradation that Plant 3 will add to the pollution already in the air from Plants 1 and 2 at Colstrip. The additional damage from Plant 3 could very well make the ranching business down wind from the plants untenable. Perhaps that is what the applicant Company would prefer, but, the Dept. of State Lands is charged with an obligation to the afflicted ranch land as well as to the royalties and severance income to the State coffers. C

Exhibit 3

Patty Kluver (Cont.)

A. Please see the response to comment D of your July 2, 1982 letter.

B. Thank you for subaitting this information.

C. Possible impacts to ranching downwind of Colstrip 3 and 4 have been reviewed through the permit process relative to that project and in the Colstrip Units 3 and 4 EIS. The Department of State Lands does not have regulatory authority in relation to the air pollution emissions of Colstrip 3 and 4. The impact to ranching as a result of Colstrip 3 and 4 air emissions is projected to be minimal.

Page 2, EIS-WECo.
Area C: Block 1
Supplement to critique
Mailed prior to July 2, 1982

Supplement to subject: Groundwater

Some time ago, Mr. Bob Ringler of your staff mailed me a copy of a thesis by Gary Levings, titled Sulfate Reduction in groundwater of Southeastern Montana. On page 10, the second paragraph is pertinent information revealing that, "the overburden strata exposed by strip-mining operations in southeastern Montana harbor appreciable numbers of bacteria of the genus Thiobacillus that are capable of oxidizing reduced sulfer compounds. The sulfer isotopes from secondary gypsum and secondary pyrite collected in the area were fractionated enough to leid the authors to suspect that sulfate-reducing bacteria may have been active at the time of formation and deposition of these minerals.

This writer has no available "copier" and would have to drive 43 miles to the County seat, or 70 miles City to purchase the use of one. This would appear foolish, since the data is available at Dept. of State Lands. Please do not overlook the thesis referred to above, however.

The EIS Team who will make the decision relative to mining of Area C: Block 1 must be aware that summer is the time on all ranches when work-days are long, so that we can provide for our livelihoods. Because of this, it is apparent that this writer will have no time to rush over to Colstrip to "brief" the ERTEC study, which probably says little that would meet with the dis-favor of the applicant Company. Certainly, it could not be objective.

It has occurred to this writer, however, that no member of the Dept. of State Lands staff has ever been on Cow Creek during the growing season, when the result of discharge of mine water is most noticable!. It has always been prior to growing season, or after that one of you has come to investigate.

In an effort to show you of the DSL who will make this momentous decision, one that could make or break the ranching business of this area, may I extend you a cordial invitation to come to our ranch. If you will accept the invitation, in approximately 4 hours of your day, you can be shown the adverse affect of coal strip-mining on Cow Creek, and could also be shown an area where there is little impact from mining yet, on Pony Creek and Spring Creek. The mining of Area C: Block 1 could spell the doom of the two above named drainages, as well as many others in the region.

Please consider this list request, and you can schedule the visit phone to 347-5590.

Most Sincerely,

Patty Kluver

Patty Kluver (Cont.)

D. Your comment is noted.

E. The Commissioner of the Montana Department of State Lands and the Secretary, U.S. Department of the Interior will make the decision as to whether to grant or deny a surface mining permit for Area C, Block I.

F. Thank you for the opportunity to visit your ranch during the growing season. The Department of State Lands will make an effort to do this very soon.

DEPARTMENT OF HEALTH & HUMAN SERVICES

Letter No. 11
Office of the
Principal Regional Official

Region VIII
Federal Office Building
1961 Stout Street
Denver CO 80294
ROFEC

June 16, 1982

Mr. Allen D. Klein
Administrator
Western Technical Center
Office of Surface Mining
State of Montana
Capitol Station
1625 11th Avenue
Helena, Montana 59620

Dear Mr. Klein:

We have reviewed the DEIS on the Western Energy Company's proposed Area C Coal Mine near Colstrip, Montana.

The DEIS indicates that the impact of this proposed mining operation on human service agencies in the vicinity would be minimal, "due to the similarity of existing and incoming work forces."

Rosebud County Welfare Office agrees with this conclusion. The community of Colstrip has already experienced a large population increase due to other related projects now in place. Colstrip will soon receive a special grant from the Montana Coal Board as a result of severance tax receipts. This grant will be used primarily to hire additional social services professional staff.

We suggest that comments on this DEIS be solicited from the Montana Department of Social and Rehabilitation Services.

Sincerely yours,

E. W. McIntire
Director, ROFEC

JUN 1982
RECEIVED

E. W. McIntire

Your comments are noted. The Montana Department of Social and Rehabilitation Services (SRS) name was mistakenly dropped from the DEIS mailing list. SRS will be sent a copy of the FEIS.

June 6, 1982

RE: Rosebud Mine Area C, Block I Draft Environmental Impact Statement.

We appreciate the opportunity to comment on the Draft Environmental Impact Statement (DEIS), for the proposed Rosebud Mine Area C, Block I permit application.

Prior to addressing the DEIS, we would like to submit for the record the "scoping" comments of the Rosebud Protective Association (RPA) that were brought to the attention of the Montana Department of State Lands (DSL) and the Earth Technology Corporation (ERTECH) at a meeting on December 16, 1981. We ask that these comments be included in the record to establish that many of the concerns raised at that "scoping" meeting were not adequately addressed in the DEIS. Some of these include: the restoration or replacement of aquifers, the cumulative impacts on hydrology from mining and industrial development at the Colstrip complex, and necessity for addressing the "last" or phaseout cycle of development. A

The Office of Surface Mining (OSM), and DSL by not requiring that supplemental field work, particularly as it might relate to hydrologic studies, have violated the intent and the language of the Memorandum of Understanding between them, ERTECH and Western Energy Company (WECo). The MOU required them to determine "whether adequate baseline and environmental data already exist and no further baseline monitoring is required". Obviously, more data is required to establish an adequate baseline. The MOU also required ERTECH to assist in this effort by reviewing and documenting the type, quality and quantity of information in the environmental assessments prepared for or on the industrial complex at Colstrip. The EIS does not address the adequacy of the type, quality or quantity of the information available except to note where there is a "lack of information available (Appendix B to these comments). B

Exhibit 3

Russ Brown

A. All scoping comments, except for the request for analysis of the phaseout cycle of the Colstrip complex have been addressed in the Final EIS. The authors will address the phaseout cycle of the Colstrip operation in the forthcoming Comprehensive EIS. A draft of the Comprehensive EIS will be available for public review in August 1982.

B. Terms of the Memorandum of Understanding and Contract with Ertec did not specify supplemental field work for preparation of the Area C EIS. The agreement requires Ertec to utilize existing environmental data, based on an evaluation of its adequacy, to prepare the analyses of environmental impact. Existing data has been evaluated by OSM and DSL and determined adequate for determining baseline conditions for purposes of Western Energy's Area C, Block I mine plan.

We requested at a very early date that verification as to the quality and quantity of data be undertaken in order to insure that a comprehensive hydraulic study be completed. In a written response to these "scoping" concerns, Bruce Hayden, Administrator Reclamation Division, DSL states "the Plan of Study did not budget for field verification of well locations, therefore verification will be limited to cross checking existing data sources. This effort will be extended to Area E and the surge and fly ash ponds to the extent that ERTECH is able to obtain data from WECo and other sources". (March 1, 1982 letter to Russ Brown, NPRC Staff) C

The DEIS does note that lack of data prevented ERTECH from making statements about much of the hydrologic regimes. Yet, why didn't the DEIS make any recommendations that further testing be done? Are DSL and OSM satisfied with the amount of data available? Was an analysis done on the quality and quality of water in the existing and proposed fly ash ponds? Weren't industrial impoundments, both present and proposed supposed to be part of the cumulative hydraulic assessment? According to Mr. Tom Hastings, the hydrologic assessment for Area C and the Comprehensive EIS were completed as of the hearing on June 11. As a result of the findings in the DEIS and due to subsequent comments, is any further analysis planned? D

The Area C EIS is supposed to be a site specific EIS for a mine permit application. It is also supposed to be used as a baseline reference document for all future assessments done at the Rosebud Mine. However, since there is inadequate data available for the Block I permit area, analyses were extrapolated from areas A,B,E, & D. Do the DSL and OSM consider this kind of extrapolation a valid approach upon which to base permit decisions? The State in a 10/2/81 letter to WECo points out that "each mine in Montana is in a different hydrologic situation and that the WECo plan is more expansive than any other mine in the State". Is there in fact information available for Area D for example, that can be accurately extrapolated and applied to Area C? E F

A major problem for those attempting to analyze the DEIS is the number of references to the various Technical Support Documents that were prepared in conjunction with the EIS. Compounding the problem with the continual references to the TSD's has been the difficulty in obtaining access to these documents. G

In an October 2, 1981 letter to Mr. Art Neill of WECo, DSL points out that a cumulative hydrologic assessment must be [illegible] prior to any permit issuance. This has not been [illegible] to issue a permit without further hydrologic studies [illegible] undertaken [illegible] Admin. Sec. 82-4-227(3)(a) and also, [illegible] this information, DEIS that indicates that affirmatively [illegible] Sec. 82-4-231(1)(III)(A) has been complied with. H

Exhibit 3

Russ Brown (Cont.)

C. Your comment is noted. These were the conditions of the Memorandum of Understanding and contract with Ertec. Hydrologic data in the technical support document used in the ground water modeling was verified in cases where more than single data sources were present.

D. The authors believe the existing data base was adequate to make the hydrologic assessments of the Rosebud Mine and Area C, Block I mine plan. As required by the Montana Strip and Underground Mine Reclamation Act, Western Energy will be required to continue hydrologic monitoring of its activities and routinely report results to the Department for its evaluation. Analyses were conducted on the existing fly ash ponds as part of the modeling effort. Data indicate that the existing fly ash ponds leak very small amounts of water which then flows downgradient and becomes diluted in the surge pond area. A "worst case" evaluation of the impact of the proposed fly ash pond on the Cow Creek alluvial system is included in the final EIS. Please refer to Chapter III, Hydrology.

E. The Comprehensive, not the Area C EIS, will serve as the reference document for future EISs for the Rosebud Mine.

F. The authors did not find hydrologic data from Area C, Block I significantly different from other areas of the Rosebud Mine. Based upon a comparison between the site specific Area C, Block I hydrologic data and other data in surrounding areas it was felt Area C, Block I was hydraulically very similar to the areas surrounding it. These similarities and those differences which may occur are discussed in Chapter II, Section b. The similarities and the amount of data for Area C, Block I were determined sufficient for modeling the hydrologic system.

G. NPRC was sent a copy of the Hydrology section of the Technical Support Document (TSD). The entire document is available for review at the locations listed in the EIS.

H. The Final EIS for Area C, Block I includes an expanded cumulative hydrological assessment. Please see Chapter II.

SUMMARY

On page ii of the summation, it is noted that "the concentrations of total dissolved solids(TDS) in the spoils aquifer would be approximately twice that of the present Rosebud coal and overburden aquifers" It then points out that spoils water would follow the regional south east flow direction and eventually reach Cow Creek. Where else is the effect of this spoils water reaching Cow Creek addressed in the DEIS? Was the effect of this high TDS water and the proposed fly ash pond on Cow Creek calculated or included in the cumulative hydrologic assessment? I

We would also like to request that the language in the summation that states that "an indirect impact from mining may result" be changed to "another impact from mining that would result is....."(DEIS p. ii 3 para.) J

p. iv 4 para. recovered is mispelled.

SCOPE OF THE ANALYSIS

The DEIS assumes that WECo will be able to implement its Block II life of mine plan If this assumption is valid, why hasn't more information been presented or made available for the Block II mine plan? Are OSM and DSL proposing to issue a supplemental EIS or just extrapolate from the already inadequate data base? Does OSM and DSL feel that enough information exists to justify a permit decision on Block II. K

The DEIS states that "approval of a permit is a process separate from the EIS." Does this imply that when the public participates in the EIS review, they are not having any input into the decision of whether or not to issue a strip mine permit? L

It is also stated in the DEIS that "the comprehensive EIS will address the cumulative impacts of all the proposed mining .....and industrial activities in the area". Isn't the Area C EIS bineg used as a data base for the comprehensive EIS? Were other projects for which there are no EIS's available considered during the preparation of this EIS? M

The DEIS mentions that "all but one mile of the conveyor system will pass thru areas presently permitted". Is this "one mile" within the Area C permit application? We request that the route of the conveyor system be clearly identified in a map or diagram in the Final EIS (FEIS). N

DESCRIPTION OF THE EXISTING ENVIRONMENT

For the purposes of this document, is the Cow Creek drainage considered a part of the Armells Creek system or as a separate drainage? O

The EIS states that only those aquifers above the Mckay coal seam would be physically disturbed. Would the existence of fractures that might allow groundwater movement once an impermeable layer is removed constitute a physical disturbance? P

An analysis of the McKay coal seam at the Rosebud Mine and Peabody's Big Sky mine show similarities in BTU and chemical composition. Why is the McKay seam considered marketable at Q

Exhibit 3

Russ Brown (Cont.)

I. A more specific discussion of the effects of spoils water quality and the proposed fly ash pond on Cow Creek have been added to Chapter III, Hydrology.

J. These impacts (i.e., population increases, increases in power facilities) are not directly attributable to the activity of mining and therefore are considered indirect.

K. Until Western Energy submits a complete application for Block II and mine plan to DSL and OSM no detailed site specific impact analysis about this area can be made. At this time there is not sufficient information for the agencies to make a permit determination on Block II. In some cases (i.e. hydrology and socio-economics) the information was presented for all of Area C. Once an application for a mine plan has been received a determination will be made as to the type of environmental document which will be developed for Block II.

L. No. Both processes provide mechanisms for public involvement. Although the EIS is a distinct and separate document for the permit evaluation document both are an integral part of the decision making process. Comments received on either or both documents are used in the permit decision making process.

M. The Area C EIS will be used as one of the data bases for the Comprehensive EIS. Other data sources will include existing EISs prepared for Colstrip Areas A, B, and E, Peabody's Big Sky Mine, Colstrip Generating Units 3 and 4, etc. These five data sources were used in preparing portions of the Area C, Block I EIS. In addition extensive data, for which mine plans had not been submitted, were also utilized in preparing the Area C EIS. These included data for the Area B extension, Area C-Block II, Area D, and additional proposed mining in Area A.

N. Portions of the conveyor not within previously permitted areas are within the proposed Area C mine area. A map of the conveyor system is shown in the text.

O. No, Cow creek is part of a separae drainage (Rosebud Creek).

P. The less permeable interburden will not be removed. There will be an increase in vertical leakage from the lower aquifers as summarized in Chapter III of the FEIS.

Q. Because Western Energy Company does not have a buyer for the McKay Coal while Peabody does.

at the Big Sky mine and not at the Rosebud mine?

The DEIS states that "in some instances, the characteristics of Area C, Block I are different from the hydrologic study area as a whole." (DEIS p. II-10) It would be helpful if the DEIS summerized these differences at this point. R

When discussing the permeability of the rubble zone as a contributing factor in the large range of transmissity values, could this be factored our more accurately? (DEIS p. II-13). The DEIS further states that "generally the hydrologic conductivity values were the same". In what instances, or under what circumstances have they been found to deviate? S

On p. II-14, the diferrences in range of transmissivity in E. Fork Armells Cree and Stocker Creek is discussed. The DEIS points out that only six tests have been conducted on the Stocker Creek drainage. It then concludes that "due to the greater number of tests performed on the East Fork Armells Creek, the mean values of these aquifers is more representative of shallow transmissive characteristics". Does this mean that the number of tests is the determining factor in cumputing transmissity? While 6 test might not be statistically significant, if an equal number of tests had been taken in both Creeks, might not the conclusion have been different? T

Clinker has been reported to have local hydrologic significance. Why then have no tests been performed in the clinker to determine its role in the hydrologic system at and around the Rosebud Mine? (DEIS II-16) U

Early in the DEIS is the statement that "the properties identified for water bearing units are constant throughout the hyfrologic study area. (DEIS II-13) However, the rest of the EIS goes on to describe how the lithologic, structural, amount of clinker and chemical composition (to name a few) are different for each water bearing unit. With so many critical determing factors different for each unit, and considering the lack of data for many of these strata, how can the properties identified for the water bearing strata be consistant? This crucial invalid assumption seems to be used as a blanket rationalization for thelack of hydrologic information available for discussion in the DEIS. V

What is the significance of one observation well in the overburden not being effected by a drawdown test at a pumped well? (DEIS II-16) Is it legitimate for the EIS to infer from one pumped well test that "the two aquifers are not connected in that area" Wouldn't the presence of a confined or unconfined aquifer at that point make a difference in the test results? Also how is "area" defined in this context? W

When the DEIS is discussing the character of the spoils groundwater system, it states that it is generally unconfined. However, it then goes on to say that evidence exists to suggest that it may be confined (DEIS II-20). Is this uncertainty due to a lack of data? X

R. Pages II-10 through II-19 of the DEIS and the initial pages of Chapter II of the FEIS address these differences.

S. Presently, variations cannot be more accurately described. Hydrologic conductivity values vary in the spoils due to lithologic variation in the material. The variations do not appear to be statisticlally significant however more data would be needed to describe the phenomena. The discussion of spoil aquifer properties was primarily a general evaluation of physical and hydraulic properties as defined by limited research. It is very often difficult to complete wells in spoil and conduct hydraulic conductivity tests without biasing the result. The bias occurs because it is difficult to install wells in coarse rubble and it is also difficult to run tests in such wells since water runs out so quickly that neither a constant or falling head test can be monitored.

T. The referenced sentence has been deleted in the FEIS because of confusion over its intent. The sentence was not meant to imply the transmissivities for East Fork Armells Creek (EFAC) were representative of both Stocker and EFAC alluvium. The 29 tests conducted in EFAC alluvium are representative of EFAC only and those tests conducted in Stocker Creek are prepresentative of Stocker Creek only.

The conclusions may or may not have been different. I would be highly speculative to comment on aquifer hydrologic properties without data to support the statement.

U. Clinker occurs in the mine area as outcrops along stream valleys and tributaries. Rosebud clinker occurs along the northern edge of Area C and is an area of ground water discharge. Similar outcrops occur along East Fork Armells Creek north of Colstrip, and are also areas of ground water discharge from the coal seams. Extensive areas of Rosebud, McKay and Sawyer clinker crop out north, west and south of Cow Creek, and form resistant bluffs. These appear to be areas of recharge for the Cow Creek drainage system. Because of the extremely permeable and porous nature of clinker, it is able to absorb and transmit large quantities of water. The location of clinker mainly in discharge zones in the Rosebud mine area means that the clinker will have very little effect on the recharge capacity of the reclaimed mine areas. Additional testing of the clinker in the Rosebud Mine area would not significantly enhance the understanding of the hydrologic system.

V. There are local variations of hydrologic properties throughout the study area. Each hydrologic unit has been examined and a constant set of values assigned to each unit throughout the hydrologic study area. Therefore each unit has different properties and these have been described in the document.

W. At the location of the observation well and within the area of influence of pumping at that well there is no evidence of hydrologic connection. It is proper to infer that the results of the testing cited demonstrate a lack of connection. Whether this relationship is maintained without discontinuities throughout the study area is unknown. For that reason the intent of their relationship has been limited to the "area" in which testing occurs. Results of this testing do not allow for an exact definition of "area".

(See X. on next page)

Exhibit 3

P. 5 was identical to P. 4

Exhibit 3

SOCIO-ECONOMICS

The DEIS notes that "coal mining in Rosebud County would cease after the year 2018" (DEIS II-92). Does this assume that no other strip mine permits will be issued in the future? We would like to request that an analysis be prepared on the socio-economic and fiscal impacts that will result from the cessation of mining at Colstrip. } Y

P. II-101 "percentage is mispelled.

SOLID WASTE

The DEIS discusses the collection and burial of solid wastes in the old mine cuts that have been sealed with clay. When did this sealing take place? What have been the findings from the monitoring reports? Who are they submitted to? Have they been? } Z

HOUSING

The DEIS doesn't reflect the assumptions that are made in the MONTCO draft environmental impact statement that a large percentage of Montco's workers will reside in Colstrip. Is this an invalid assumption? If the State feels that it is not, then it should be factored into this analysis. } AA

CULTURAL RESOURCES

The survey of cultural resources seems thorough. It is unclear however if the Block II mining plan would have more of an impact on cultural resources than Block I. Is this the case?

Prior to the issuance of the FEIS, are any consultations proposed with Native Americans to discuss possible concerns under the American Religious Freedom Act of 1978? } BB

ANALYSIS OF IMPACTS

The DEIS notes that "overburden sampling on a grid pattern with hole density similar to that of Area C (1500-2000 ft.). is only about 50% reliable in predicting the occurence of unsuitable overburden material" How does the State propose to improve this flip of the coin accuracy? What would be a realistic frequency to improve on the sampling technique? } CC

Exhibit 3

X. The base of the spoils apparently exhibits confined characteristics. The upper parts of the aquifer spoils are unconfined characteristics. It is clearly atated on page II-20 that groundwater in spoils is generally unconfined but that it appeara that confining condition may occur in some areaa. The information indicating confined conditiona include the height of the piezometric aurface and with respect to the top of the spoil in that location.

Y. No it does not. The 2018 analyais is made becauae Western Energy's comprehenaive mine lan projecta mining to that period of time. The socio-economic effects of ceaaation of mining at Colatrip will be addressed in the forthcoming Comprehenaive EIS for the Colstrip area.

Z. The burial of solid waste in the old mine cuts ia done by Rosebud county under a permit from the Montana Department of Health and Environmental Sciences. Prior to the uae of the pit aa a landfill by the County on December 17, 1981, the old cuts were aealed with clay. Monitoring reports for the landfill are being aubmitted to the Solid Waste Bureau semi-annually. These reports indicate that no trenda are occurring dow gradient of the landfill. Recent aampling for aresenic indicate arsenic doea not occur in detectable levela.

AA. In keeping with aite specific EISs the Area C impact acenario aasnmes that no other new mines would be developed. This allows the analysis to focus on the probable impacts of the propoaed section rather than maaking them behind a acren of other projecta aaumed into exiatence. The Comprehenaive aaaeaament document currently being prepared will addreaa the effects of poaaible mines.

BB. Block II mining will not have more of an impact on cultural resources than Block I mining. Sites determined to be eligible for the National Register of Historic Places will be mitigated according to an approved plan prior to disturbance. P.L. 95-341, the American Indian Religious Freedom Act, recognizes the constitutional right of Native Americans to practice their traditional religions. Most landa affected by this law are managed by the Forest Service and the National Park Service. Since mining of Area C would occur on private lands and there are no American Indian cemetaries which were in uae at the time of Federal aubjugation or are there within the proposed mining are physical locations to which American Indians have traditionally had accesa, the agencies will not be pursuing this matter further.

CC. The Department's guideline of a 2000-foot grid sampling pattern for overburden characterization haa been in effect aince about 1975. Based upon aome research findings since then, primarily those of Dollhopf et al. (1978, Reaearch Report #135) and Dollhopf et al. (1981) as referenced in Chapter VI of the DEIS and baaed upon experience gained in reviewing a large quantity of overburden information in the paat aeveral yeara, DSL is currently reviewing ita guidelinea regarding overburden aampling proce-durea. (Pleaae aee the "note" in paragraph 4 of page III-3 in the DEIS.) Hopefully, this review will result in a guideline that will effectively and efficiently provide the amount of information necesaary to make aound evaluationa of overburden quality. The frequency and pattern of overburden aampling that will "realiatically" accomplish this goal will be suggested when a draft reviaion to the current guidelines ia diatributed for comment.

What does WECo propose to do to avoid leaving cuts of coal when faults are encountered? (DEIS III-4) } DD

In general on hydrology. It seems that ERTECH spent so much time developing a groundwater model that major, significant impacts were lost in the shuffle. For example, when were the present and proposed fly ash ponds dropped from the groundwater study? } EE

DD. Western Energy would have a number of options available should they encounter suddenly deeper coal due to the inferred fault discussed in Chapter II. Western Energy could continue to use the dragline to recover the deeper coal. This might require further handling of spoils requiring that it be cast closer to the boxcut in order to gain spoil space. In this case it may be necessary to leave behind one or two cuts of coal. Trucks and shovels, as another option, could be used to move spoils out of the way to gain spoils space needed to recover the the deeper coal. However, the EIS does not conclude that major displacement is present in Block I and Western Energy does not foresee major faulting causing a problem with coal recovery in Block I. Faults inferred by the EIS in Area C, Block I have displacements of less than 30 feet which would not affect coal recovery.

EE. Ertec did not overlook significant impacts while the proces of refining the groundwater model. A discusion of the model and hydrologic impacts used by Ertec are discussed in the Final EIS, Chapter III, Hydrology.

In Appendix B to these comments we list numerous instances of major data deficiencies. In those areas where there is a noted lack of data, rendering analysis impossible, what does DSL and OSM propose to be done? Do the respective agencies concur that Sec 82-4-222(1)(l) is not presently being complied with? FF

The DEIS states that the only water bearing unit of significance that will be effected is the Rosebud coal seam. Will the removal of this seam increase the hydrologic significance of the Rosebud /McKay interburden ot other strata? GG

On page III-11 5. the terms lower aquifers and deeper aquifers are interchanged. Is this meant to be? HH

The DEIS states that replacement wells will be drilled into the sub-McKay aquifer. What is the water quality of the sub-MaKay aquifer? We would like to point out that it was difficult to reference well data to map correlations. Would it be possible to clarify this situation? II

The DEIS states that the TDS concentrations predicted for the spoils aquifer should be suitable for livestock watering in emergencies. Isn't this in violation of the States duty to protect the hydrologic balance of a water system? JJ

The DEIS discusses the dilution of TDS in spoils over time. What sort of time frame is being discussed? Was the February 1982 VAn Voast Open File report on spoils quality included in this analysis? If more data was available, would it be possible to better predict the dilution effect on spoils water quality? KK

The DEIS states that flood irrigation downstream from the town of Colstrip would be little effected by Area C, Block I mining. Would the effect from mining Block II be similar? More importantly, did the model used predict the effect on flood irrigation from all the cumulative(life of mine) impacts and all Colstrip related industrial facilities? LL

The DEIS concludes that "the cumulative surface water impacts from mining are insignificant" This statement seems to ignore the relationship between surface and groundwater systems. We take particular exception to the statement that "any cumulative impact on stream quality would be insignificant.....Groundwater inflow to the streams from the valley fill during low flow conditions would be the same and slightly more concentrated that at the present.....and not distinquishable from the present variation in stream quality". (DEIS III-25). Does this statement apply to stream quality before mining and industrial development began? Also, why does this conclusion differ form those of the DEIS and FEIS on Area E, not only in area E, but from proposed mining in areas B & D? Finally, does this statement reflect the effets of all the mining and industrial related facilities on Cow Creek Armells Creek and other drainages in the area? MM

Exhibit 3

FF. Please refer to response to comment MMM. No, OSM and DSL do not concur that Section 82-4-222 (1) (L) MCA is not presently being complied with.

GG. The significance of deeper aquifers as water producing units will increase. It has determined that the lower aquifers can support the increased stress. Increased costs are discussed in Chapter III.a. of the FEIS.

HH. Lower and deeper are used synonomously.

II. The water quality of the Sub-McKay aquifer is of suitable quality for domestic use. We are sorry it is difficult to locate well locations on the map but the map scale make this problem difficult to rectify.

JJ. This statement was incorrect in the draft EIS and has been changed in the final. While groundwater of the East Fork Armells Creek and Stocker Creek would have a higher TDS concentration after mining it would still be suitable for liveatock purposes as indicatd by water quality criteria for livestock.

KK. Any attempt at predicting a return to premining water quality would be extremely speculative. The Van Voast report was reviewed prior to preparing the Final EIS. The Final EIS discuases the length of time for return to premining water quality conditions (Chapter III, Hydrology).

LL. Only known quantifiable impacts were evaluated. These include, the surge pond, fly ash ponds, power plant ponds, aewage effluent, and changes in discharge due to mining. Existing water levels were used in the model which reflect effects of irrigation.

MM. The statement is made based on several items; the analysis of surface water quality data from East Fork Armells Creek above Colstrip although there have been very few flow events in the upstream portion of the creek to sample. The relationship between groundwater discharge and streamflow was included in the analysis as well as a review of groundwaier quality in wells that are now between mined areas and surface drainages.

To some degree, this applies to premining conditions, however, there is little data to form a pre-mining base since mining has been going on in the area since the 1920's. This statement doea not differ from the Area E EIS for cumulative surface water impacts.

Refer to response in paragraph LL.

AIR

What restrictions, if any, does Colstrip's being a "non-attainment" are have on mining development at the Rosebud Mine? NN

The DEIS states that "the projects" TSP would not effect the Northern Cheyenne Indian Reservation (DEIS III-38) Does this apply just for Area C or for the likfe of mine and all related industrial facilities? OO

SOILS

Would the changes in the soil moisture regimes and run-off conditions lower the agricultural productivity of the area? PP

What kind of plant pathogens might "attack" stored reproductive plant parts? QQ

The DEIS state that "bulk densities are impossible to predict" Is this always the case? Can problems created by high bulk densities be mitigated at a later date? RR

CHEMICAL IMPACTS

The vague statement concerning the frequency or quantity of trace elements (DEIS III-47) illustrates the necessity for aquiring more data. Would more data collection enable more to be said about the location, frequency and quantity of trace elements that may be found in the overburden? SS

The proportion of loamy and clayey soils in Block I as compared to Block II is noted on III-50. However this comparison raises more questions that it answers. Why weren't more direct comparisons made between the impacts expected from Block II and Block I ? TT

WILDLIFE

The Block II mining plan would destroy the sandstone cliff eagle and prairie falcon nesting sites and two sharp-tailed grouse dancing grounds. Does the State propose to selectively deny these areas? Furthermore, would the mining in Block II constitute a "taking" as defined in 16 USC 668a ? UU

CULTURAL RESOURCES

Has a mitigation plan been submitted for those sites found to be eligible for the National Register? Can the State issue a permit until such a plan is submitted and approved? VV

ALTERNATIVES

The DEIS states that policy dictates that the department must either approve or deny an application.....within 240 days of receipt of a "complete application". Would the State please define what they interpret a complete application to be? Does the State have any guidlines or time limits to determine when an application must be complete, or could the process of sending deficiency letters continue indefinitely? WW

Exhibit 3

Russ Brown (Cont.)

NN. Due to the fact that the Area C operation is located partially within a non-attainment area, the application of Lowest Achievable Emission Rate (LAER) must be applied. LAER generally refers to the most stringent air pollution emission limitation achieved in practice by similar sources. The effect of this requirement is that the emission control limitations placed on the Area C operation are more stringent than would be the case if the operation were located in an attainment area. The Air Quality Bureau (AQB) has deemed the emission control technologies and practices to be utilized in Area C to constitute LAER. The specific control requirements are discussed in the Western Energy's Air Quality permit application and in AQB's air quality permit analysis.

OO. Just for Area C.

PP. Page III-50 of the DEIS discusses the expected effects of mining on water availability and on the agricultural (crop) potential of the proposed distribution of various textural classes of soils in the post-mining landscape. Other changes that could adversely affect post-mining soil moisture conditions, such as increased runoff and reduced infiltration, include loss of soil structure and soil apoil compaction due to equipment handling and traffic. These latter changes can be reversed or mitigated by sufficient vegetative development and subsequent organic matter accumulation in soils by ripping or scarification of soil/spoil materials, and by handling soil materials during relatively dry periods of the year when compaction can be expected to be minimal.

QQ. Several kinds of pathogens may attack stored reproductive parts, including certain species of bacteria and fungi.

RR. The actual statement in the DEIS is "the areas in which increased bulk denaities are likely to occur are impossible to predict due to...." (Please see paragraph 2 on page III-46.) Problems created by high bulk densities could be mitigated after topsoil placement and initial seeding. This could be done by a deep ripping implement or "subsoiler." Complete reseeding would probably be necessary following such a treatment.

SS. Additional data collection could give OSM and DSL more information concerning the trace elements in overburden. However, your question regarding trace elements is associated with the overall question of overburden sampling pattern and intensity which is discussed in response to comment CC.

TT. Significantly less information is available for the specific actions proposed for Block II, because it waa not included in the existing permit application for Area C.

UU. OSM and DSL do not propose to firmly resolve these Block II mining problems until such time as an application is received showing whether or not WECO proposes to mine the nesting sites and dancing grounds. A selective denial decision will be made by the State after a permit application is received. The statutory provisions you cite (16 USC 168a) applies to the taking of bald and golden eagles and their nests for scientific, cultural and religious purposes etc. and establishes a permit system for such uses. A 1978 amendment to this law allows the Secretary of Interior to permit the taking of golden eagle nests that interfere with resource development or recovery projects. A decision regarding WECO compliance with this law as amended may have to be made by the Secretary when the Block II application is reviewed.

Were any other studies other than the Pacific Northwest Utilities Conference Committee Report (PNUCC) of 1981 utilized in the DEIS alternative energy section? This forecast estimates a load growth of 3.2% annually. The credibility of PNUCC's projections are dubious at best since they have been steadily revised downward since 1977. In fact, the 1982 PNUCC forecast uses a projected growth rate of 2.1%. } XX

It is disappointing to see an EIS gloss over the basic assumptions that will justify the need for Area C and future mining at Colstrip and the vicinity, namely the energy demand forecast. Lower energy demand growth due to price-induced conservation has caused the deferment or cancelling of power plants such as WPPSS 1,4 & 5, Creston 1-4, Pebble Springs 1 & 2 and the deferment of Montana Power Co's own Resource 89. } YY

It is foolish to merely write conservation off. The Northwest Electrical Power Planning and Conservation Act mandates the use of all cost-effective conservation prior to any thermal development. In fact, the "Model Electric Power and Conservation Plan for the Pacific Northwest" developed by the Northwest Conservation Coalition concludes that no further power plants will be necessary until at least the year 2000. } ZZ

Will the final EIS reflect more realistic demand scenarios? This would necessitate the use of up to date forecasts and a broader spectrum of independent forecasts. We suggest that the analysis done by the Washington State legislature on regional energy needs and WPPSS 4 & 5 might be a good place to start. } AAA

The DEIS is unclear concerning the "pit realignment" proposal and the Block II mining plan. Are they different proposals? Are both dependent on Federal leases? } BBB

We would like to request that the following stipulations (at a minimum), be required prior to the issuance of a strip mine permit for Area C. } CCC

* That selective handling of the material with significant trace metal content be undertaken to insure that it will be kept below the top ten feet of spoils. Does DSL propose to stipulate this?

* Does the DSL propose to have WECo or ERTECH do more mapping of the faults to insure that maximum recovery of coal is achieved and to further the understanding of hydrology in the area? } DDD

This DEIS is supposed to include in its analyses all the activities that might have an effect on groundwater in the area. Isn't the statement on p. IV-10 6. a. then in error? If it was determined that the cumulative impacts of mining and industrial related activities would irreperably damage the hydrologic balance of a water system, could DSL limit or deny a permit based on the combined effects of mining and the industrial complex? We submit that they do have the authority. } EEE

VV. WECO's consultant is now preparing a mitigation plan for those sites in Block I determined to be eligible for the National Register of Historic Places. Approved mitigation plans not eligible have been mitigated already by virtue of their thorough recording. Permit approval is not contingent upon completion of mitigation. Stipulations will be added to the permit if necessary.

WW. With regard to the statutory provision of making a permit decision within 240 days of the receipt of a complete application, DSL defines a complete application to be one that has all of the necessary data and other information to determine whether or not the company's mining and reclamation plan complies with all the requirements of the Act and DSL's rules adopted pursuant to the Act. DSL interprets the act to require that an application completeness decision be made within 240 days of the receipt of an application or application revision. DSL's goal is to send a letter (regarding completeness) within 60 days of the receipt of an application or application revision. The process of sending deficiency letters potentially could go on indefinitely or the Department could deny the permit on the grounds that the application is incomplete, this requiring the company to reapply.

XX. Yea, one other used was the Bonneville Administrations Forecase of Electricity Consumption in the Pacific Northwest 1980-2000 (Division of Power Requirements, Draft 1982). The rest of your comment is noted.

YY. Your comment is noted. Regardless of the accuracy of any specific energy demand forecast, Montana Power Company and others have contracted to purchase the Area C coal.

ZZ. Your comment is noted. Area C coal is dedicated to generating Units 3 and 4.

AAA. Because Western Energy has a long term contract (35 years) with Montana Power for coal from Area C electricity demand in the Pacific Northwest would not affect ultilization of Block I coal. Additional analysis of demand scenarios would therefore not add substantively to the environment statement.

BBB. Mining of Block II would require that Western Energy realign its pits in Area C, Block I. Plans for realignment would be submitted as part of Western Energy's Block II mine plan application which is dependent upon the issuance of a new federal coal lease.

CCC. This is required by law and addressed in WECO's application. As such it would be redundant to make it a permit stipulation.

DDD. If the Department finds upon further investigation that faulting would interfere with Western Energy's dragline operations and the recovery of coal, it would require further mapping by Western Energy. Although the faults are inferred, Western Energy data does not indicate a situation of faulting (or folding) exists that would result n coal being left unmined within the Area C, Block I permit application area.

EEE. The authors find no error with the statement that Area C will affect the existing hydrologic environment. It if was determined that the cumulative impacts of mining at Colstrip would damage the hydrologic balance to the degree of impairing or irrepuably damaging beneficial use DSL could limit or deny a permit. Industrial activity at Colstrip was included in the long-term hydrologic baseline to which the impacts of coal mining were added.

* Does the DSL plan on requiring WECo to reclaim the aquifers that are destroyed by mining? Do they have the authority to make this kind of condition? } FFF

* Does the State propose to stipulate that chisel plowing techniques be employed? } GGG

* The DEIS states that several soil mitigation measures could be employed. Which of these will the DSL insist on? } HHH

* What techniques or stipulations will the State be requiring from WECo to offset piping and other possible settling problems? } III

CONCLUSION

The DEIS for the Area C, Block I mine permit application is inadequate as adecision making document or as a planning tool. } JJJ
The paucity of data on hydrology speaks for itself. We are also deeply concerned with the EIS's brief review of the effects of the "pit relignment" or the Block II mining plan. What will be the effects of Block II on Armells Creek? In the Block II proposal wouldn't WECo be mining right across the creek? } KKK

The whole discussion on the impacts of mining on water qaulity and quantity is rendered meaninjless by the lack of data and the omission of the effects of all the industrial facilities. Until this data gap is closed the mining permit submitted by WECo has not complied with Section 82-4-222(1)(l), and the State may not approve this application until the requirements of 82-4-223(3)(a) are met. This has not been done. } LLL

We thank you for the opportunity to comment.

Sincerely,

Russ Brown

Russ Brown
NPRC Staff

encl/prb

FFF. DSL's Rule 26.4.642 (2) for the Strip Mine Act states that "Backfilled materials shall be placed to minimize adverse effects on groundwater flow and quality to minimize off-site effects, and to support the approved land use ..." DSL has determined that the mine plan submited by WECO is in compliance with this rule.

GGG. Western Energy has proposed to chisel plow the replaced soil as indicated in the 2nd full paragraph on page 1-14 of the DEIS.

HHH. The only soils related measure that DSL is considering requiring in addition to those proposed in WECO's mining and reclamation plan is:

"Western Energy Company shall submit a plan for reestablisiment of plant rooting zones which are compatible with the intended post-mining plant communities. The plan must take into account plant rooting composition and condition (26.4.711)."

III. The Department is not proposing any specific messures at this time to prevent possible piping or settling problems. WECO would be required in the normal course of operations to monitor, regrade, retopsoil, and/or reseed areas that are subject to these occurrences. Please see the response to Nick Golder's comments J and L for further discussion of this subject.

JJJ. Your comment is noted.

KKK. The effects of mining Block II on East Fork of Armells Creek has been addressed in the cumulative hydrologic impact section of the FEIS. A detailed analysis of Block II impacts on East Fork of Armells Creek will be made when Western Energy submits its Block II mine plan. Western Energy mine Block II would mine through East Fork Armella Creek.

LLL. Your comment is noted. Please see resonse to comment D.

NPRC AREA C Comment

APPENDIX B MMM

The following section is intended to highlight the sections of the hydrologic study about which no comments can be made or conclusions reached due to a lack of data. Western Energy and Hydrometrics have repeatedly stressed the number of hydrologic data points that are already on record. It is apparent that the location and quality of these data points are inadequate.

We would appreciate a response as to what is being proposed for each of the following areas to provide the information necessary to make a cumulative hydrologic analysis of the Rosebud Mine area.

* The DEIS notes that in some areas, the overburden includes clinker, which is usually brittle and highly fractured. According to Dollhoph (1978), fracturing in the clinker creates potential areas groundwater recharge or discharge. However, there have been no aquifer tests in the clinker at the Rosebud Mine to confirm this postulate. (DEIS II-16) } 1

* Available information indicates that the sub-McKay is a confined aquifer system, however very little hydraulic data exists for the sub-McKay. (DEIS II-18) } 2

* "VERY LITTLE HYDRAULIC DATA EXISTS FOR AREA C" (DEIS II-19) } 3

* The DEIS points out that "the McKay Coal and the Rosebud McKay interburden Area C hydraulic characteristics can not be compared to the hydrologic study area test results because only one aquifer test was performed in each aquifer. (II-19) } 4

* There seems to be some confusion whether the groundwater in the Rosebud spoils is confined or unconfined. "The groundwater in the spoils is generally unconfined; however, it should be noted that there is evidence to suggest that spoils water may be confined in some areas" (II-20). Would more data enable a more definitive statement to be made? } 5

* The DEIS notes that "there is not enough water level data for the Rosebud overburden to construct an accurate potentiometric map for the overburden.....The source of water in the overburden is probably due to direct infiltration from precipitaion, but may also be due to upward leakage from the Rosebud coal (II-22) } 6

* The DEIS also admits that "As with the Rosebud overburden, the nature of flow in the Rosebud/McKay interburden has not been well defined" (II-25) } 7

* The DEIS points our that "although a large percentage of wells are completed in the sub-McKay unit there is little specific data on the nature of the groundwater flow." (II-25) } 8

Exhibit 3

Russ Brown (Cont.)

MMM. Appendix B

1. As discussed previously, the clinker occupies areas of groundwater discharge in the Rosebud mine area. Because of this and the Department's experience with clinker in other mines, it was not thought necessary to require aquifer tests in clinker in the Rosebud Mine area. They would not significantly enhance the understanding of the hydrology of the area.

2. Available information indicates the sub-McKay is adequate for development as an alternative groundwater source once the Rosebud coal is mined. Since this is the only foreseeable use of the sub-McKay, and since Western Energy has committed to replacing any water supply destroyed by mining, it was felt that no additional data was necessary to characterize aquifer characteristics of the sub-McKay.

3. This phrase was deleted from the final EIS. The Department feels there is sufficient data available to characterize the hydrology of Area C.

4. Although there is insufficient data for a statistical analysis, the Department feels there is sufficient data available over the mine area. To characterize the McKay coal and Rosebud-McKay interburden. These characteristics are relatively uniform over the mine are and additional data collection was not deemed necessary for the permit decision.

5. Whether the groundwater in the Rosebud spoils is confined or unconfined depends on a number of factors: 1) the texture and lithology of the spoils, 2) the thickness of the spoils, 3) the proximity of the outcrop area, and 4) the location of the monitoring well with respect to rubble zones in the spoils. It was not considered necessary to have a detailed understanding of the confined versus unconfined nature of groundwater in the spoils when so many factors can affect that aquifer property.

6. Due to the extremely discontinuous nature of lithologic units within the overburden, a representative potentiometric surface map cannot be constructed. Because textures and lithologies display rapid lateral and vertical variation, it would be impossible to drill sufficient wells to characterize and delineate each individual unit. The recharge capacity of the reclaimed spoils will approximate the recharge capacity of pre-mining conditions.

7. The lithologic units comprising the interburden are highly discontinuous and generally fine-grained. Because of this, the construction of a representative potentiometric map is not possible (see answer to 6 above).

8. Most of the wells completed in the sub-McKay are domestic or stock wells for which water level and aquifer test data are difficult or impossible to obtain. Because of well construction and the fact that the wells are generally pumped frequently, accurate water level data are not available. The large number of wells completed in the sub-McKay is indictive of its viability as a groundwater resource.

* What do all the questionmarks on Figure II-19, p. II-DEIS refer to? } 9

* The following statement is indicative of why this permit cannot be granted until much more data is gathered and analyzed. "as an area of groundwater recharge, Area C ultimately contributes to flow in tributaries to Rosebud Creek. A paucity of hydraulic and hydrogeologic data specific to Area C, and Area C Block I precludes a more detailed comparison between groundwater flow in Area C and the study area as a whole. (DEIS II-33) } 10

MMM. Appendix B (Cont.)

9. We think you are referring to Figure II-9. The question marks are inferred locationa of the potentiometric aurface and fault planes in the McKay and Roaebud Coal aeams.

10. While it ia true that groundwater from Area C ultimately contributes to flow in tributariea to Roaebud Creek, available data indicates that thia component of flow ia inaignificant compared to that contributed from other recharge areas.

Exhibit 3

JUL 8 1982

STATE LANDS

COMMENTS ON THE DEIS FOR WESTERN ENERGY'S ROSEBUD MINE, AREA C Letter No. 13

It is good to see the progress that has been made by Western Energy in the area of revegetation. I wish there was reason to feel encouraged about progress made in the area of hydrology.

It seems reasonable to assume that landowners down-gradient from a mine should be able to expect no significant change on their property regardless of what their upstream neighbors' business happens to be. If, due to mining, there is a change in water quantity, quality or placement outside of the mine's boundaries, then this becomes a case of tampering with property belonging to someone else. I assume the State does not intend to be supportive of violating property rights as a matter of course. Is that assumption correct? This draft EIS seems to indicate a lack of concern for what impacts mining might cause on the land downgradient from the mine. A

The DEIS points out that mining will deteriorate spoils water to about double the normal TDS concentrations (pg. III-11). Pg. III-15 says the high concentration spoils water will migrate further with time and the estimation is that it will migrate about one-third mile per year. I saw no estimate on whether it would take decades, centuries or eons to flush out the spoils leachate. I did not see any mention made of what effect the leachate would have on the down-gradient property, especially where the water comes near enough to the surface to deposit the dissolved solids when the water evaporates. What is the scenario you predict on this? B

I found no mention of provision to improve the quality of the polluted water recieved by down-gradient neighbors, nor is there mention of compensation to them for detrimental changes on their property. What is the State's thinking on this? C

The section on cumulative impacts on pg. III-25 only touched on one corner of cumulative impacts of good and bad water due to mining. Nearly all of the water storage ponds at Colstrip are there because of the mining. Without mining those ponds would not be there. Therefore it seems to me to be an exercise in semantics, rather than objective assessment, to say "surface water hydrology impacts from mining are insignificant." Leaking and draining storage ponds have to be a very significant part of the water quality and quantity problems that are now apparent. To omit such major sources of surface and underground water in the Colstrip area's environment certainly does not lend an aura of credibility to an environmental impact statement. D

There also has been a tendency to address water quantity separately from water quality. I recommend you employ some "general practitioners" that are equipped to take an overview of the whole issue. The too-narrow scope of the "specialists" allows insufficient perspective to arrive at a cumulatively total picture. DSL personnel have said there has to be a cumulative hydrologic assesment done of the whole mining complex before another permit is issued. The word "cumulative" speaks to me of adding together the total, not discussing isolated parts of the total. E

I saw no mention in this DEIS of the existing and proposed fly ash (or sludge) ponds, although in years ahead they are very likely to emerge as the most dangerous part of a hydrologic time bomb. Unless there has been a recent change, there are not nearly enough monitoring wells to keep track of the underground movement of the toxic water that has to be radiating out through the porous soils at the existing fly ash pond. Perhaps the estimation of one-third mile per year (pg III-15) might be plugged into this case also. However, it seems reasonable to assume that the velocity would vary considerably depending on slope, type of soil, existing water channels, etc. What are your plans to correct problems with this toxic water before it spreads further? F

The proposed fly ash pond on the Cow Cr. drainage has the probability of causing more long term damage than the existing fly ash pond can be expected to cause. The aquifer water that makes Cow Cr. a subirrigated creek could be expected to carry the toxic seepage away from the pond area and on downstream quite rapidly. Additionally, the MPC plan wherein vegetation would be left in place in the bottom of the pond would, according to my experience, increase infiltration of that toxic water into the soil. What is your assessment of this plan?

Condition 12d of the DNRC Board order of July, 1976 says that sludge ponds shall G

Exhibit 3

Nick Golder

A. The Montana Strip and Underground Reclamation Act contains numerous safeguards designed to protect downstream property owners from the effects of surface coal mining. The Department of State Lands must enforce such safeguards or is subject to a suit of mandamus. The state does not intend to violate property rights.

B. A discussion of how long it takes for spoils water quality to return to premining conditions has been added to the FEIS (Chapter III, Hydrology).

C. Project water quality changes downstream for Colstrip are not anticipated to be detrimental to the present or future users.

D. All cumulative hydrologic impacts of mining in the Colstrip area are addressed in the FEIS. The most severe water quality roblem at Colstrip is that cussed by the surge pond. Water quality deterioration from power plant pond seepage is also addressed in the FEIS.

It was not the author's intent to play with semantics relative to "mining" and "non-mining" affects. The FEIS assesses the hydrologic influences of the actual mining rocess as well as the effects of other activities which are related to mining such as the fly ash and surge ponds, etc.

E. Chapter III, Hydrology 1. Groundwater of the FEIS describes the groundwater model used to characterize the hydrologic system. Included is a description of the modeling concepts and inputs used by the researchers.

F. OSM and DSL appreciate your concern relative to both the existing and proposed fly ash ponds. These issues have been dealth with in the final EIS within the impacts secion, Chapter III, Hydrology. In brief, the data indicassaate that the existing fly ash pond is leaking only a very small amount but if it were leaking large quantities of fluid, the water would move downgradient into the surge pond where dilution would mask the contamination. With respect to the proposed fly ash pond, Montana Power Company proposes some specific mitigation measures to prevent fly ash pond contamination from entering the Cow Creek alluvial system. The FEIS addresses what the impacts on Cow Creek water quality and land use would be if maximum leakage from the proposed fly ash pond occurred.

G. To reiterate, the Montana Power Company is proposing mitigating measures with respect to the proposed fly ash pond. It is true the vegetation left in place within the pond prior to filling would result in a higher initial seepage becaus the plant roots could provide vertical conduits for flow. It is also true that the nature of fly ash ponds is to seal themselves over time. This is the probable reason that no contamination or evidence of leakage exists downsgradient from the existing fly ash ponds.

be completely sealed, including a plastic membrane if necessary. There has been a lot of semantic gymnastics about this particular issue, but the long-term effects of this are far too serious to play games with now. Does DSL have plans of how to handle this toxic seepage as per DNRC's condition? H

The horse appears to already be out of the barn on the existing fly ash pond. That toxic material has been radiating out for some time. It is imperative that properly located monitoring wells be drilled at various down-gradient locations and that mitigating measures be taken as soon as possible to keep the toxic material corralled as much as possible. I

In the last sentence on pg. III-18 I notice the word "reclamation" is used where it seems "revegetation" would more accurately describe the situation. In the previous paragraph is brief mention of subsidence or differential erosion at the highwall interface. I expect it would be very fortunate if it only occurs there, but I do expect it to be worse along the pit walls. This is an important factor to be considered in reclamation, but is seperate from revegetation itself. J

On pg. III-19 it says that with time the spoils will settle to a density similar to the pre-mining density. This seems quite reasonable. It is as used there will be a 22% swell factor in the spoils. Does this mean it will settle 22 feet per 100 feet of backfilled pit by the time settling is completed? Do you expect differential settling as is so common with fill dirt in non-mine situations? If not, why not? Do you expect spoils to settle to pre-mining density within ten years? K

What mitigating measures do you have in mind where you anticipate possible subsidence, differential erosion or piping? Do you anticipate any possibility of areas becoming too unstable to be safe to drive machinery over? L

It seems to me that true reclamation should be a composite of three things: stable, self-sustaining vegetation; stable, unpolluted aquifer water passing across the minesite and continuing on as it has done for centuries with the surface water handled similarly; and the soil stabilized so that subsidence and piping are not problems, and erosion is no greater than in centuries past. If there is a decision to accept less than this, then that decision should be common knowledge so that the American people have a better idea of the true costs of stripmining. M

Nick Golder

Nick Golder
Forsyth, MT

Exhibit 3

H. Regulatory responsibility for proper design and construction of the fly ash pond lies with the Montana Department of Natural Resources and Conservation. We concur that the fly ash pond needs to be properly constructed and that the potential for adverse impacts resulting from leakage could be very real if proper construction and mitigation measures are not invoked.

I. A very small amount of seepage and contamination of groundwater is occurring from the existing fly ash pond. This contamination is not affecting and will not affect any groundwater users. The level and type of contamination occurring is not classified as toxic. There are existing monitoring wells down gradient of the fly ash pond. The wells indicate only a minor amount of seepage.

J. Your comment is noted. We agree that subsidence would occur along the spoils/bedrock interfaces of the end (pit) walls however we do not feel the problem would be any greater than along the highwall. Western Energy would be required to correct any subsidence problems that arise during the bonding period. Because there are presently no predictive methods available to evaluate potential for subsidence it is not possible to determine the amount of subsidence to be expected in an area of spoils replacement.

K. The 22 percent swell factor is a volumetric measure not a linear measure. The actual linear settlement is not predictable. Refer to the Geologic Hazards Section, Chapter III of the FEIS, for discussion of the settlement issue. Density reestablishment cannot be predicted.

L. Mitigation measures to treat subsidence problems would be applied at the time problems occur. In some cases, areas where unusual subsidence is anticipated, special compaction techniques could be used to reduce the changes of subsidence. Once subsidence occurs the effected area would be regraded, topsoiled and reseeded. In some cases, topsoiling and revegetation might be delayed temporarily to allow for complete settling before topsoil is spread.

M. Your comments are noted. The criteria you list are all standards by which the Montana Department of State Lands and OSM will use to determine whether or not coal mine reclamation is successful.

July 6, 1982

Kit Walther
EIS Team Leader
Department of State Lands

JUL 10 1982

Dear Kit:

After reviewing the draft environmental impact statement (EIS) for Western Energy Company's Area C Colstrip Mine for possible air, water and solid waste disposal impacts, the Solid Waste Management Bureau (SWMB) had the following comments:

The draft EIS indicates all wastes will be collected and disposed of in the Rosebud County landfill at Colstrip. The draft doesn't say what kinds of wastes these will be. The current license conditions prohibit semi-liquids, liquids and hazardous wastes. The present general contractor maintains an unlicensed disposal site somewhere in the Colstrip area by claiming the exclusion in Section 75-10-214 MCA. SWMB has no information as to what types of wastes are disposed of at that site.

In summary, the proposal for solid waste disposal presented in the draft EIS appears adequate, but the SWMB needs the following information to fully evaluate this adequacy:

1. Specifically what types of wastes will be generated and disposed of in the Rosebud County site. } A

2. Detailed location of the Bechtel disposal site and specific description of the materials to be disposed. } B

Thank you for the opportunity to comment on the impact statement.

Sincerely,

Thomas M. Ellerhoff
Technical Writer

jg

Exhibit 3

A. Wastes associated with mining are disposed of in accordance with sections 26.4.505 and 26.4.507 of the Montana Department of State Lands rules adopted pursuant to the Montana Strip and Underground Mine Reclamation Act and the Western Energy Company Area C, Block I application indicates that they will comply with these rules. Mineral seams are required to be buried under a minimum of 4 feet of the best available non-toxic, non-combustible materials. Also acid forming, toxic-forming, combustible or any other waste material identified by DSL, that are exposed, used, or produced during mining must be covered with a minimum of 8 feet of the best available non-toxic, non-combustible material.

Non-coal wastes include, but are not limited to, grease, lubricants, paints, flammable liquids, garbage, abandoned machinery, lumber, and other combustibles generated during mining activities. These materials are required to be placed and stored in a controlled manner in a designated portion of the permit area. Placement is required to be done in such a manner as to ensure that: 1. leachate and surface runoff do not degrade surface and groundwater, 2. fires are prevented, and 3. the area remains stable and suitable for reclamation. Western Energy has indicated that liquid, semi-liquid and hazardous wastes will not be disposed of in the Rosebud County landfill and that most, if not all, of the liquid and semi-liquid waste are reprocessed (personal communication with Chris Cull, Western Energy Co. on 7/23/82). The Western Energy Company's Rosebud Mine Complex does not generate hazardous wastes.

B. Because the DSL does not permit Bechtel for the construction of Generating Units 3 and 4, information regarding Bechtel's disposal sites was submitted to DSL as a part of Western Energy's permit application. Bechtel claims exclusion from permitting of this site on the grounds that they are disposing of their own wastes on their own property. The Montana Department of Natural Resources and Conservation has indicated that under the Unit 3 and 4/Conditions of Certificate issued to MPC no restrictions have been made on Bechtel or MPC for waste disposal.

JUL 21 1982

Mr. Kit Walther
EIS Team Leader
Montana Department of State Lands
1539 11th Avenue
Helena, Montana 59620

Dear Mr. Walther:

We have completed our review of the draft environmental impact statement for Western Energy Company's proposed Area C coal mine near Colstrip, Montana. The EIS appears to be complete and well written.

We suggest that the EIS more clearly state that modeling indicates that the mine neither causes nor contributes to a violation of Montana nor National Air Quality Standards. The mine is located in a "clean" part of the non-attainment area. A

The mine appears to meet applicable state and federal water and reclamation standards. This would depend, of course, on the issuance of necessary permits by the various state and federal agencies.

As stated in the EIS, the larger and regional impacts in the long-term Western Energy mining plan will be covered under a separate EIS process.

According to EPA's rating system for draft impact statements, this EIS is rated LO-1 (lack of objections - sufficient information).

If you have any questions, please contact Mr. Gene Taylor in our Montana Office, Helena, at 449-5486.

Sincerely yours,

Steven J. Durham
Regional Administrator

Steven J. Durham

A. A square area 18 kilometers by 18 kilometers, centered on Colstrip, has been designated "nonattainment" for TSP. The Area C mining operations are bisected by the boundary of this area. However, all the high measured concentrations within this NA area are located in a much smaller area, far away from the proposed mining operations. As the EIS states, the impact of the project on the area of high measured concentrations (town of Colstrip) is negligible. However, it is incorrect to state that the impact of the project on the nonattainment area is negligible. From a regulatory standpoint, all portions of the nonattainment area are accorded equal protection from further degradation. The comprehensive EIS will expand upon the current and future TSP levels in and around Colstrip. The Area C project is exempt from nonattainment review, therefore no action to redesignate the Area C mining area to an attainment status will be made -- but it is precisely such an action which would be necessary to treat the "clean areas" of the nonattainment area any different from the areas truly violating the NAAQS.

RE: Comments on Draft Environmental Impact Statement -
Western Energy Company's Rosebud Mine, Area C, Block 1

Dear Mr. Walther:

On behalf of the Colstrip Project, Montana Power Company has the following comments on the Draft EIS for Area C, Block 1, Rosebud Mine:

1. Pages II-30 and II-33 of the Draft refer to "leakage" from the Colstrip Project surge pond. The term used suggests an unexpected or accidental movement of water, but in fact, seepage up to about 112 gpm was fully anticipated and specifically authorized by the State Board that permitted the facility. Recent indications suggest the actual seepage from the surge pond is less than this amount. } A

2. Figure II-12 depicts a cross-section across the surge pond but omits the subsurface concrete cut-off wall in place in each abutment. This wall is a major seepage reducing measure. } B

3. As depicted by Figures II-11 and II-12, the surge pond is located over valley fill material. In fact, the surge pond is generally underlaid by bedrock. Only a small strip of valley fill material or alluvium underlays the pond. } C

4. The section on noise (page II-69) should include the noise mitigation efforts of the Colstrip Project. Stack noise silencing or muffling equipment has been installed on Colstrip Unit #2 and is planned for installation on Unit #1. Silencer equipment has been purchased for Colstrip Units #3 and #4. When all four } D

D. T. Berube

A. The influence of the surge pond is discussed in the EIS. The terms leakage and seepage were considered to be synonomous.

B. Your comment is correct. The graphic was intended as a rough schematic.

C. Your comment is correct (see above).

D. Your comment is noted. The authors, who obtained information on stack noise silencing equipment from the Becthel Corporation, were notified in writing by the Western Energy Company that the Montana Power Company considered such data confidential. Thus all references to this data were deleted from the EIS.

Exhibit 3

units are operating at full load, Montana Power Company expects that the noise level at the property boundary will not exceed about 50 dBA.

Sincerely,

D. T. Berube

Letter No. 17

JUL 07 1982

Mr. Joe Walther
Team Leader
Montana Dept of State Lands
1539 11th Avenue
Helena, Mt 59620

Dear Mr Walther,

In reading the draft EIS for Western Energy Company's proposed Area C coal mine near Colstrip, Mt. I would like to comment on the damage to the lower lying sub-irrigated areas along the East Fork Armells Creek on my ranch 6 to 10 miles downstream from Colstrip.

It appears that the EIS was careful not to include these areas in its study other than a casual statement or two concerning possible problems downstream. } A

My ranch has probably suffered more damage than all the studied areas put together, because all the waste water, seep water, mine water, and sewage disposal water eventually piles down on the ranch which has the low lying hay meadows and a creek channel not deep enough to carry this water without raising it so close to the surface that the meadows are swamping up and are now heavily alkalied.

This summer once again my higher-lying meadows and benches have a decent hay crop, and the lower lying meadows produce just weeds and foxtail due to damage from the Colstrip Complex's water.

Your corrected Table III-3 of June 7, 1982 shows an anticipated 45% increase in the East Fork Armells Creek from 1983 to 1987. I absolutely do not know what to do with the presently expanded water much less a 45% increase by 1987. } B

I ask you not to gloss over my damage but to study these areas downstream where heavy damages are found and are certain to be increased by the added water from Area C. } C

Thank you

Sincerely,

J.R. Lee

Exhibit 3

J.R. Lee

A. Thank you for your comment. Please see the cumulative hydrologic impact section, Chapter III, Hydrology in the Final EIS for coverage of the referenced areas.

B. The 47% increase in flow in East Fork Armells Creek was incorrect because of a technical error in data input to the model. Because of the data input error, groundwater was allowed to discharge to the creek that was actually flowing in the aquifers below the creek. Within the model, nodes (data points) located along East Fork Armells Creek were allowed to discharge groundwater to the stream or the valley fill system if the bedrock aquifer water level was above the stream bed. It happened that a portion of three of these nodes were also mining and spoiling locations. After the node was spoiled it was not reset as a creek discharge node. The effect of this was to cause the node to have a constant water level assigned to it without stream discharge. The flow through the node below the creek bottom was therefore inadvertently added into the stream flow component. In reality the number was bedrock flow and not stream flow.

Because of this error, each of the 9800 nodes was individually checked to make sure that the same type of error was not occurring elsewhere. Additional quality assurance checks involving location, extent and elevation of mining nodes were also performed so that the Department of State Lands and its contractor could be certain of the model being free from data input errors.

C. See response to comment A above.

AREA C PUBLIC HEARING COMMENTS

June 14, 1982

Nick Golder:

I'm Nick Golder and I'm here representing Rosebud Protective Association. I really don't have a whole lot to say. I got my copy of that thing last Thursday or Friday and so far I've read about six pages in it and with the exception of two of our members why we just simply haven't had a chance to look at it so I guess we'll have to basically put in written testimony. I would like to say that what I hear of it why, what little I've read into it, I'd like to comment that we were told that before any further permits were issued there would be a cumulative hydrologic impact assessment done on the whole mine area here and I have the impression that it has not been done. We're concerned about the off-site hydrologic impact, off the mining area and we're very concerned about what leaks out of the Fly Ash Pond and into the subsurface and on down Armells Creek and I understand that hasn't been addressed at all in here. I think that's a pretty serious oversight. I assume you people will take care of that. I don't have anymore to say about that right now.

Nick Golder

Thank you for your comments. Please refer to the section on Cumulative Hydrologic Impact, Chapter III for discussion of off-site hydrologic impacts of Western Energy's Rosebud Mine.

Exhibit 3

Patty Kluver:

The hydrology section of this draft EIS we are addressing tonight reports there is a paucity of data concerning Area C, Block I pertaining to the hydrology. One can only ask; why? There's been ample time since the permit for plan 3 and 4 was granted to obtain baseline data for Hay Coulee, Lee Coulee, Richard Coulee, and Miller Coulee. There is only one conclusion that can be drawn from this paucity. No one, not the Department of State Lands, the State Water Quality Bureau, or the ambitious mining company obtained any baseline data for the East Fork of Armells Creek or for Cow Creek until after the mining had commenced and the ground water was degraded beyond redemption. By not establishing a baseline criteria the mine companies and various agencies of state government can find themselves in the clear when the contaminating ground water makes way through the mineral and metal laden spoils to new outlets down the syncline in the Rosebud coal vein aquifer. While that water perculating from the mine is generally unfit for domestic, livestock, or irrigation use because there is no record of how it was there is no way for the victim of the degredation to prove that the degredation is or was caused by stripmining the Rosebud coal aquifer. One has to have the facts to prove in order to make the mining company pay for its destruction. The investigative enforcement agencies of our state government failed us in that regard. It appears they are ready to repeat the past performance. Of course I understand the situation. Were it not for the stripmining of coal, many of the personnel of those departments would be in the same positions as the miners in Butte. Indeed it is a difficult role those heads in staff of the various appointed agencies of Montana government must play. The short-term advantages are with the coal industry, while the long-term story is like that of the Anaconda Copper Company and the Berkley Pit. A

Recently I obtained an article that was titled the Next Energy Crisis, with a second lead, Water, Water Running Out. The article began with this paragraph of horror. The United States has entered a period of grave crisis with both quality and quantity of its water and though that crisis is duplicated elsehwere and not only as one might expect, among the highly industrialized region it is here that it is likely to be felt with particular intensity. Yet this cherished natural resource is admittedly destroyed by the mining of the very aquifers through which it flows at the Rosebud and Big Sky Mines. To replace the loss, the coal companies attempt to reestablish an assemblence of an aquifer by throwing in the empty coal pit, the very earth which coal has been a few eons filtering out. Minerals and heavy metals are reintroduced into the ground water to flow out somewhere, to contaminate the streams, wells, and springs down syncline; as in Cow Creek. This EIS refers to the area C as a recharge area. It speaks little of the fault except to say they hamper coal mining. It is those faults through which the Rosebud vein becomes an aquifer and it is more than just an aquifer, its also a perched water table. B C

Some years ago our ranch was visited by Roger Wright and the late Overt Rye. It was in response to my complaint that mining was damaging our artesian wells east of Colstrip. Mr. Rye employed a chief geologist at the time from Montana Power Company who said the mining couldn't be

Exhibit 3

Patty Kluver

A. Montana Department of State Lands and the Office of Surface Mining have found the present data base sufficient to make a hydrologic assessment of impacts of the Area C, Block I Mine and Rosebud Mine. Analysis of baseline data has shown that groundwater quality has not been degraded "beyond redemption" and that benefitical water uses have not been impaired because of mining at Colstrip.

B. Your comment is noted. Please refer to Chapter III, Hydrology for the assessment of the significance of the impacts.

C. It is true that evidence indicates Area C is a local recharge area. Existing data and results of groundwater modeling indicates that groundwater flow is continuous across the fault zone and that the Rosebud aquifer is continuously saturated both upgradient and downgradient of the fault zone. Please refer to Figure II-9 in the EIS. There is no evidence that water in the Rosebud is a perched aquifer.

damaging. We must be 200 feet lower than the coal seam. At that time I hand't to become a student of geology and I did try to argue with Mr. Wright. If this incident were to have to have occurred today, I would respond to Mr. Wright, what do you think the water in the coal vein does? Stop at the end of the seam? There is little use in recounting the destruction of north Cow Creek at the hands of Western Energy Company. Because of them and because of the Montana Power Company pitchs for putting their solid waste disposal and other assorted disposals down syncline from their town we have the dubious distinction of having partial ownership of the first Love Canal in southeastern Montana. The reason I mention Cow Creek is because just as surely as coal burns into ash, the people along the Rosebud drainage around the bend, southwest of Cow Creek will know the decline in water supplies, the degredation of the water available that we already have. D

The DSL is obliged by law to recheck this volume and its contents because of Section 82-4-227. It reads the Department may not approve an application for a strip or underground coal mining permit or major revision unless the application affirmatively demonstrates that, part B, the proposed strip and underground coal mine operation would not interrupt, discontinue, or preclude farming on alluvial valley floors that are irrigated or naturally sub-irrigated, materially damage quantity or quality or water in surface water or underground water that supply these water floors in subsection 3 (b)ii.

In addition, on October 2, 1981, the Montana DSL sent a letter to Art Neill of Western Energy Company stating no further permits will be granted until a cumulative hydrology assessment is done. It has not been done. It has not even addressed the proposed fly ash pond on Cow Creek, estimated to leak over 54 million gallons a year into that luckless tributary to the Rosebud. May I point out the regulation 824-227-3a. Read them again and again when you consider this application. E

We have here a map which we obtained at grave financial costs. It is one like the Department of State Lands received with their first application for exploration, August 6, 1978. For some unaccountable reason, the map has disappeared from the files in Helena. If you want one, you can get it from a mining company as we did. Not only does this map show the fault extending along the north side of Area C, Block I but what the EIS calls the vertical fault or a right angle fault extends down to the south. From the description refered to in the EIS this is the site of the new county road from Colstrip to Castle Rock. Not only do my neighbors and friends travel on that little used, to quote the EIS, road but so do mining executives from Westmoreland, state officials, going from one mine to the other, so does the school bus on which my grandchildren will probably ride. You walk through this section of unmined land between Area A and B, weakened by blasting and mining on either side, that really poses the character of this company you would oversee. Of course the company doesn't have children to be concerned with, it just has subsidiaries. F

Thank you.

Exhibit 3

Patty Kluver (Cont.)

D. Your comment is noted.

E. The EIS presents a cumulative hydrologic assessment of hydrologic impacts of the Rosebud Mine. Based on modeling of surface and groundwater systems cumulative impacts were assessed for the five year permit period, life of mine and 100 years beyond. The proposed fly ash pond and its effects on Cow Creek are presented in the final draft EIS, Chapter III, Hydrology.

F. Your comment is noted.

Exhibit 3

The printing and distribution costs were paid by Western Energy Company pursuant to Title 75, Chapter 1, Part 2 MCA.

1.0 INTRODUCTION

The Montana Department of Environmental Quality (DEQ) is the regulatory authority for coal mining operations in the state of Montana. *See* §§ 82-4-203(15), 205, MCA. The state implements the Montana Strip and Underground Mine Reclamation Act (MSUMRA or the Act) which is set forth in §§ 82-4-201 through 254, Montana Code Annotated (MCA), and the administrative rules pursuant to the Act Administrative Rules of Montana (ARM) 17.24.301 through 17.24.1826. The Federal Office of Surface Mining Reclamation and Enforcement (OSMRE) implements the Surface Mining Reclamation and Control Act of 1977 (SMCRA), and has granted primacy to DEQ as the regulatory agency for coal mining in Montana. As such, DEQ is responsible for the review and decisions on all permit applications to conduct surface coal mining operations within the state with oversight from OSMRE.

This assessment of cumulative hydrologic impacts (CHIA or this Assessment) is prepared by DEQ as part of the written findings for Amendment 4 (AM4), initially submitted to DEQ by Western Energy Company (SMP C1984003B) in June 2009. It includes an analysis of anticipated hydrologic impacts associated with proposed additional mining in Area B of the Rosebud Mine (**Figure 1-1**).

2.0 REGULATORY ENVIRONMENT

Under MSUMRA, DEQ must prepare this Assessment as part of the written findings the DEQ must issue when it approves a permit or an amended permit. *See* ARM 17.24.314(5); 17.24.405(1).

In pertinent part, MSUMRA conditions approval of an application for coal mine operating permit on demonstration by the applicant that "the assessment of the probable cumulative impact of all anticipated mining in the area on the hydrologic balance has been made by the department and the proposed operation of the mining operation has been designed to prevent material damage to the hydrologic balance outside the permit area." § 82-4-227(3)(a), MCA; *see also* ARM 17.24.405(6)(c).

This requirement was adopted to make MSUMRA's requirements equivalent to an identical requirement in the Surface Mining Control and Reclamation Act of 1977. *See* Chapter 550, Laws of 1979. Neither SMCRA nor the applicable federal rules provide a definition of "material damage" or "designed to prevent material damage." [1] However, MSUMRA was amended to define "material damage" in 2003. *See* 2003 Mont. Laws p. 651, 655 (Ch. 204, § 2)(adopting definition for "material damage"). MSUMRA defines "material damage" as follows:

> *"with respect to protection of the hydrologic balance, degradation or reduction by coal mining and reclamation operations of the quality or quantity of water outside of the permit area in a manner or to an extent that land uses or beneficial uses of water are adversely affected, water quality standards are violated, or water rights are impacted. Violation of a water quality standard, whether or not an existing water use is affected, is material damage."*

§ 82-4-203 (32), MCA. MSUMRA also provides a definition of "hydrologic balance":

> *"the relationship between the quality and quantity of water inflow to, water outflow from, and water storage in a hydrologic unit, such as a drainage basin, aquifer, soil zone, lake, or reservoir, and encompasses the dynamic relationships among precipitation, runoff, evaporation, and changes in ground water and surface water storage."*

§ 82-4-203 (24), MCA.

[1] On July 17, 2015, the Office of Surface Mining, Reclamation, and Enforcement proposed to adopt a definition of the term "material damage to the hydrologic balance outside the permit area." The proposed definition is:

> [A]ny adverse impact from surface coal mining and reclamation operations or from underground mining activities, including any adverse impacts from subsidence that may occur as a result of underground mining activities, on the quality or quantity of surface water or groundwater, or on the biological condition of a perennial or intermittent stream, that would—
>
> (a) Preclude any designated use under sections 101(a) or 303(c) of the Clean Water Act or any existing or reasonably foreseeable use of surface water or groundwater outside the permit area; or
>
> (b) Impact threatened or endangered species, or have an adverse effect on designated critical habitat, outside the permit area in violation of the Endangered Species Act of 1973, 16 U.S.C. 1531 et seq.

This rulemaking proceeding is pending as of the date of this Assessment. *See* Federal Register, Vol. 80, No. 143, July 27, 2015 (82 Fed. Reg. 44436 at 44473).

MSUMRA does not define "prevent" or "designed to prevent." Accordingly, "designed to prevent" should be understood according to its plain meaning within its statutory context. "Prevent" means "to stop (something) from happening or existing." (Merriam-Webster on-line dictionary: http://www.merriam-webster.com/dictionary/prevent). Therefore, "designed to prevent material damage" means designed to stop material damage from occurring.

An assessment of proposed "measures to be taken during and after mining activities to minimize disturbance to the hydrologic balance on and off the mine permit area, and prevent material damage to the hydrologic balance outside the permit area." ARM 17.24.314(1) must consider the context of the proposed action. This Assessment considers measures and cumulative impacts for the rather limited proposed expansion of Area B of the Rosebud Mine. Accordingly, CHIAs incorporated into the findings of other current Rosebud Mine permits, Area A, Area C, and Area D are not modified or amended by this Assessment for the Area B extension. Although this Assessment considers possible cumulative impacts of mining under the other Rosebud permits and the Big Sky Mine, as explained below, the expanded operations proposed for Area B do not intensify or augment potential impacts that assessed in the CHIAs prepared for the other Rosebud Mine permits.

2.1 MATERIAL DAMAGE CRITERIA

Following the general principles explained above, material damage criteria are established for the evaluation of both groundwater and surface water quality and quantity, and are used to determine whether water quality standards and beneficial uses of water, including water rights, outside the permit boundary have been or are expected to be impacted by mining activities.

Material damage criteria include applicable numeric and narrative water quality standards, and criteria established to protect existing beneficial uses of water. Baseline water quantity and quality is compared against changes or anticipated changes in quantity and quality associated with mine activity to determine if uses have been impacted or water quality standards exceeded outside the permit boundary.

The Montana Water Quality Act (MWQA), codified at §§ 75-5-101 through 75-5-410, MCA, is the primary basis for water quality protection in the state of Montana. Rules promulgated under the authority of MWQA establish surface water and groundwater standards (ARM 17.30, Subchapters 6, 7, and 10) to protect the designated beneficial uses of state waters. Numeric standards published in Circular DEQ-7, Montana Numeric Water Quality Standards (MDEQ, 2012), were developed using guidance from the Environmental Protection Agency (EPA) that includes:

- National Recommended Water Quality Criteria (NRWQC) developed under Section 304(a) of the Clean Water Act
- Drinking Water Lifetime Health Advisory (HA) and Maximum Contaminant Levels (MCL) developed under the Safe Drinking Water Act

Montana's surface water and groundwater rules also contain narrative standards (ARM 17.30.620 through 17.30.670, and 17.30.1001 through 17.30.1045, respectively). The narrative standards are designed to address water quality for which sufficient information does not yet exist to develop parameter-specific numeric standards. These narrative standards are established to protect beneficial uses from adverse effects, supplementing the existing numeric standards.

The interruption or diminution of a surface water or groundwater supply to the extent that an existing use is precluded is considered material damage. When material damage occurs mitigation is required; mitigation would include dependable, long-term replacement of a resource [ARM 17.24.314(1)(c) and 17.24.648] or treatment to return water to the quality needed for the designated use or to meet numeric state standards, if exceeded [ARM 17.24.631(4)].

2.1.1 Surface Water Material Damage Criteria

Material damage to surface water occurs when, because of mining, any of the following are met:

- Surface water quality standards outside of the permit area are violated
- Land uses or beneficial uses of water outside of the permit area are adversely affected to the extent that an existing use is precluded
- A surface water right is adversely impacted

Material damage criteria for surface waters[2] include the numeric water quality standards established in Circular DEQ-7 (where applicable) and water use criteria established for parameters where specific numeric standards have not been developed. Beneficial uses of surface waters are established according to stream water use classification. Specific water quality standards (along with general provisions) protect the established beneficial uses for each classification [ARM 17.30.620]. Surface water quality standards contained in ARM 17.30.620 through 17.30.670 vary according to stream classification. Surface waters in the Colstrip area are classified as C3 surface waters [ARM 17.30.611(1)(c)].

Beneficial uses of C3 waters are given in ARM 17.30.629:

> *"Waters classified C-3 are to be maintained suitable for bathing, swimming, and recreation, and growth and propagation of non-salmonid fishes and associated aquatic life, waterfowl, and furbearers. The quality of these waters is naturally marginal for drinking, culinary, and food processing purposes, agriculture, and industrial water supply. Degradation which will impact established beneficial uses will not be allowed."*

As defined by 82-4-203(18), MCA, ARM 17.24.301(39), and ARM 17.30.602(10), an ephemeral stream ("ephemeral drainage way") flows only in direct response to precipitation in the immediate watershed or in response to the melting of a cover of snow and ice, and which has a channel bottom that is always above the local water table. As defined in 82-4-203(29), MCA, ARM 17.24.301(61), and ARM 17.30.602(61), an intermittent stream is a stream or reach of a stream that is below the local water table for at least some part of the water year, and obtains its flow from both surface runoff and ground water discharge. According to ARM 17.30.637(4), ephemeral streams are not subject to the specific water quality standards of ARM 17.30.620 through 17.30.629 (including Circular DEQ-7, Montana Numeric Water Quality Standards). Applicable water quality standards for ephemeral surface waters are therefore narrative standards and also include the General Treatment Standards (ARM 17.30.635), General Operation Standards (ARM 17.30.636), General Prohibitions (ARM 17.30.637), and other descriptive portions of the surface water quality standards.

[2] "Surface waters" means any waters on the earth's surface including, but not limited to, streams, lakes, ponds, and reservoirs; and irrigation and drainage systems discharging directly into a stream, lake, pond, reservoir, or other surface water. Water bodies used solely for treating, transporting, or impounding pollutants shall not be considered surface water. [ARM 17.30.602(31)]

All surface water in the greater Colstrip area, with the exception of ponds used for treating and impounding pollutants, are state waters as defined in 75-5-103(34), MCA. A subset of state waters are classified as high quality waters under 75-5-103(13), MCA. High-quality waters are state waters that support one or more of the designated uses for their classification and have flow or surface expression for more than 95 days during most years. Under the definition of high quality waters in 75-5-103(13), MCA, many wetlands and premine ponded features would be considered high quality waters. The requirement of high quality waters to have flow or surface expression for more than 95 days would result in a subset of state waters that would be similar to but not identical to the subset of state waters that would be defined as intermittent or perennial streams under 82-4-203, MCA and ARM 17.24.301. As a result, intermittent streams are state waters but not necessarily high quality waters. High quality waters are protected from nondegradation from point sources. Discussion of nondegradation policy and protection can be found in **Section 2.1.3**.

Standards for electrical conductivity (EC) and sodium adsorption ratio (SAR) set forth by ARM 17.30.670(4) apply to tributaries of Rosebud Creek.

Numeric surface water standards for perennial and intermittent streams are in **Table 2-1**. The parameter list includes only selected parameters known to be potentially associated with coal mining impacts monitored by Montana coal mines. These numeric water quality standards apply to perennial/intermittent streams but not to ephemeral streams.

The predominant beneficial use of surface water in the area is drinking water for livestock and wildlife. Water quality guidelines established for livestock use are based on limits for livestock consumption found in documents published by the Montana State University Extension Service (Sigler and Bauder, 2012; Hutcheson, 2001). **Table 2-2** lists the parameters of concern and guideline limits for livestock water quality. These limits are not enforceable standards but are used by DEQ for guidance in evaluating suitability of pre- and postmine water quality for livestock use. It is common for water quality in the area to naturally exceed these livestock water quality guidelines.

In addition to the livestock guidelines, a chronic aquatic life limit of 230 mg/L for chloride is also used in this document to assess the suitability of surface water to support aquatic life. The EPA lists a chloride chronic limit of 230 mg/L and an acute limit of 860 mg/L for freshwater sources, but DEQ does not have a numeric limit for chloride. Recent studies on a small subset of macroinvertebrate species has indicated that toxicity can be caused by sulfate and/or chloride (Elphick et al., 2011; Iowa DNR, 2009; Soucek et al., 2011). The toxicity of sulfate and chloride are interdependent, and are also dependent on hardness. **Table 2-3** lists a water quality guideline for sulfate to protect for aquatic life use. While these toxicity values were developed for macroinvertebrates commonly found the Midwest, some of the indicator species used can also be found in Eastern Montana streams. As with **Table 2-2**, **Table 2-3** is not an enforceable standard, and it serves only as guidance for evaluating the suitability of pre- and postmine water quality for aquatic life use.

Surface water runoff models are also used to assess water quantity impacts to downstream users and uses from the capture and/or attenuation of storm runoff. Runoff from areas disturbed by mining operations is required to be managed in a manner that prevents surface water pollution (e.g. prevents increased suspended solids, changes in pH, increases in metals of concern, etc.) outside the permit area to the extent possible with the best technology currently available (ARM 17.24.633).

Impacts to surface water supply and water rights are evaluated with respect to regional and local impacts to surface water resources and natural variations in seasonal and yearly runoff. Mitigation for the loss of a beneficial use of surface water or a water right requires provision of a dependable, long-term replacement water resource of acceptable quality for the designated use and adequate quantity to support the existing and/or planned future use [ARM 17.24.314(1)(c) and 17.24.648].

Material damage criteria are therefore a combination of applicable narrative standards, numeric standards, and livestock beneficial use criteria. Impacts to surface water rights are evaluated on a case-by-case basis, and include an analysis of climatic conditions and the natural availability of surface water.

2.1.2 Groundwater Material Damage Criteria

Groundwater material damage occurs when any of the following circumstances occur because of mining:

- Groundwater quality standards outside of the permit area are violated
- Beneficial uses of groundwater outside of the permit area are adversely affected to the extent that an existing use is precluded
- A groundwater right is adversely impacted

Protection of groundwater quality for beneficial uses is based on narrative standards set forth in ARM 17.30.1006 and numeric standards for individual parameters in Circular DEQ-7. Beneficial uses listed by ARM 17.30.1006 are in **Table 2-4**. DEQ-7 numeric groundwater standards are human health standards. Numeric standards for parameters monitored by the mines are listed in **Table 2-1**.

Groundwater in the Colstrip area exhibits a locally variable, natural specific conductance that spans Class I, Class II and Class III, with Class II and Class III most common. For all groundwater classes, concentrations of parameters for which human health standards for groundwater are not listed in DEQ-7, there is to be no increase of a parameter to a level that renders the waters unsuitable for existing or anticipated uses, or harmful, detrimental, or injurious to the beneficial uses listed for the class (ARM 17.30.1006).

Existing beneficial uses of groundwater outside the permit boundary include livestock and domestic use. Wells completed in alluvium and shallow aquifers typically only supply livestock water. Water quality guidelines established for livestock use are shown in **Table 2-2** (see discussion in **Section 6.3**). The limits are not enforceable standards but are used by DEQ for guidance in evaluating suitability of pre- and postmine water quality for livestock use. Locally, groundwater quality in the area naturally exceeds these livestock water quality guidelines.

As wells completed in the coal or other shallow units typically deliver inadequate amounts of water for sustained domestic use, domestic wells typically have completion depths in sandstone units in the underburden. The location of private wells and water rights are discussed in **Section 6.0**, Water Resource Uses.

Water levels and water quality are monitored inside and outside the permit boundary to establish baseline conditions and measure subsequent changes during and after mining. Analytical results of water quality parameters most likely to be affected by mining are compared to standards to determine suitability of the water for current and anticipated uses. Groundwater level decline outside the permit

boundary must not impact a use to the extent that groundwater supply for the use is no longer adequate. Baseline water levels or water quality that are marginally supportive of a given use are more vulnerable to changes that may cause material damage than water levels or water quality more supportive of an established use.

2.1.3 Nondegradation of Water Quality

Montana's nondegradation policy is codified at Title 75, Chapter 5, Part 3, MCA and implemented in the ARM Title 17, Chapter 30, Subchapter 7. As stated in ARM 17.30.703, this policy applies to any activity of man resulting in a new or increased source that may cause degradation of state waters. All state waters are subject to Tier 1 nondegradation policy which means that existing and anticipated uses and the water quality necessary to protect those uses must be maintained and protected. *See* ARM 17.30.705(2)(a). Authorization is required to degrade any high quality water per ARM 17.30.705(2)(b). An authorization to degrade follows a detailed process described in 75-5-301(5)(c), MCA and the supporting administrative rules. As stated in 75-5-303(3)(c), MCA, existing and anticipated uses must be protected even with an authorization to degrade.

The material damage determination in the context of permit review is a design review function (*see* 82-4-227(3)(a), MCA) that is not intended to serve as a groundwater discharge permit or an authorization to degrade. The process for authorization to degrade is not appropriate during MSUMRA permit review absent objective evidence of a discrete, quantifiable, potential point-source discharge to be evaluated. *See* ARM 17.30.707 and 708. At such time as of a discrete, quantifiable, potential point-source discharge outside the permit area is indicated, the process for an authorization to degrade may be warranted. Accordingly, except for potential discharges to tributaries of Rosebud Creek which would be subject to numerical standards for specific conductivity and sodium adsorption ratio under ARM 17.30.670(4), the parameters of concern for potential point-source discharges to surface and groundwater are subject to narrative standards for salinity which permit changes to water quality that do not have a measurable effect on an existing or anticipated use or cause measurable changes in aquatic life or ecological integrity. *See* ARM 17.30.715(1)(h).

Section 75-5-317, MCA, establishes categories and classes of activities that cause nonsignificant changes in water quality from the process for an authorization to degrade. These activities include, in pertinent part:

> *"(2)(a) existing activities that are nonpoint sources of pollution as of April 29, 1993;*
>
> *(2)(b) activities that are nonpoint sources of pollution initiated after April 29, 1993, when reasonable land, soil, and water conservation practices are applied and existing and anticipated beneficial uses will be fully protected;"*

The definition of point source is found in 75-5-103(29), MCA:

> *'"Point source" means a discernible, confined, and discrete conveyance, including but not limited to any pipe, ditch, channel, tunnel, conduit, well, discrete fissure, container, rolling stock, or vessel or other floating craft, from which pollutants are or may be discharged.'*

Point sources for surface waters at Area B and other areas of the Rosebud Mine comply with the nondegradation rules through their MPDES permit. *See* ARM 17.30.629(2)(i). Protection from point source pollution is ensured by the MPDES discharge permit.

A source is a "nonpoint source" when "the source of pollutants which originates from diffuse runoff, seepage, drainage, or infiltration." ARM 17.30.602(18). New source discharges to groundwater from mineralized spoil recharge water are exempt from the nongradation policy under 75-5-317(2)(b), MCA, "when reasonable land, soil, and water conservation practices are applied and existing and anticipated beneficial uses will be fully protected." "Reasonable land, soil, and water conservation practices" in turn means

> *"[M]ethods, measures, or practices that protect present and reasonably anticipated beneficial uses. These practices include, but are not limited to, structural and nonstructural controls and operation and maintenance procedures. Appropriate practices may be applied before, during, or after pollution-producing activities. "*

ARM 17.30.602(23). Nonpoint source discharges by mineralized mine spoil water qualify for nonsignificance status because the mine operation applies "reasonable land, soil, and water conservation practices" that include measures to protect present and reasonably anticipated beneficial uses of groundwater such as backfill and regrading of spoil, contouring spoil backfill to approximate premine topography including drainage morphology and density, revegetation of disturbed soil, reestablishment and protection of riparian areas, drainage control, and impoundments which detain surface runoff or for sediment control and management of pit and runoff water. *See* ARM 17.30.602(23).

The protection of existing uses of state waters is honored by MSUMRA's protection of water rights and private wells from mining impacts [ARM 17.24.314(1)(b)]. MSUMRA and attending administrative rules also require implementation of reasonable land, soil and water conservation practices [e.g. ARM 17.24.314(1)(a); ARM 17.24.314(2)(a) and (b); ARM 17.24.701(1) and (3); and 82-4-231(1), MCA].

2.2 CUMULATIVE HYDROLOGIC IMPACT ASSESSMENT

The Cumulative Hydrologic Impact Assessment (CHIA) includes an assessment of the Probable Hydrologic Consequences (PHC) of the proposed operation that is submitted by the operator with the application. The PHC determination is prepared by the applicant [ARM 17.24.314(3)] and approved by the regulatory authority (DEQ). Prior to making a permitting decision, DEQ makes an assessment of all hydrologic impacts of the proposed operation as well as existing, previous, or anticipated mining that may collectively impact surface and groundwater systems. The CHIA analysis must determine whether the proposed operation has been designed to minimize impacts to the hydrologic balance on and off the permit area and prevent material damage outside the permit area [ARM 17.24.314(5)].

CHIA development involves the analysis of critical aspects of the hydrologic system within a defined cumulative impact area to predict the type and magnitude of impacts to the hydrologic system from proposed and existing mining. The CHIA process includes the following: 1) define the area to the studied, 2) describe the hydrologic system, the baseline values, and subsequent changes, 3) identify hydrologic resources likely to be affected, 4) develop criteria for evaluating the impacts, 5) estimate the impacts of mining on hydrologic resources, and 6) make a material damage determination and prepare a statement of findings.

3.0 PROPOSED PERMITTING ACTION

The Rosebud Mine and Big Sky Mine are located adjacent to one another outside the town of Colstrip in Rosebud County, Montana, approximately 123 miles east of Billings, Montana and 36 miles south of Forsyth, Montana **(Figure 1-1**). Western Energy Company submitted permit amendment application AM4 that, if approved, would increase the mine permit area of Rosebud Mine Permit Area B (SMP C1984003B) by adding 49 acres to the current permit area of 6,182 acres, 146 acres of additional disturbance, and approximately 12.1 million tons of coal (**Figure 3-1**) . If approved, AM4 mining represents an 8.3% increase in the amount of Rosebud coal aquifer removed.

3.1 BACKGROUND & MINING HISTORY

Colstrip was established by the Northern Pacific Railway in 1924 as a company town to provide coal for the company's steam locomotives. Northern Pacific mined about 44 million tons of coal from the Rosebud coal seam (MDSL and OSMRE, 1983) and by 1958 had disturbed approximately 1,800 acres of land around what are now Area D and Area E of the Rosebud Mine, and Pit 6, a former permit area south of Area E. In 1958, the railroad switched to using diesel locomotives and the Colstrip mine was shut down. In 1959, Montana Power Company purchased the rights to the mine and the town. In 1966, Montana Power Company formed a wholly owned subsidiary, Western Energy Company, to manage and develop the Colstrip properties. Western Energy Company began mining in Pit 6 in 1968. Western Energy Company became a subsidiary of Westmoreland Mining, LLC, when Westmoreland purchased the Rosebud Coal Mine in 2001.

Mining permitted under MSUMRA was active in Rosebud Mine Area D from 1986 to 2013. Mining in Area E was permitted in 1976. Mining in Area E was completed by late 1986 and reclamation was completed by 1996. Mining in Pit 6, located south of Area E, was completed in the middle 1970's with much of the reclamation completed by the late 1970's. Final reclamation of Pit 6 (roads, facilities, ponds) was completed in 2004 and the permit area was released from bond in 2006.

Mining in Area A, Area B and Area C began prior to enactment of MSUMRA, but mining was permitted under MSUMRA when it was enacted in 1973. Mining and reclamation activities in Area A began in 1975. Mining was idled in Area A in 2000 but resumed in 2014. Mining at the northeast end of Area B began in 1976. By the early 1980's, mining in Area B moved southwest, taking advantage of shallow coal adjacent to East Fork Armells Creek (EFAC). By the middle 1990's, mining in Area B expanded to the west along EFAC. Mining in the east and west part of Area B has moved to the south, away from EFAC and remains active. Mining in Area C began in 1983 and was extended to the north and west under subsequent permit revisions. Mining in the north part of Area C was completed in 2010. Mining in the west part of Area C began in 2007 and remains active. Mining also remains active in the central part of Area C.

The Big Sky Mine lies immediately south of the Rosebud Mine. Due to its proximity to and shared hydrogeologic system with the Rosebud Mine, the Big Sky Mine is included in the cumulative impact area (CIA) and CHIA analysis. There are two permit areas in the Big Sky Mine, Area A and Area B. Peabody Coal Company began mining at Area A in 1969, prior to passage of laws that regulated coal mining. Area A mining and reclamation plans were permitted in 1973 under the Strip and Underground Mine Siting Act and later under MSUMRA with several permit revisions, expansions and consolidations until mining was completed in September 1989. Reclamation in Area A was largely completed by 1992. Pre-law mining areas in Area A were released from bond in 2014. Area B was permitted in 1988. Area B

Mining activities began in 1989 and were completed in December 2003. Reclamation was completed by 2007. Phase I and Phase II bond release have been completed in Area B and 731 acres have been released from Phase III.

3.2 CURRENT MINING OPERATIONS

Strip mining at the Rosebud Mine, and formerly at the Big Sky Mine, consists of topsoil salvage, overburden removal to expose the coal seam, and removal of the coal seam. Blasting is used to fracture overburden prior to removal by the dragline. Once exposed, the Rosebud coal seam is blasted to fragment it for removal by electric shovel or loader. Haul trucks deliver the coal to the conveyor terminal and the coal is transported via conveyor to the Colstrip power plant. Overburden from each successive cut is used to backfill the previous cut. Overburden backfill material is commonly referred to as spoil. The backfilled spoil is regraded to an approved postmine topography and the salvaged topsoil or other suitable material is spread on the surface. Seeding and planting of approved vegetation follows.

The Rosebud Mine currently has a total permit area of approximately 25,752 acres in five individual permit areas: Area A, Area B, Area C, Area D, and Area E. The mine areas include federal, state, and private surface ownership. Mineral ownership is divided between federal, state, and private entities. In 2014, active mining at the Rosebud Mine took place in Area A, Area B, and Area C. Coal removal in Area D was completed in early 2013; final pits are still being backfilled and the surface regraded to the approved topography. Annual coal production from the mine is approximately 12 million tons.

There are two mine areas at Big Sky Mine, Area A and Area B, totaling 7,191 permitted acres. Both areas have been backfilled, graded, contoured, and vegetated and are progressing toward qualification for Phase III and Phase IV bond release.

4.0 REGIONAL OVERVIEW

The permit and proposed amendment area is located in Colstrip, Montana, in the north part of the coal-rich Powder River Basin, which covers an area of approximately 7,765 square miles (Haacke and others, 2013) (**Figure 4-1**). The climate is semi-arid. Typical vegetation includes silver sagebrush-mixed grasslands, mixed grasslands, ponderosa pine-mixed grassland, and areas of improved pasture and wetlands.

Exposed rocks are sedimentary and of early Tertiary age. Differential erosion of rocks of varying hardness and resistance is the main process active in forming the present landscape. Interbedded claystones, siltstones, coals, and sandstones are often capped by resistant "clinker" mesas and ridges. The siltstones and claystones tend to be easily eroded, while the sandstone and clinker, a term used to describe the baked sedimentary rock formed during natural burning of coal beds, are more resistant to erosion. Sheet and rill erosion are active geomorphic processes in the upper drainage basins, and mass wasting occurs locally along the steep-walled ridges. Ephemeral streams occur throughout the area, with less common intermittent to perennial drainages.

4.1 CLIMATE

The climate of southeast Montana is classified as semi-arid continental. Precipitation and temperature measurements have been collected at the mine and also at the nearby climate stations at Colstrip and Billings, MT (National Weather Service Cooperative Observer ID 240807). Climate data are available from the Western Regional Climate Center (WRCC (b), 2014).

Storms often produce highly localized precipitation events in the Colstrip area. Graphs representing precipitation and temperature based on data collected between 1981 and 2010 are shown in **Figure 4-2.** The 30-year average annual precipitation at Colstrip is 14.45 inches. The average peak precipitation month is June with 2.67 inches; minimum precipitation occurs in January with only 0.37 inches. Highest average temperatures are in July and August at approximately 70^0F. December through February are the coldest months with average temperatures between 26^0F and 28^0F. The largest amount of precipitation in the last 30 years occurred in 2011 when the area received almost 24 inches of rain, a 65% increase over the 30-year average.

The closest pan evaporation station to Colstrip is at Yellowtail Dam, MT. Pan evaporation measured at Yellowtail Dam averaged 47.56 inches between 1948 and 2005, the most recent period of record available (WRCC, 2014 (a)). A pan coefficient of 0.7 to 0.8 is typically applied to the pan evaporation data to obtain an estimate for evaporation from a surface water body. Assuming a factor of 0.75 for the pan evaporation average at Yellowtail Dam, the approximate annual evaporation at the Rosebud Mine is 35.67 inches. Evaporation is greatest from April to September with peak evaporation in July.

4.2 TOPOGRAPHY

The Rosebud and Big Sky mines lie within the unglaciated Missouri Plateau, a division of the Northern Great Plains physiographic province. In the Colstrip area, the landforms have developed on the essentially flat-lying Tertiary sediments of the Fort Union Formation.

The topography is characterized by gently sloping valleys bounded by moderately steep to very steep ridges capped by isolated sandstone and clinker mesas. Surface elevations above mean sea level range from approximately 3,100 feet along East Fork Armells Creek (EFAC) north of Colstrip to over 4,000 feet to the south and southwest, near the headwaters of EFAC. Surface slopes vary from near zero to 30 percent in the vicinity of the divide between Big Sky Area A and Area B, and slopes become as steep as 45 percent or more in the higher elevations in the Little Wolf Mountains.

In the Colstrip area ephemeral to intermittent streams have incised the sedimentary sequence, exposing the gently dipping coal seams. EFAC is an ephemeral to intermittent stream that flows through the Rosebud Mine between Area B and Area C to the west, and Area A and Area B to the east. Rosebud Mine Area A, Area B, Area C, and the west part of Area D drain to EFAC. Rosebud Mine Area E, the east part of Area D, and the Big Sky Mine drain to Rosebud Creek. EFAC enters the Yellowstone River west of Forsyth, MT and Rosebud Creek enters the Yellowstone River at Rosebud, MT.

4.3 GEOLOGY

The coal producing region of southeastern Montana is located in the northernmost extent of the Powder River Basin (PRB). The PRB is an asymmetrical structural and topographic basin approximately 230 miles long and 100 miles wide, oriented southeast to northwest in northeast Wyoming and southeast Montana (**Figure 4-1**). The basin dips more steeply on the western side, where it is bounded by the Bighorn Mountains, and has a more gentle dip to the east where it is bounded by the Black Hills. Sedimentary rocks within the Basin have a maximum thickness of about 18,000 feet and represent rocks of Paleozoic through Cenozoic age. The basin interior is characterized by a gently dipping, wide expanse of lower Tertiary rocks, including the Paleocene Fort Union Formation and the Eocene Wasatch Formation (**Figure 4-3**). Most of the Wasatch Formation has been removed by erosion in the Colstrip area.

Quaternary alluvial and colluvial deposits in the Colstrip area are generally unconsolidated clay, silt and sand and typically occur in ephemeral drainages or areas of lower elevation in the stream and valley bottom areas. Alluvial deposits are generally less than 40 feet in thickness. Most coal production in the Powder River Basin is from the 2,300 foot to 6,000 foot thick Fort Union Formation. In the Colstrip area, coal production comes from mining coal seams in the Tongue River Member of the Fort Union Formation. Thin, discontinuous siltstone, claystone, and sandstone beds bound the coal seams. These sedimentary units typically are high in sulfate bearing minerals (e.g. gypsum and anhydrite), are moderately to highly alkaline, and are moderately high in soluble salts.

The depositional setting of the Fort Union Formation is characteristic of braided stream, floodplain and peat accumulating swamp environments (Flores et al., 1999). An oxidized, reddish and highly erosion resistant rock known as “clinker” commonly caps ridges and plateaus. Clinker formed when coal beds burned and baked the adjacent sediments into oxidized, vitreous and often brecciated rocks.

The package of Tongue River Member siltstones, claystones, and sandstones above the first mineable coal seam is termed overburden and ranges from a few feet to approximately 300 feet. The same lithologies separate the Rosebud coal and McKay coal and are referred to as interburden, which ranges from as little as three to 5 feet thick to 75 feet. The stratigraphic units below the McKay coal are referred to as underburden. Like the overburden and interburden, the underburden is composed of siltstones, claystones and sandstones.

The Rosebud Mine is located at the northern extent of the Rosebud and McKay coal beds (**Figure 4-4**). The Rosebud coal is 18 feet to 23 feet thick. At the Big Sky Mine, the Rosebud coal seam is reported to be 23 feet to 26 feet thick (BSCC, 1988). The McKay coal ranges between 7 feet and 10 feet thick. The Rosebud coal is mined at the Rosebud Mine and was the main target of mining at the Big Sky Mine. In limited areas of Big Sky Mine Area A, the McKay coal was also mined.

Structural imprint on the mine areas is subtle. The dip of the beds is one to two degrees to the southeast. The Ashland syncline, a west –northwest trending shallow structural trough cuts the southwest quarter of T1N, R40E in Area C of the Rosebud Mine. Several normal faults of small displacement (generally less than 100 feet) have been mapped or inferred from aerial photos in the mine areas. Fault orientation ranges from northeast to northwest.

The Big Sky Mine Area B permit application describes the local geology (BSCC, 1998). The coal seams have a generally flat structure with subtle domes and depressions with a symmetrical anticline, the axis of which parallels Lee Coulee. This structure is subtle, with the flanks and southeast plunge dipping less than one degree, and with smaller, local structures obscuring it at some localities. A few low-displacement, high-angle faults are mapped in the vicinity of the mine.

5.0 CUMULATIVE IMPACT AREA

A cumulative hydrologic impact area (CIA) is defined by ARM 17.24.301(32): '"Cumulative hydrologic impact area" means the area, including, but not limited to, the permit and mine plan area within which impacts to the hydrologic balance resulting from the proposed operation may interact with the impacts of all previous, existing and anticipated mining on surface and ground water systems'." Anticipated mining" includes the entire projected life through bond release of all permitted operations and all operations required to meet diligent development requirements for leased federal coal for which there is actual mine-development information available. The size and location of a given CIA depends on the surface water and groundwater system characteristics, the hydrologic resources of concern, and projected impacts from the operations included in the assessment. For this CHIA, a surface water CIA and a groundwater CIA are delineated to assess impacts associated within these distinct hydrologic resource areas (**Figure 5-1**).

5.1 SURFACE WATER CUMULATIVE IMPACT AREA

The surface water CIA includes all areas that may see a measurable change in water quantity or water quality due to mining activities at the Rosebud Mine and Big Sky Mine. The cumulative impact area covers upstream portions of West Fork Armells Creek to the confluence with Donley Creek, East Fork Armells Creek to the confluence with Stocker Creek, and Rosebud Creek to the confluence with Spring Creek. The CIA boundaries are established down gradient from potentially affected streams and springs, and include all surface water monitoring stations to allow assessment of impacts to stream water quality and quantity. Only impacts from coal mining are included in the CHIA, and although the power plant, power plant ash ponds, the town of Colstrip, and active agricultural activities are within the CIA, the impacts from these sources are only mentioned when their impacts are measured in data collected by the coal mines.

5.2 GROUNDWATER CUMULATIVE IMPACT AREA

The groundwater CIA includes the limits of all mining-induced groundwater impacts or potential impacts based on the hydrology of the mines and adjacent area. Potential impacts to groundwater include changes to water level or water quality such that the resource is no longer available or suitable for established uses. Results of two transient groundwater flow models in the Rosebud Mine, one for permit areas A, B, and C (Western Energy Company, 2014) and one for Area D (Western Energy Company, 1999), and the currently observed drawdown and recovery at the reclaimed Big Sky Mine are the basis for determining the extent of drawdown impacts for the CIA. Mining-induced water quality impacts are determined and evaluated based on observed changes to baseline water quality and anticipated changes based on location of resources and their potential to be affected.

6.0 WATER RESOURCE USES

Historic and current surface and groundwater uses in and adjacent to the mine area include domestic, livestock, wildlife, and industrial. These are also the anticipated postmine uses of water in the area. Private wells located within and immediately adjacent to the CIA were identified from the Montana Bureau of Mines and Geology Groundwater Information Center (GWIC). Registered surface water and groundwater rights were identified from records at the Montana Department of Natural Resources and Conservation (DNRC). Groundwater users (wells and groundwater rights) are shown in **Table 6-1** and located on **Figure 6-1;** surface water users (surface water rights) are shown in **Table 6-2** and located on **Figure 6-2.**

As shown in **Table 6-2**, surface water rights outside of the permit boundaries in each of the major drainages are dominated by a few users. Except for two springs in the upper most headwaters, water rights on East Fork Armells Creek upstream of the state highway are all held by the Booth Brothers Land and Livestock Company. Surface water rights in Stocker Creek are equally divided amongst Booth Brothers Land and Livestock Company and Great Northern Properties Ltd (GNP). Pony Creek surface water rights are divided between GNP, Genie Land Co, and the Garfield family. Cow Creek water rights are divided between Genie Land Co and the PPL power plant. Water rights are held by Greenleaf Land and Livestock Co and GNP in Miller Coulee. Lee Coulee water rights are predominately held by Bailey. WFAC water rights are held mostly by GNP and KL Ranch LLC, excluding the mine. Finally, Spring Creek water rights are held by a variety of users including GNP, the Valdez and Beverly Trust, Cornwell Land and Livestock Co, and Genie Land Co.

The mine operator must replace water rights or water supply interrupted by strip or underground mining (ARM 17.24.648). Supply of water for domestic, agricultural, industrial or other legitimate use of surface or groundwater is protected from diminution, contamination or interruption resulting from coal mining.

6.1 DOMESTIC

Domestic use is listed in GWIC or DNRC records for numerous wells within the groundwater cumulative impact area. Domestic wells in the area generally produce water from sandstone units in the deeper underburden because it is the most reliable resource. The Rosebud coal and other shallow units generally cannot deliver adequate and/or sustainable amounts of water for domestic use. The municipal public water supply for the town of Colstrip relies on water from the Yellowstone River stored in Castle Rock Lake. Total municipal usage is estimated at 630 acre-feet per year (MDSL and OSMRE, 1983).

6.2 INDUSTRIAL

Industrial users include the Rosebud Mine and the Colstrip Power Plant. A 29-mile long pipeline from the Yellowstone River brings water to Colstrip for use at the power plant. The water is stored in a large pond known as Castle Rock Lake, a reservoir located on the west side of town adjacent to Rosebud Mine Area A. The power plant uses 90 to 95 percent of the annual reservoir storage with the overwhelming majority of that water lost to evaporation through cooling processes, from pond surfaces and in dust suppression. The Rosebud Mine utilizes municipal water for most uses. Shallow wells formerly used by the Rosebud Mine have been abandoned. As part of the mining operations, water retained in sediment

ponds and pits is applied to roads to control dust. The Big Sky Mine used a production well completed in the underburden. This well has been converted to livestock supply.

6.3 LIVESTOCK

Water for livestock is the most common use of surface and shallow groundwater in the CIA. Surface water, springs, and groundwater wells in the CIA area provide drinking water for livestock. Water quantity and quality in surface water, springs, and shallow wells are variable and may change seasonally with the availability and use of the water source. Based on reported completion depths, stock wells are completed in alluvium, overburden, Rosebud or McKay coal, and underburden. Wells completed in deeper, underburden units provide a more consistent and reliable water source. A number of groundwater rights are listed for stock water use at springs in the CIA. Spring sources include alluvium, overburden or coal units. Surface water rights within the CIA for livestock are typically directly from the source or at a stock pond.

Water quality guidelines for livestock used in this CHIA are based on limits for livestock consumption found in documents published by the Montana State University Extension Service (Sigler and Bauder, 2012, Hutcheson, 2001). **Table 2-2** lists the parameters of concern and guideline limits for livestock water quality. These limits are not enforceable standards but are used by DEQ for guidance in evaluating suitability of pre- and postmine water quality for livestock use. Locally, water quality in the naturally exceed these livestock water quality guidelines.

There is a lack of consensus in the scientific and agricultural communities on the appropriate or acceptable concentration of livestock drinking water quality. This is especially true for the constituents with narrative standards, such as sulfate and TDS. The guidelines presented for Montana are within the limits for sulfate and TDS determined in a risk assessment for livestock drinking water that incorporated an extensive literature research with empirical data from Wyoming ranchers (Geomega, 2007).

Trace metal concentration limits are more uniform among published studies, often using the HHS as the standard for livestock. Surface water and shallow groundwater in eastern Montana are highly variable and locally may be marginal for supporting livestock. Yet, surface and shallow groundwater have supported ranching in Montana for more than a century.

6.4 AQUATIC AND WILDLIFE HABITAT

In semi-arid Eastern Montana, wetlands are predominately found by springs, stock ponds, and intermittent reaches of drainages. Many stock ponds and intermittent reaches are fed by springs. Wetland inventories and assessments are required in baseline surveys to satisfy the requirements to assess the hydrologic resources, vegetative communities, and wildlife habitat. An inventory of wetlands that may be impacted by mining activities are also required to be submitted to the Army Corps of Engineers to determine federal jurisdictional status. If a wetland is considered jurisdictional, the Army Corps of Engineers can require mitigation to offset the impact to wetland resources in the area.

At both the Rosebud and Big Sky mines, baseline surveys and mining occurred before requirements for wetland inventories and assessments were enacted, and consequently there is no comprehensive list of premine wetland sites or their areal extent for the mines. The most complete wetland survey for the area was done for the Rosebud Mine in 1995, and the areas delineated as potential wetland habitat are shown in **Figure 6-3** (MME, 1995). In addition, aquatic life surveys were conducted on EFAC and other

locations prior to or shortly after mining started (**Table 6-3**). Results from these surveys are difficult to use for premine and postmine comparison due to different sampling techniques, but the survey results give a qualitative representation of the aquatic habitat and community.

7.0 MONITORING PROGRAM

Surface water and groundwater monitoring programs are required to meet permit obligations pursuant to ARM 17.24.314, ARM 17.24.645 and 17.24.646. Monitoring results from the Rosebud Mine and Big Sky Mine are the basis for assessment of mining impacts on water resources. The monitoring plan has been designed to collect water quantity and quality information in order to address the questions: 1) To what extent are impacts to the hydrologic balance occurring on or off the permit area as a result of mining operations, and 2) Is material damage occurring as a result of mining operations?

The monitoring plan identifies site locations, hydrogeologic units monitored, sampling frequency, and parameters. Quality assurance is an integral part of sampling and analytical requirements. As mining proceeds or the potential for additional impacts are recognized, the monitoring plan is revised to accommodate changes, including replacement of monitoring sites or development of new sites. Monitoring is required to continue through the final phase of bond release.

In addition to monitoring commitments required by the mine permits, the Rosebud Mine and Big Sky Mine also monitor MPDES-regulated discharges. Big Sky MPDES Permit No. MT-0000884 authorizes discharges to Lee, Emile, Miller and Hay coulees. Rosebud Mine MPDES Permit No. MT-0023965 authorizes discharges to Stocker Creek, Hay Coulee, South Fork Cow Creek, Cow Creek, East Fork Armells Creek, Castle Rock Reservoir, Spring Creek, West Fork Armells Creek, Black Hank Creek, Donley Creek, Lee Coulee and Pony Creek.

7.1 SURFACE WATER

Surface water monitoring at the mines includes stream, spring (and seep), and pond sites. Currently required analytical parameters and methods for surface water monitoring are in **Table 7-1**. The surface water monitoring plans for the Rosebud and Big Sky mines are in **Table 7-2**. The current and historic monitoring sites are shown in **Figure 7-1**. This figure shows that the current surface water monitoring network at the Rosebud Mine is a fraction of the total number of sites that have been monitored. Most of the stream monitoring and sampling was conducted in the early to middle 1980's, and more surface water quality data exists for this time period than any other. Analysis of impacts to surface water from mining is greatly complicated by the inconsistent temporal and spatial distribution of surface water data collection and from the inherent nature of ephemeral stream hydrology.

The Rosebud Mine implements and complies with MPDES permits at 151 drainage outfalls. Of the 151 individual outfalls, 60 discharge to East Fork Armells Creek, 16 discharge to West Fork Armells Creek, 24 discharge to Stocker Creek, 13 discharge to Spring Creek, nine discharge to Pony Creek, seven discharge to Lee Coulee, 20 discharge to Cow Creek, one discharges to Black Hank Creek and one discharges to Donley Creek. A total of 126 discharge events were reported for the period of record from December 1999 through June 2011. Thirty-seven discharges were to Stocker Creek, 31 were to West Fork Armells Creek, 29 were to East Fork Armells Creek, 13 were to Pony Creek, nine were to Cow Creek, six were to Spring Creek, and one was to Black Hank Creek. Sixty-nine of the 151 outfalls are associated with reclaimed drainages and are covered under Western Alkaline Coal Mining standards. The Federal Environmental Protection Agency (EPA) established Western Alkaline standards that require coal mine operators to implement best management practices (BMPs) so that postmine lands are reclaimed to mimic natural conditions that were present prior to mining activities. A total of 181 monitored discharge events were reported for the period of record from December 1999 through 2013. Thirty-one discharges

were to Stocker Creek, 29 were to West Fork Armells Creek, 107 were to East Fork Armells Creek, seven were to Pony Creek, six were to Spring Creek, and one was to Black Hank Creek.

7.2 GROUNDWATER

Monitoring takes place in each potentially affected hydrologic unit at the mines. Water level and water quality data have been collected from monitoring wells at and adjacent to the Rosebud Mine and Big Sky Mine since the 1970's. As there was no monitoring required prior to passage of MSUMRA, there is no baseline for some of the earliest mining disturbance. The first monitoring wells were installed by the MBMG (from 1973 to 1975) to study the impacts of mining on the hydrologic system. Many of these wells have a long monitoring history and some remain active. Mine-wide installation of monitoring wells at the Rosebud Mine by Western Energy Company began in 1979 and additional wells have been installed as mining expanded. Peabody Energy began installation of monitoring wells at Big Sky Mine Area A in the middle 1970's after mining had begun. Installation of wells in Big Sky Area B in the middle 1980's recorded baseline conditions prior to the beginning of mining.

The currently approved groundwater monitoring parameters at the Rosebud Mine are in **Table 7-3.** The currently approved groundwater monitoring parameters at Big Sky Mine are in **Tables 7-4** and **7-4A**. The monitoring plan for Rosebud Mine is in **Table 7-5** and well locations are on **Figure 7-2**. The monitoring plan for the Big Sky Mine is in **Table 7-6** and the well locations are shown on **Figure 7-3**.

8.0 BASELINE HYDROLOGIC CONDITIONS

The goals in establishment of baseline hydrologic conditions are to characterize the local premine hydrology, understand the regional and local hydrologic balance, and identify potential water resources or uses that could be affected by the mining operation. Monitoring surface water and groundwater prior to mining is key to understanding the hydrologic condition and informs the regulating agency of the potential for and location of impacts. Hydrologic monitoring was not required by statute prior to enactment of MSUMRA in 1978, thus there is no baseline data for some mine areas. Prior to enactment of MSUMRA, mining began in Area D, Area E, Pit 6 and parts of Area A and Area B of the Rosebud Mine, and at Big Sky Mine Area A.

Although the majority of existing hydrologic information was collected after mining operations began, the substantial data sets developed over the last 30 years of monitoring provide insight into baseline conditions based on observed water quality and quantity trends. Up gradient groundwater quality data from all monitored units are representative of baseline water quality, as areas up gradient of mining have not been impacted by mine activity.

8.1 SURFACE WATER BASELINE

Baseline surface water conditions were derived from a network of surface water monitoring stations (springs/seeps, streams, ponds) established during initial permit development. Characterizing background conditions for surface water quantity for the drainages crossing the mine areas requires years of measurements in a variety of precipitation events and climate conditions. Premine water monitoring sites located at the downstream end of the mine permit boundary have limited use in establishing a long-term record of premine conditions because mining upstream of the stations occurred within 2 years after the sites were installed. In many cases mining occurred upstream of the sites before the start of monitoring.

For baseline analysis, surface water samples are broken into two categories: streams and stock ponds, and springs. Springs are analyzed separately as they are sourced from groundwater but the sampling location, often a man-made pond or stream bottom, may also be influenced by surface water sources. For this CHIA, stream and pond water quality samples were chosen as representing baseline conditions if the sample was taken before mining commenced upstream of the sampling location.

Within the CIA, many springs, seeps, and spring-fed ponds have been identified and monitored. Most springs in the area produce only small rates of flow (a few gpm) and many become dry for extended periods of time. However, these springs provide an important source of water for livestock and wildlife while they are flowing. All of the major near-surface aquifers have been identified as a source for springs: clinker, Rosebud coal, McKay coal, and sub-McKay sandstones. Some reclaimed areas have developed springs sourced from spoil.

8.1.1 Regional Drainage System

The region is drained by tributaries of the Yellowstone River. The Rosebud Mine intersects eight major drainages. Area A drains to both Stocker Creek and East Fork Armells Creek. Area B is immediately south of East Fork Armells Creek, however a small portion of the permit area crosses the divide into the Lee Coulee drainage. Area C spans multiple drainage basins including East Fork Armells Creek, Stocker Creek, West Fork Armells Creek, and a small portion is located in the Black Hank Creek basin. Area D is located

at the intersection of four drainage divides: Spring Creek, Pony Creek, Cow Creek, and East Fork Armells Creek. Area E is located in Cow Creek and East Fork Armells Creek drainage basins. Pre-law mining in Pit 6 occurred in areas that drain to Cow Creek and Hay Coulee. Most of the mining occurred in the headwaters of the drainages and left the main channels of the drainage basins undisturbed. Area C mined through the upstream-most channel of Stocker Creek. Mining occurred within a few hundred feet of the East Fork Armells Creek main channel, but no mining has disturbed the actual creek bed. Haul roads and county roads cross the main channel.

The Big Sky Mine is situated among coulees that drain east-southeastward into Rosebud Creek. These include, from north to south, Emile (or Coal Bank) Coulee and Miller Coulee in Big Sky Area A, and Lee Coulee in Big Sky Area B. Emile Coulee is a tributary to Miller Coulee and is analyzed as part of Miller Coulee in this CHIA. The coulees are generally ephemeral. Miller Coulee and Emile Coulee are ephemeral. Lee Coulee is ephemeral above and at the upper end of Big Sky Area B, and downstream of Big Sky Area B. Within Big Sky Area B, there is a wet reach confined within the permit area about 1.5 miles long that sustained small ponds, flowing reaches, and sub-irrigated rangeland before mining (**Figure 6-3**). The wet reach discontinues and the stream is again ephemeral before Lee Coulee exits the Big Sky Area B permit boundary. Lee Coulee extends from about one mile upstream of the Rosebud coal outcrop to near the McKay coal outcrop. The wet reach is an intermittent stream, but contains short reaches within it that may be perennial. This reach has been the focus of special studies to evaluate conditions within the reach both before mining and as mining approached the area. Mine reclamation included a plan to reproduce the wet reach.

8.1.2 Surface Water Quantity

Judgments on the nature of flow in the creeks within the CIA monitored by the Rosebud Mine and Big Sky Mine can only be made at locations with surface water monitoring sufficient to determine the nature of flow. With the exception of some intermittent stream reaches and stock water ponds, the surface water that is monitored by the mines in and near the Rosebud and Big Sky mines are ephemeral, flowing only in response to precipitation events or snowmelt, or for short reaches below the issue point of springs or seeps. Reaches of some of the larger drainages within the CIA but downstream of the stream monitoring network may also be intermittent (e.g. West Fork Armells Creek (WFAC), East Fork Armells Creek (EFAC), Spring Creek, and Hay Coulee).

Long term monitoring at Rosebud and Big Sky indicates some stream segments that have had periods of flow that would be classified as intermittent. These monitored intermittent stream segments include one on Stocker Creek, two on upper EFAC, one on Lee Coulee, and most of Cow Creek. With the exception of the mainstem of Cow Creek, these stream segments are isolated and do not provide connectivity to downstream perennial water bodies (e.g. Rosebud Creek and lower EFAC). Rosebud Creek is perennial within the CIA. Stream flow measurements on Stocker Creek indicate that some upstream sections may be intermittent after heavy precipitation years when clinker and alluvium are temporarily recharged. There are likely other reaches on the impacted drainages that behave similarly where intermittent flow may occur for one or two years after a large precipitation year. While no long term continuous flow monitoring equipment has been installed on WFAC, there are eighteen springs within the CIA that have been monitored in this drainage, and there are likely reaches of spring-fed intermittent streams on WFAC.

The criteria for determining if a stream reach is ephemeral, intermittent, or perennial differs between an MPDES discharge permit and MSUMRA mining permit. The MPDES program considers the flow regime

for large segments of streams when characterizing receiving waters, and consequently Stocker Creek, EFAC, and Lee Coulee are currently designated as C-3 ephemeral for the purposes of the MPDES discharge permits for the Rosebud Mine and Big Sky Mine. In the context of MSUMRA, however, some monitored segments of EFAC, Stocker Creek, and Lee Coulee have had enough continuous flow to classify small reaches of the stream as intermittent per ARM 17.24.301(61).

The site with the longest record of monitoring upstream of mining disturbances at the Rosebud Mine is SW-75 on East Fork Armells Creek. This station is on a part of the creek that rarely experiences flows and has numerous data gaps in the flume's flow record. This location is not representative of baseline conditions at other segments of the stream. For instance, other segments of EFAC may have had baseflow or ponded water for many months of the year, but these locations were not regularly monitored. With only one continually monitored site upstream of mining, natural flow conditions along the entire reach of EFAC cannot be established by the existing record of empirical measurements. Similarly, none of the other drainages have a large enough data set to characterize natural flow conditions before mining. On Stocker Creek, WFAC, Spring Creek, Pond Creek, and Cow Creek mining started in the basins near the drainage headwaters, and consequently baseline data is extremely limited. For these drainage basins, there is no ability to place sites upstream of mining to contemporaneously monitor natural and mine-impacted flow conditions.

In basins with insufficient data, premine water quantity can be roughly estimated by using flow data from a comparable undisturbed basin. The natural ranges of peak flows can be calculated for a number of recurrence intervals in similarly sized basins monitored by the USGS (**Figure 8-1**). The USGS also offers a service to estimate peak flows in Montana from the simplistic basin characteristics of size, location, and elevation using a method developed by Parrett and Johnson (2004). Both of these techniques along with calculated peak flows at long-term monitoring stations operated by the Rosebud and Big Sky mines are shown in **Table 8-1**.

Table 8-1 shows that the peak flows calculated from empirical data collected at mine-monitored sites SW-55, B33FL, SW-75, and SW-65 are all much smaller than peak flows estimated by the Parrett and Johnson (2004) method or peak flows calculated from empirical data collected at similarly sized drainage basins by the USGS. As mentioned above, the mine-monitored sites suffer from numerous data gaps in the record that can lead to erroneous calculated peak flows. The records at these sites are also in average daily flow, and the true peak flow of an event will always be higher than the maximum average daily flow that is shown in the table. In stream dams and changes in stream bed permeability also have a significant impact on peak flows which are not accounted for in the Parrett and Johnson method. Additionally, monitoring sites downstream of mine impacts may experience reduced flows due to the use of sediment ponds on contributing upstream tributaries. Sediment ponds can remain in place for decades during mining and reclamation, and they are typically sized to retain a 10-yr, 24-hr storm event. Consequently, for storm events smaller than the theoretical 10-yr, 24-hr, the ponds can potentially fully retain runoff from downstream channels. As seen in **Table 8-1**, peak flows in all but the largest drainages range by at least one order of magnitude between the 2 year and 100 year recurrence storms.

8.1.3 Surface Water Quality

As with water quantity data, little baseline surface quality water data is available for Pony Creek, Spring Creek, Miller Coulee, and Cow Creek. Because the drainages are mostly ephemeral, many drainage basins have a poor distribution of stream and pond sample points (**Figure 8-2**). More data was collected on EFAC and WFAC. In the early 1980's, a series of synoptic runs were conducted on EFAC where water

quality was sampled from multiple locations on the same day. This resulted in a large number of data points, but this sampling methodology also resulted in very few sampling locations that were used for repeated sampling. The synoptic runs allow for an evaluation of changes in water quality as water flows downstream through areas not impacted by mining, though active mining, and on into the town Colstrip. WFAC has a larger quantity of baseline sampling because mining commenced in this basin later than other sections, allowing for a longer baseline monitoring period.

In general, baseline water quality in any given drainage channel or pond is variable, but some water quality parameters showing a strong seasonality (**Figure 8-3** and **Figure 8-4**). Water quality samples from streams and ponds have lower total suspended sediment (TSS) in the winter and early spring because the ground remains frozen during runoff events. Runoff in the early and middle spring can often represent the majority of water volume carried by the stream all year. Conversely, water quality samples from streams and ponds collected in the summer have higher TSS. Not only is the ground unfrozen and dry in the summer but storm events tend to be locally intense and of short duration. These precipitation events in turn create flashy, erosive flows through the drainages. Total dissolved solids (TDS) concentration and its major constituents do not show a strong seasonal change, in part because the data set used to make **Figure 8-3a** is mainly from sites on ephemeral drainages. The elevated concentration of dissolved analytes from October water quality samples is a result of sampling bias – all of the October samples used to create **Figure 8-3a** were from the Lee Coulee wet reach.

A comparison of water quality between drainage basins (**Figure 8-4)** shows a wide range in water quality. None of the drainages have a distinct chemical signature that would distinguish water from one basin from other surface water in the area. Individual sampling sites may have a unique chemical composition due to a combination of water sources (e.g. groundwater from various aquifers, municipal water drinking water from Castle Rock Reservoir, municipal waste water, etc.).

For sample sites with contributions from baseflow and runoff, there could be strong seasonal changes in water quality as the mixture of groundwater, snow melt, and runoff changes through the year. **Figure 8-3b** shows data collected along the wet reach of Lee Coulee. October samples have elevated calcium, magnesium, potassium, sodium, and sulfate compared to other samples taken in other months. This difference is likely from an increase in baseflow contribution to the wet reach of Lee Coulee in October.

Some spring water quality is also seasonally-dependent if the spring's source aquifer is influenced by precipitation. Spring water samples collected from ponded areas can also receive runoff contributions which can influence the measured water quality. Baseline spring water quality will be discussed on an individual basis in **Section 9.0**.

8.2 GROUNDWATER BASELINE

Baseline describes the condition that exists prior to influence or potential influence of mining on a groundwater resource. Although baseline data is available for many mine areas, early mining preempted baseline data gathering in some areas of disturbance. Pre-law mining in Rosebud Mine Area E, Pit 6 and the south part of Area D, as well as Big Sky Mine Area A preempted collection of baseline data. The easternmost part of Rosebud Mine Area A and the southeast part of Area B were mined in the middle 1970's prior to the widespread installation of monitoring wells. Alluvial and bedrock wells installed in the early 1980's adjacent to EFAC between Rosebud Mine Areas A and Area B, began gathering data after mining had begun in the middle 1970's. Even though baseline data are absent from some areas, more than thirty years of monitoring data indicates change or lack of change to groundwater adjacent to

mined areas and is an insight to the effects of mining on groundwater resources. As mining typically does not affect water quality up gradient of mining, data from up gradient wells remain representative of background water quality.

Selecting wells and time periods as representative of baseline requires some level of judgment and discretion by the observer. One must have insight into if and when a long-term monitoring site became influenced by mining. Climate plays a significant role in the change in groundwater level and it is not always straightforward when to attribute a change in water level or quality to climate versus mining, particularly in alluvial wells.

Only water quality analyses that include all major ionic parameters were chosen to represent baseline water quality. Samples with obvious analytical errors such as reported lab errors, unbalanced charges, and obvious analytical or recording errors (e.g. analyte concentration that exceeds the total dissolved solids (TDS) concentration in a sample) were not included.

A number of wells that recorded baseline data are still active, although most have been mined through or abandoned for another reason. As the currently active monitoring sites may not have the exact location or completion as the baseline wells, direct comparison between baseline and current water quality is generally, but not directly, comparable.

8.2.1 Groundwater Regime

The local groundwater regime lies within the regional regime, although the systems may not be in direct connection. To understand the system response to stresses from mining, components of the local groundwater system must be understood. These components include recharge, discharge, aquifer parameters, water levels, flow, and water quality.

8.2.1.1 Regional

In the Montana part of the Powder River Basin, the regional aquifers are part of the terrestrial Upper Cretaceous geologic units that crop out north of Colstrip near the Yellowstone River (**Figure 4-3**). The Bearpaw Shale, at a depth of approximately 2,000 feet below the Colstrip area (Slagle and others, 1983), forms the lower confining unit for the overlying Fox Hills and Hell Creek formations. Together the Fox Hills and lower Hell Creek formations form a deep, artesian sandstone aquifer as much as 2,500 feet thick (Lewis and Hotchkiss, 1981). This regional aquifer flows north toward the Yellowstone, Powder, and Tongue rivers. Yields to domestic and stock wells generally are less than 70 gallons per minute (gpm) and may flow as much as 20 gpm under artesian pressure along major river valleys (Slagle and others, 1983). TDS concentration reportedly ranges between 600 mg/L and 3,500 mg/L based on data developed from the Montana Groundwater Assessment Program of MBMG. In the Colstrip area, the aquifer occurs at depths greater than can be economically tapped for stock or domestic supplies.

A confining unit in the upper Hell Creek Formation underlies the Paleocene Tullock member of the lower Fort Union Formation, where the fine-grained sandstones and coal beds of the Tullock aquifer generally averages a yield of 15 gpm (Lewis and Hotchkiss, 1981). A confining layer known as the Lebo Shale overlies the Tullock aquifer and underlies the Wasatch-Tongue River Formation aquifer. This aquifer produces about 8 gpm from sandstone and coal units and represents the local aquifer system (Slagle and others, 1983).

8.2.1.2 Local

The shallow, local water bearing strata in the Colstrip area include alluvium/colluvium, and bedrock units of the Tongue River Member of the Paleocene Fort Union Formation. Within the mine area the bedrock hydrogeologic units are designated as overburden, Rosebud coal, interburden, McKay coal, and underburden. Due to the low conductivity of the fine grained, laterally discontinuous and thinly bedded claystones, siltstones, and silty sandstones that make up the overburden and interburden units, they generally are not regarded as aquifers, although locally they may offer a limited water supply. Due to the lateral continuity and secondary permeability created by fracturing, the Rosebud and McKay coal seams are the most reliable sources of shallow groundwater in the area. However, the low transmissivity and low yield from the coal seams makes them a less than desirable source as a dependable water supply. The most reliable water supply comes from sandstone units in the underburden and thus most wells are completed in the underburden.

8.2.1.2.1 Aquifer parameters

The material making up the valley fill in the stream bottoms and adjacent terraces consists of alluvial and colluvial deposits of interbedded silts, sands, and gravel that are generally less than 40 feet thick. The hydraulic conductivity of these deposits is highly variable. Aquifer tests results from Rosebud Mine and Big Sky Mine are summarized in **Table 8-2** and **Table 8-3**. These results show a wide range of hydraulic conductivity. Depending upon location, the Rosebud and McKay seams may be confined or unconfined. Confined coal aquifers in the area are estimated to have a storage coefficient of .0001 (Western Energy Company, 1997).

8.2.1.2.2 Flow

Flow in the alluvial aquifers follows the gradient of the individual drainage. Flow direction in the bedrock aquifers is generally controlled by bedrock geologic structure. The series of low-displacement, down dropped normal faults across Rosebud Mine permit areas A, B and C influence flow direction from the highlands to the west, up gradient of mining. This is demonstrated by the potentiometric surfaces of the Rosebud coal and McKay coal **(Figure 8-5** and **Figure 8-6**). A sizeable stock pond is coincident with the groundwater mound between the west end of Rosebud Mine Area B and south part of Area C. An apparent recharge area also is visible in the higher elevations at the northeast part of Big Sky Mine Area A. In Rosebud Mine Area D and Area E, and at the Big Sky Mine, flow direction is south southeast toward Rosebud Creek.

Where saturated, alluvial and overburden aquifers are usually unconfined and represent the local water table. Depending on location, the Rosebud coal may be confined or unconfined. The McKay coal is typically confined. Both coals become unconfined and thinly saturated as they approach the crop limits. They are usually dry at the outcrop. Underburden wells typically have a substantial hydraulic head. A vertical downward gradient between all stratigraphic intervals is prevalent in all mine areas.

8.2.1.2.3 Recharge and Discharge

Recharge depends largely on lateral up gradient flow. Vertical infiltration from precipitation is limited by low precipitation and a high evaporation rate. There is some local recharge from snowmelt and precipitation in drainages and depressions. Fractured clinker permits greater infiltration of precipitation and surface flow and locally may be a source of recharge. Mine pits, sediment ponds, and stock ponds are also sources of local recharge. Local bedrock discharges are to alluvium and springs. Outcrop margins are generally dry except in EFAC and Lee Coulee, which have intermittent reaches fed by bedrock aquifers.

Lateral up gradient flow of saturated Rosebud coal is generally from the west at the Rosebud Mine and from the north to northwest at the Big Sky Mine (see **Figure 8-5**). Due to the removal of the Rosebud coal and aquifer during mining, each pit area creates a groundwater depression, which means that it is down gradient in all directions from adjacent, saturated Rosebud coal or saturated spoil. Where mining extends to the up gradient coal crop margin, normal lateral recharge is eliminated as the Rosebud coal does not extend up gradient. This condition exists in Area A, the north part of Area C and Area D. As a result recharge to these areas and the development of a spoil aquifer will take longer than mine areas with up gradient recharge.

8.2.1.2.4 Water Quality

Early water quality samples from wells and springs in the Colstrip area indicate a wide range of dissolved solids concentrations, from 420 mg/L to 5,860 mg/L (Van Voast et al., 1977). The chemical character of water from any of the bedrock aquifers is similar, but ionic concentration commonly varies from location to location. Aquifer mineralization and chemical signature cannot be used to distinguish stratigraphic position, location in the flow system, or areal distribution of aquifers. At the Rosebud Mine, total dissolved solids concentration (TDS) generally increases with increasing bedrock aquifer depth.

Sulfate is the predominant anion in most groundwater, generally followed by bicarbonate, although bicarbonate dominates in some samples. Calcium, magnesium, sodium, sulfate, and bicarbonate typically comprise more than 97 percent of all dissolved constituents in groundwater. Potassium and chloride are also common, but usually in very low concentrations. The quality of groundwater in the Colstrip area is a product of salt dissolution and, to a lesser degree, cation exchange. Salts are produced in recharge areas by weathering and oxidation and are then dissolved by percolating groundwater.

8.2.2 Alluvial Baseline

The unconsolidated geologic deposits of hydrologic interest in the immediate vicinity of the Rosebud Mine are Quaternary age alluvium and colluvium. Alluvium at the Rosebud Mine is found in EFAC (areas A, B and C), Stocker Creek (Area C), Cow Creek (Area D), Pony Creek (Area D), Spring Creek (Area D), and the tributaries to these drainages. At the Big Sky Mine, alluvium is found in Emile Coulee (Area A), Miller Coulee (Area A), and Lee Coulee (Area B).

The valley fill material that makes up the alluvium is typically composed of differing amounts of silt, sand, and gravel depending on degree of stream development. Alluvial thickness in the drainages varies depending on extent of drainage development and may be thinly saturated, seasonally saturated, or unsaturated. Alluvium is not regarded as a reliable source of water in the Colstrip area, although locally and seasonally it may serve as a source of livestock drinking water. Most of the streams are ephemeral and flow only in response to precipitation or runoff events. Alluvial monitoring well hydrographs reflect seasonal water level fluctuation, with levels rising in response to snowmelt and precipitation in spring and early summer, and declining in late summer and early fall. Many baseline measurements in alluvial wells were taken during periods of drought in the 1970's and 1980's. This strongly affects alluvial water levels and water quality. Alluvium is recharged mainly by precipitation and spring runoff events. Discharges from Rosebud coal and McKay coal contribute locally to flow and alluvial recharge in EFAC and Lee Coulee.

As indicated by Piper plots **(Figure 8-7** and **Figure 8-8)** and box and whisker plots **(Figure 8-9** and **Figure 8-10)** of single, initial baseline samples taken from alluvial monitoring wells at Rosebud and Big Sky mines, the dominant cations are magnesium and calcium, followed by sodium. The dominant anion is

sulfate. Rosebud Mine alluvial baseline samples have higher median concentrations of TDS and higher conductivity than the Big Sky alluvium largely due to higher concentrations of sulfate, magnesium, calcium, and sodium. In contrast to Big Sky Mine alluvium, Rosebud Mine alluvium has a higher median conductivity than bedrock water bearing units. Specific conductivity measurements place alluvial groundwater at the Rosebud and Big Sky mines into Class ll and Class lll groundwater. The median concentration at both mines is Class III.

8.2.2.1 East Fork Armells Creek

EFAC is an ephemeral to intermittent stream that flows through the Rosebud Mine. It flows between Area A and Area B in the east (downstream) part of the mine area, and Area B and Area C to the west (upstream). Most of the creek bed upstream of Area A is dry. Short stretches of intermittent flow have been identified downstream (see surface water discussion of EFAC). Ponded sections, facilitated by the presence of four small dams built to retain water for livestock, contribute to intermittent flow conditions. The stream has eroded through stratigraphically lower units as it flows downstream.

The thickest alluvial deposits at the Rosebud Mine are in EFAC where alluvium ranges to 40 feet. During baseline in the late 1970's through 1980's, water levels measured in alluvial wells reflect a period of drought. Initial water measurements indicate that alluvial wells contained between 11 feet and 35 feet of water, with an average of approximately 20 feet. During baseline, recharge to EFAC alluvium was restricted to stream flow and bedrock aquifers that subcrop and outcrop in the valley fill. Logs from wells installed in EFAC alluvium show gravel deposited onto Rosebud coal in Section 15, T2N, R40E and lateral to McKay coal in Section 4, T2N, R41E. Up gradient of Area B, alluvium is bounded by overburden and does not receive significant groundwater recharge.

Aquifer tests conducted in EFAC alluvium produced a lognormal mean conductivity of 3,865 gpd/ft and a lognormal mean storage coefficient estimated at 0.002 (Western Energy Company, 1984). Groundwater flow is variable, ranging between 18 gpm to 158 gpm.

Because early mining took place at the east end of Rosebud Mine Area B and Area A, there are few baseline samples from alluvium in easternmost EFAC. Changes to alluvial water quality recorded from wells in the east part of the drainage are discussed in the groundwater impacts section (**Section 9.2.5.1.1**). TDS concentrations of initial baseline samples in the central and west part of the drainage range from 1,330 mg/L to 4,680 mg/L. The average and median are 2,302 mg/L and 1,900 mg/L, respectively. Based on electrical conductivity, EFAC alluvial groundwater is Class ll and Class lll. During early observations of alluvial water quality in EFAC Van Voast et al., 1977, identified that TDS concentrations in EFAC were 50 percent greater downstream from the town of Colstrip than upstream of Colstrip. Early water chemistry also identified that water in alluvium upstream from Colstrip is chemically similar to water in the adjacent McKay coal bed.

8.2.2.2 Stocker Creek

Stocker Creek is an ephemeral stream that drains the north parts of Rosebud Mine Area C and the northwest part of Area A, joining EFAC north of Colstrip. Mining initiated in Area C in 1984 and in Area A in 1988 represents the first potential mining effects to Stocker Creek alluvium. Alluvial thickness in Stocker Creek ranges from 13 feet to 34 feet and wells have a saturated thickness of between five feet and 18 feet. Initial water level measurements in Stocker Creek wells indicate the alluvium held between two feet and 18 feet of water. TDS concentrations from initial baseline samples ranged from 1,720 mg/L

to 5,360 mg/L, with an average and median of 2,861 mg/L and 2,545 mg/L, respectively. Groundwater in these wells ranges between Class ll and Class lll.

8.2.2.3 Upper West Fork Armells Creek

The west and northwestern most parts of Rosebud Mine Area C drains to West Fork Armells Creek (WFAC). Baseline measurements began in the early to middle 1980's. Mining began in 2001 in the north part of Area C and in 2008 in the west part of Area C. Alluvial thickness ranges from nine feet to 19 feet and initial water levels in monitored wells ranged from two feet to 11 feet. TDS concentrations in initial baseline samples ranged from 1,800 mg/L to 5,230 mg/L, with an average TDS of 3,440 mg/L and a median of 3,570 mg/L. Groundwater in these wells is in the range of Class ll and Class lll.

8.2.2.4 Pony Creek and Cow Creek

Cow Creek, South Fork Cow Creek and Pony Creek are ephemeral tributaries to Rosebud Creek and drain Rosebud Mine Area D and Area E. Surface flow in Pony Creek and Cow Creek is ephemeral and occurs only during runoff events. Although monitoring of the alluvium in these drainages began as early as 1981, the results do not represent baseline as there was pre-law disturbance in the headwaters of these drainages.

Pony Creek flows east from Area D. Measurements in Pony Creek were taken as early as 1983 from a two- foot deep alluvial monitoring well near the head of the drainage at the permit margin. The well was often dry and monitoring was discontinued in 2007. As consultants to the Colstrip power plant, Battelle, a science and technology company, has installed and monitored wells in both Cow Creek and Pony Creek for water level and water quality changes associated with the Talen Energy power plant ash ponds in Cow Creek. Battelle's investigations indicate that Pony Creek has less than a foot of unsaturated, fine-grained alluvium (PPNL, 2000).

Cow Creek alluvial wells are mainly in the upland tributaries of the drainage. Monitoring wells in Cow Creek indicate alluvium in the main channel is 14 feet to 18 feet thick, with water levels between 6 feet and 16 feet below surface. The drainage is underlain by underburden and water levels in this unit suggest that it discharges locally into overlying alluvium (PPNL, 2000).

Aquifer pumping tests were completed in six wells in Cow Creek alluvium (Western Energy Company, 1983). Transmissivity estimated from these tests ranged from 350 gpd/ft to 72,000 gpd/ft. Test of five wells completed in tributary alluvium ranged from less than one gpd/ft to more than 6,000 gpd/ft.

Initial water quality samples (taken in 1982) from two wells in Cow Creek had a TDS of 2,060 mg/L and 3,120 mg/L. Two initial samples from wells in Pony Creek were 1,570 mg/L and 1,860 mg/L.

8.2.2.5 Spring Creek

Spring Creek flows northeast from Rosebud Mine Area D. Five alluvial wells were installed in Spring Creek or its tributaries in 1982 to 1984. The wells were dry or infrequently held a scant amount of water during the monitoring period that lasted through 1997. No water quality measurements were taken.

8.2.2.6 Miller Coulee and Emile Coulee

At the Big Sky Mine Area A, alluvial wells were installed in Miller and Emile coulees in the 1970's and early 1980's, after pre-law mining in the area had begun. Thus, the earliest monitoring data does not reflect baseline conditions but serves to document subsequent changes associated with mining and

reclamation in Area A that is discussed in the impacts section of this document. Both permit areas in Big Sky Mine (Area A and Area B) drain to Rosebud Creek, a perennial creek that empties into the Yellowstone River near Forsyth, Montana. Alluvial thickness in Miller and Emile coulees ranges between 12 feet and 31 feet. Changes to alluvial groundwater in these two drainages are discussed under the groundwater impacts section (**Section 9.2.5.2.1**).

8.2.2.7 Lee Coulee

Lee Coulee is an ephemeral to intermittent stream that flows through Big Sky Mine Area B into Rosebud Creek. Alluvial thickness varies from 28 feet in the upland part of the monitored drainage to almost 40 feet in the downstream area. Yields of 5 gpm to 50 gpm were measured during aquifer testing in alluvium of upper Lee Coulee. Baseline water level measurements in Lee Coulee and associated drainages ranged from dry to almost 40 feet of water in a well immediately up gradient of the Rosebud crop line (BSCC, 1988).

In uppermost Lee Coulee groundwater is discharged to the alluvial aquifer principally from the overburden aquifer and to a lesser degree from the coal and interburden aquifers. Where the main drainage widens and the coal crops are further upslope and away from the stream, alluvial water is lost to the underburden sandstone. Further downstream and still within the permit boundary, the saturated underburden discharges to the alluvium.

Water quality samples were collected as early as 1984 from a monitoring well network that spanned the length of the stream. The best water quality was near the head of the stream. TDS concentrations ranged from 436 mg/L to 3,630 mg/L, with an average and median of 1,956 mg/L and 1,840 mg/L, respectively.

8.2.3 Overburden Baseline

Bedrock strata above the Rosebud coal are referred to collectively as overburden. Overburden ranges in thickness from a foot or less near the coal crop to 250 feet in Rosebud Mine Area C. It consists of thin, discontinuous beds and lenses of brown to grey siltstone, claystone, and silty sandstones. Clinker is also found as overburden. Overburden locally may be recharged by snowmelt and rainfall, especially where clinker is exposed. Clinker thickness ranges from as little as 10 feet to 300 feet (Vuke et al., 2001). From a hydrogeologic perspective, these deposits are very permeable but generally the saturated thickness of clinker deposits is limited. Groundwater that is present in these deposits at the Rosebud Mine tends to be perched and is often hydraulically isolated from the underlying strata.

Where available, overburden groundwater is typically unconfined, perched, and produces little water although saturated thickness as great as 68 feet is reported at Big Sky Area B Mine (BSCC, 1988). Springs sourced by overburden have been identified at both the Rosebud Mine and Big Sky Mine. Rosebud Mine overburden has a wide range of transmissivity values, from 1 gpd/ft to 79,000 gpd/ft (**Table 8-2**; MDSL and OSMRE, 1983) which may be attributable to the variable lithologies in the overburden. Transmissivity values (**Table 8-3**) from aquifer tests in overburden at Big Sky Mine Area B ranged from 19.4 ft^2/day to 29 ft^2/day (3.7 gpd/ft to 209 gpd/ft) (BSCC, 1988).

In initial baseline samples from both the Rosebud and Big Sky mines, overburden water quality is dominated by sulfate, magnesium, and calcium, although it also trends to bicarbonate and sodium in some samples (**Figure 8-7;** and **Figure 8-8**). TDS in the overburden aquifer has a wide range in concentration, from 136 mg/L to 6,280 mg/L at the Rosebud Mine, and 356 mg/L to 3,920 mg/L at the

Big Sky Mine (**Figure 8-9** and **Figure 8-10**). Averages and medians for TDS from overburden at the two mines are 1,564 mg/L and 1,480 mg/L at the Rosebud Mine, and 1,666 mg/L and 1,200 mg/L at the Big Sky Mine. At the Big Sky Mine, overburden median TDS concentration and conductivity are lower than in the other water bearing units. Overburden baseline conductivity ranged from 455 μS/cm to 6,280 μS/cm at the Rosebud Mine and from 660 μS/cm to 4,310 μS/cm at the Big Sky Mine, which places overburden groundwater in Class I, Class II and Class III. Most wells produce Class II water. Locally, overburden baseline water quality meets suitability guidelines for livestock.

8.2.4 Rosebud Coal Baseline

The Rosebud coal aquifer is the aquifer most disturbed by mining because it is removed during mining. A full thickness of the Rosebud coal ranges between 18 feet and 25 feet and averages 22 feet. Pit margins commonly mark the extent of coal in most mine areas. Flow in the coal aquifers is controlled by secondary permeability caused by fractures. The results of aquifer tests in the Rosebud coal at the Rosebud Mine and Big Sky Mine are in **Table 8-2** and **Table 8-3,** respectively. As in all of the shallow, local bedrock aquifers, the main source of recharge originates from uplands west of active mining in the Rosebud Mine and north of mining in Big Sky Mine. Alluvium in downstream reaches of EFAC overlies Rosebud coal, forming a hydrologic connection between the two units.

The Rosebud coal aquifer may be confined or unconfined locally in both the Rosebud Mine and Big Sky Mine. Typically, unconfined conditions exist nearer the crop line. The Rosebud coal aquifer in Rosebud Mine Area C originally was confined near the middle of the permit area, with confined heads ranging between 30 and 70 feet above the top of the unit. The Rosebud coal was unconfined in all areas of Area D prior to mining. At Big Sky Mine Area B, the Rosebud coal aquifer was confined in the north and northwest parts of the permit area and unconfined in the south and southeast parts prior to mining. Although pressure head or water level have changed, the local status (confined or unconfined) of the Rosebud aquifer at Big Sky Area B remains as it was pre-mining.

The most common anion in baseline Rosebud coal groundwater samples from the Big Sky Mine Area B is sulfate (**Figure 8-7** and **Figure 8-8**). Anionic composition of Rosebud coal groundwater at the Rosebud Mine is equally sulfate and bicarbonate. Major cations in Rosebud coal groundwater at both mines are calcium and magnesium although sodium is dominant in some samples from Big Sky Area B. TDS concentration in Rosebud coal baseline samples ranged from 332 mg/L to 6,660 mg/L (average = 1,678 mg/L; median = 1,220 mg/L) at the Rosebud Mine and from 1430 mg/L to 4,300 mg/L (average = 2,411 mg/L; median = 2,020 mg/L) at Big Sky Area B (**Figure 8-9** and **Figure 8-10**). Based on specific conductivity, Rosebud coal groundwater at the Rosebud Mine is Class I, Class II and Class III, with most samples falling into Class II. At Big Sky Area B, Rosebud coal groundwater is Class II and Class III.

8.2.5 Interburden Baseline

The interburden between the Rosebud and McKay coal seams ranges in thickness from 10 feet to over 100 feet with an average thickness of 40 feet to 60 feet. Like the overburden, it is composed mostly of thin, discontinuous beds of siltstone and claystone and is not considered a productive water bearing stratum. It has the lowest geometric mean hydraulic conductivity of all water bearing units in the Rosebud Mine and Big Sky Mine (**Table 8-2** and **Table 8-3**). Locally, as in the east part of Area B at Rosebud Mine, the interburden may be saturated and appear to be in hydraulic connection with the McKay coal. In Rosebud Mine Area D where the interburden is notably thin, it has heads that vary to above the base of the Rosebud coal. At Big Sky Mine Area B, the interburden in the north and northwest part of the permit area is in hydraulic connection with the McKay coal.

As in most of the shallow aquifers, in interburden baseline samples, sulfate is the dominant anion. (**Figure 8-7** and **Figure 8-8**). At the Rosebud Mine, magnesium and calcium are the dominant cations. However, interburden samples at the Big Sky Mine have notably higher medians of sodium and potassium than at the Rosebud Mine (**Figure 8-9** and **Figure 8-10)**. Interburden baseline TDS concentrations at the Rosebud Mine range from 112 mg/L to 5,990 mg/L, with an average and median of 1,912 mg/L and 1,680 mg/L, respectively. Groundwater class includes Class I, Class II and Class III. Big Sky Mine Area B baseline interburden has a range of 1,720 mg/L to 3,670 mg/L with an average and median of 2,620 mg/L and 2,595 mg/L, respectively.

8.2.6 McKay Coal Baseline

The McKay coal is eight to 12 feet thick. It was the target of early mining in Big Sky Mine Area A, but has not been mined elsewhere in the Colstrip area. The McKay coal aquifer is generally confined except near outcrop boundaries. In Big Sky Area B, the McKay coal aquifer is confined more commonly in the northwest than the southeast. It was confined throughout Rosebud Mine Area C prior to mining with more than 100 feet of head commonly measured in monitoring wells. In Area D, it and was unconfined only in the northwest permit area.

As in the Rosebud coal, permeability in the McKay coal depends on the secondary permeability of fracturing. Based on aquifer tests, the McKay coal has a smaller range of hydraulic conductivity than the Rosebud coal (**Table 8-2** and **Table 8-3**).

In baseline samples, the water quality of the McKay coal is dominated by sulfate with few samples ranging to bicarbonate (**Figure 8-7**, **Figure 8-8**, **Figure 8-9**, and **Figure 8-10**). None of the baseline samples from Big Sky Area B are dominated by bicarbonate, only sulfate. Samples from the Big Sky Mine are not as dominated by calcium and magnesium as at the Rosebud Mine, and more commonly range to sodium. Potassium concentrations also typically are higher at Big Sky Mine Area B. McKay coal groundwater at both mines generally contains more sodium and potassium than the Rosebud coal. TDS concentrations in McKay coal baseline samples from the Rosebud Mine range from 380 mg/L to 5,770 mg/L, with an average of 1,213 mg/L and a median of 1,970 mg/L. At the Big Sky Mine Area B, TDS concentrations in McKay coal baseline samples range from 1,660 mg/L to 3,510 mg/L, with an average and median of 2,425 mg/L and 2,440 mg/L, respectively.

8.2.7 Underburden Baseline

The term “underburden” describes all strata below the McKay coal. It is generally composed of the same, fine-grained rock types found in the overburden and interburden but is distinguished by widespread sandstone and silty sandstone units with greater hydraulic conductivity and more reliable groundwater yield than found in overlying aquifers. The water bearing units are generally 50 feet to 100 feet or more below the McKay coal. It is the best shallow groundwater resource in the mine area and is utilized for domestic and livestock supply.

Monitoring wells in the underburden are completed at various depths, with an average of approximately 200 feet but a range to over 500 feet. Some contain as little as 19 feet of water and others as much as 330 feet of water. The head in some of the deeper underburden wells suggests that the aquifer is confined. Aquifer tests on three underburden wells near Rosebud Mine Area C had a transmissivity range from 58 gpd/ft to 933 gpd/ft with a lognormal mean of 205 gpd/ft (Western Energy Co., 1984). The underburden aquifer is both confined and unconfined in Big Sky Area B, with saturation measured

between one foot and 35 feet in unconfined locations with confined sections measuring almost 150 feet. The underburden maintains the downward vertical gradient common between the shallow aquifers in the area.

As in all the shallower aquifers, baseline water quality in the underburden is dominated by sulfate as the major anion. Calcium and magnesium are the dominant cations, but samples commonly trend to sodium as the dominant cation (**Figure 8-7**, **Figure 8-8**, **Figure 8-9**, and **Figure 8-10**). At the Rosebud Mine, underburden baseline samples had TDS concentrations that ranged from 890 mg/L to 4,460 mg/L, with an average of 2,034 mg/L and median of 1,905 mg/L. Baseline underburden samples at Big Sky Area B had TDS concentrations that ranged from 1,150 mg/L to 4,540 mg/L, with an average of 2,205 mg/L and median of 2,035 mg/L.

Baseline underburden groundwater is Class II and III at both the Rosebud Mine and Big Sky Mine Area B. Underburden wells are typically suitable for livestock use, and some are marginally suitable for domestic use.

9.0 HYDROLOGIC IMPACT & MATERIAL DAMAGE ASSESSMENT

As required by ARM 17.24.314(5), DEQ must provide an assessment of the cumulative hydrologic impacts of the proposed operation and all anticipated mining upon surface and groundwater systems in the cumulative impact area. The assessment must be sufficient to determine if the proposed amendment (AM4) at the Rosebud Mine has been designed to minimize impacts to the hydrologic balance inside and outside the permit area and to prevent material damage to the hydrologic balance outside the permit area.

9.1 MINIMIZATION OF IMPACTS AND PREVENTION OF MATERIAL DAMAGE

Montana's Strip and Underground Mine Reclamation Act requires permit holders to employ measures to minimize disturbance to the hydrologic balance on and off the mine plan area and to prevent material damage to the hydrologic balance outside the permit area. Per ARM 17.24.314(1), the proposed measures must minimize disturbance to the hydrologic balance sufficiently to sustain the approved postmining land use and the performance standards of ARM 17.24 subchapters 5 through 12, and must provide protection of:

> *"(a) the quality of surface and groundwater systems, within both the proposed mine plan and adjacent areas, from the adverse effects of the proposed strip or underground mine operations;*
> *(b) the rights of present users of surface and ground water; and*
> *(c) the quantity of surface and ground water within both the proposed mine plan area and adjacent areas from adverse effects of the proposed mining activities, or to provide alternative sources of water in accordance with ARM 17.24.304(1)(e) and (f) and ARM 17.24.648, where the protection of quantity cannot be ensured."*

Among these measures are requirements and performance standards given for a variety of processes and activities. These include requirements and standards for drainage control, pond design and maintenance, sediment control, road design and maintenance, reclamation, permitted discharges to surface water, and protection of undisturbed drainages.

Specific provisions for protection of and minimization of impacts to groundwater include requirement for prevention or control of harmful mine drainage into groundwater (ARM 17.24.643), restoration of the approximate recharge capacity (ARM 17.24.644), selective placement of acid and toxic forming materials in mine backfill to prevent leaching (ARM 17.24.501, 17.24.643), and permanent sealing of drilled holes (ARM 17.24.632).

In addition, adherence to Best Technology Currently Available (BTCA) and Best Management Practices (BMPs) in the design and implementation of facilities, equipment, devices, systems, methods, and techniques is required for the minimization of hydrologic disturbance. These requirements and performance standards established in ARM 17.24 subchapter 5 through subchapter 12 are incorporated into mine operation and reclamation plans.

As defined by Montana statute [82-4-203(32), MCA], "material damage means, with respect to protection of the hydrologic balance, degradation or reduction by coal mining and reclamation operations of the quality or quantity of water outside the permit area in a manner or to an extent that land uses or beneficial uses of water are adversely affected, water quality standards are violated, or

water rights are impacted. Violation of a water quality standard, whether or not an existing water use is affected, is 'material damage'". Each mine permit application must be designed to prevent material damage to the hydrologic balance outside the permit area [ARM 17.24.314(1)].

9.2 MINING IMPACTS

Impacts to the hydrologic system are expected as a result of mining. Groundwater and surface water will experience both short term and long term impacts that include diminishment of surface water flow due to sediment ponds placed below mine disturbance, drawdown of groundwater levels or declines in pressure head, and changes in water quality in both surface water and groundwater. Impacts to surface and groundwater are discussed in detail below.

9.2.1 Historic, Pre-law Mining

Mining in the Colstrip area by Northern Pacific (NP) from 1925 to 1958, left approximately 2,100 acres of pre-law mine spoils ("NP spoils") at or adjacent to Rosebud Mine Area D and Area E. Another pre-law area known as Pit 6, located adjacent to and south of Area E and was mined during the 1960's and 1970's. Extensive areas of Big Sky Mine Area A were also mined prior to enactment of MSUMRA. The mines are held to the reclamation standards in the law and rules in effect at the time of mining.

Approximately 460 acres of unreclaimed mine spoils and open pits remained in the current Area D permit boundary when Western Energy Company began mining Area D in 1986. Although the area had not been reclaimed, 40 to 50 years of vegetation colonization had occurred, resulting in development of grasses, forbs, shrubs and some trees in favorable habitats. Western Energy Company reclaimed parts of the pre-law disturbance adjacent to permitted mining, but small areas of pre-law mining disturbance remain unreclaimed. Pre-law spoils and pits significantly altered the pre-1925 (unmined) drainage topography, intercepting undisturbed areas above and creating large areas of internal drainage within the Cow Creek drainage basin and within the East Fork Armells Creek drainage basin.

9.2.2 Alluvial Valley Floors

As defined in 82-4-203(3)(a) and (b), MCA, "'Alluvial valley floor' means the unconsolidated stream-laid deposits holding streams where water availability is sufficient for subirrigation or flood irrigation agricultural activities. The term does not include upland areas that are generally overlain by a thin veneer of colluvial deposits composed chiefly of debris from sheet erosion and deposits by unconcentrated runoff or slope wash, together with talus, other mass movement accumulation, and windblown deposits".

MSUMRA requires that DEQ not approve an application for mining an alluvial valley floor (AVF) unless certain requirements are met [82-4-227(3)(b)(i)and (ii), MCA]. To make an AVF determination DEQ must make a finding regarding the existence of an AVF within or adjacent to any surface mine permit application in accordance with ARM 17.24.325.

In *re Permanent Surface Mining Regulation Litigation*, 1980 U.S. Dist. LEXIS 17722, at *70-71 (Dist. D.C. 1980), Judge Flannery noted that an alluvial valley floor must satisfy both geologic criteria and hydrologic criteria which together provide sufficient water to sustain agricultural activities. Thus, the key to the existence of an AVF is the presence of both geomorphic characteristics and water availability which together support agricultural activities, and unless both sets of criteria are met, an AVF does not exist.

The alluvial valley floor (AVF) decisions in the Colstrip area were made in the early to middle 1980's (**Table 9-1**). The Office of Surface Mining, Reclamation, and Enforcement (OSMRE) made a negative AVF decision for Big Sky Mine's Coalbank (Emile) Coulee in its December 1979 Technical Environmental Assessment (TEA) of the area based on the failure to meet the geomorphic criteria for stream channels. The Department of State Lands concurred with OSMRE's findings in a memo dated October 14, 1982. The memo stated that "Coalbank Coulee is cut in consolidated bedrock and subsequently filled with slope wash colluvial material. No alluvial terraces are present and the area …has historically been used as undeveloped rangeland" and "does not meet the requirements of an AVF as defined by ARM 26.4.325."

A more comprehensive study was conducted by Peabody Coal Company in the Lee Coulee AVF study, including detail on geomorphic features, soils, vegetation, irrigation, subirrigation, hydrology, and present and historic land use. In March 1986, The Department of State Lands published an AVF decision document for Lee Coulee. The determination stated that the Lee Coulee valley "contains alluvial fans, isolated terraces, residual surfaces, and aeolian deposits. As a result of this geomorphic description, the Department has determined that Lee Coulee and its tributaries meet the definition of upland areas, and therefore, do not satisfy the geologic criteria of an alluvial valley floor."

In the Rosebud Mine area, AVF decisions were made for East Fork Armells Creek, Stocker Creek, Pony Creek, Spring Creek and Cow Creeks. Only a part of Cow Creek and a downstream section of East Fork Armells Creek affirmatively met the definition of an alluvial valley floor. The decisions were based on rules in effect at the time of the decisions [per ARM 26.4.325(2)(b)]. These rules were similar but not identical to the current rules. [Note: A rule update subsequent to early AVF determinations has renumbered ARM 26.4.325(2)(b) to ARM 17.24.325(2)(b)].

The Cow Creek Alluvial Valley Floor Investigation in 1984 (Western Energy Company, 1984), notes that the agricultural land use in the Cow Creek Study area had been affected by construction activities associated with Montana Power Company's ash disposal pond. Alluvial/colluvial deposits along the main Cow Creek channel were excavated to provide materials for pond construction. This took hay fields out of production, including moisture-enhanced areas of vegetation. The total area of cropped fields was reduced from 338 acres to 279 acres.

The area of EFAC between Stocker Creek and Corral Creek (north of the surface water and groundwater CIA boundaries) is the only AVF identified in the Colstrip area. This section is downstream of the town of Colstrip and is subject to impacts from numerous sources other than mining. Changes in water level and water quality can be expected from leaks from ash ponds associated with the Colstrip Power Plant, discharge from municipal utilities in the town of Colstrip, and infiltration from the water storage facility known as Castle Rock Lake. There are no surface water sites within the AVF reach that have been monitored since 1985. A USGS stream gauge and sampling site has the longest record spanning 1975 to 1985.

9.2.3 Mine Surface Facilities

Rosebud Mine surface facilities are located in Area A and Area C. The Area A facilities are at the mine entrance, on the north side of EFAC. The facilities include an office complex and supporting infrastructure, shop for heavy equipment maintenance, warehouse, storage tanks for non-hazardous liquids, fuel storage and dispensing sites, lined sewage lagoons and evaporation ponds for wastewater.

The Area C facilities area is smaller but has similar support facilities that provide the same services found in Area A. Field support facilities include mobile oil and fuel trucks and electrical substations.

The Big Sky Mine also had similar support facilities in Area A. As the Big Sky Mine is in full reclamation, surface facilities are no longer present. Sampling and cleanup of surface contaminants was completed as part of the facilities closeout. Groundwater monitoring for contaminants in the former facilities area is ongoing.

9.2.3.1 Surface Facilities Impacts to Groundwater and Surface Water

Due to its close proximity, the water resources most likely to be affected by Rosebud Mine Area A facilities is the alluvial aquifer and surface water in EFAC. Increase in the concentration of chloride in surface water and alluvium from the use of magnesium chloride for road stabilization is evident in water quality samples of EFAC in Area A and Area B. Magnesium chloride salt is easily dissolved in water, and due to chemical properties of chloride that facilitate mobility, it has most likely moved into the surface and shallow groundwater system adjacent to the facilities area via infiltration from sediment ponds. Monitoring wells adjacent to roads in more remote areas of the mine also have elevated concentrations of chloride that likely results from the use of road stabilization compounds.

Infrequent releases and incidental spills onto the ground at fueling stations are excavated immediately and placed in the Rosebud Mine Area A landfarm for treatment. There is no indication of petroleum contamination in surface water or groundwater at the Rosebud Mine or Big Sky Mine.

The lack of nitrate nitrogen in water quality samples from EFAC alluvial wells indicates that the stream is not receiving contamination from the Rosebud Mine Area A sewage lagoons. Waste water from vehicle wash bays at maintenance shops in both Area A and Area C are routed to lined ponds for evaporation. Water quality analyses do not indicate contaminated fluids have leaked from these ponds.

9.2.4 Surface Water

Potential impacts to surface water from mining include impacts to wetlands, streams and springs. Determination of impacts has been hampered by sparse premine data due to pre-law and early mining in some drainage basins.

9.2.4.1 Wetlands

The oldest comprehensive wetland inventory for the Rosebud Mine was done in 1995 to determine jurisdictional status of wetlands and other waters of the U.S. (MME, 1995). At the time of the report, 66 wetlands comprising 27 acres of land were identified within and adjacent to the Rosebud Mine permit areas A, B, C, D, and E using the 1987 Corps of Engineers Wetlands Delineation Manual (**Figure 6-3**). Because the study was done during mining, many of the wetland features within the mine area occur around the edges of and downstream of temporary sediment control ponds. Other wetlands are associated with stock ponds and dikes created by ranchers to retain surface water. Almost half of the wetlands acreage was associated with the Area C permit, and these wetlands are predominately located in the West Fork Armells Creek watershed downstream of springs, and will not be affected by the proposed action.

Pond PO-151 is a permanent impoundment located immediately to the east of the power plant facilities within the Rosebud Area D permit. This pond has been left as a permanent impoundment for wildlife use and stock watering after mining at the southwest end of the current mine area. The pond is an

internal drainage within the Cow Creek basin. The pond was intended to replace some of the water resources and aquatic habitat associated with former pre-law Northern Pacific pit ponds. Surface runoff is not likely to overflow the deep closed basin because the pond surface is approximately 40 feet below the lowest surface outlet to Cow Creek tributaries. Groundwater recharge from the pond may supplement down gradient springs, stream reaches, and ponds in nearby tributaries. No water quality or quantity data has been collected at PO-151 and no wetland assessment has been done at the pond to determine the quality of habitat the pond is providing. The 1995 survey did not identify the perimeter of the pond as a wetland. PO-151 will not be affected by the proposed action.

The proposed AM4 amendment and associated disturbance area in Rosebud Area B do not contain any springs or stock water ponds. The amendment area would mine through upstream ephemeral reaches. No wetlands have been identified in the amendment area.

9.2.4.2 Changes to Surface Water Hydrology by Drainage

A discussion of impacts to surface water is given below. For each drainage basin, setting & mining history, pollutant sources and pathways, and relevant monitoring data are discussed. Impacts to the drainage basins below fall under the following categories:

- Alterations in surface and or spring flows from source aquifer drawdown
- Alterations in surface flows from disturbance of the watershed and stream channels
- Removal of tributary sources during mining
- Surface water quality changes from changes in source groundwater quality
- Surface water quality and quantity changes from MPDES discharges to surface water
- Water quality changes from runoff from mining infrastructure (roads & industrial facilities)

9.2.4.2.1 **Cow Creek**

Cow Creek and South Fork Cow Creek drain east to Rosebud Creek, with the ephemeral headwaters of these streams located within the Rosebud Area D and Area E permit boundaries. Pre-law mining occurred in Cow and South Fork Cow Creek drainages leaving behind spoil ridges and unreclaimed pits, altering the natural drainage pattern of the upper watershed. The last mine cut in the Cow Creek drainage was in Area D in 2010. Presently, there is no mining occurring in the Cow Creek drainage, and mine pits have been filled and are in various phases of reclamation.

In addition to mine-related impacts, east of the mine area, the Colstrip power plant uses ponds for the storage of ash in the Cow Creek basin (see **Section 9.3.1** on impacts to alluvial wells).

Premine baseline surface water data is limited due to the extensive pre-law mining in the headwaters of Cow Creek, and do not allow meaningful comparisons of pre and postmine water quality and quantity conditions. The most extensive set of surface water data comes from one monitoring station: spring SP-26 located adjacent to Area D mining.

In the Rosebud Mine Area D permit and previous CHIAs, SP-26 was predicted to potentially experience decreased flow from mining. Spring SP-26 is located in an upper Cow Creek tributary on the life of mine disturbance boundary and a quarter mile south of the nearest mine cut. The spring is within the permit boundary. It is sourced by the McKay coal aquifer, and the McKay coal was not mined in the area. The area up gradient of the spring has a large outcrop of clinker, and the clinker and coal units may be in communication with each other. The spring was not disturbed, but a portion of the drainage area upstream of the spring has been disturbed.

Prior to mining, flow at SP-26 was observed to range between 3 gpm to less than 0.5 gpm with a median of 1 gpm (**Figure 9-1**). The lowest flow measurements were made in the late fall and winter when the spring could have been partially frozen. In late 1996 water levels in the nearby McKay well WM-125 rose by approximately 0.3 ft and remained near 3,254.5 ft until 2002. When mining started up gradient in 2001, SP-26 experienced a delayed reduction in water quantity while WM-125 responded more immediately. Water levels decreased in WM-125 by up to 0.4 ft, and flow from SP-26 decreased by almost 0.5 gpm, and the spring was reported as dry or nearly dry on multiple field visits during this time. Spring flows during these time periods reflect the variability in precipitation over the monitoring period. In late 2005 water levels and flows started to recover in WM-125 and SP-26, respectively. Similarly, recovery of water levels and coincides with a series of years in the middle to late 2000's with higher than average precipitation. The spring and well are located in the vicinity of a large clinker area.

Water quality (TDS) during this period reflects the variability in precipitation (**Figure 9-1**). Prior to 2006, TDS in SP-26 had shown seasonal variation on the order of 250 mg/L or less. After 2006, seasonal variation in TDS increased up to 800 mg/L. There are no obvious means for mining to have introduced higher TDS water to SP-26: there are no large sediment ponds upstream of SP-26 that could have leaked into the source aquifer; up gradient spoils have only one to two feet of water so the spoils remain almost dry, and the McKay aquifer was left intact. TDS measured in WM-125 does not strongly correlate with TDS measured at SP-26. The increase in TDS could be a result of increased flushing of previously unsaturated horizons from years with increased precipitation, thereby increasing seasonal TDS concentrations at this spring. Regardless of the cause of the temporary increase in TDS and decrease in flow, the spring is within the permit boundary so the requirement to prevent material damage does not apply. Furthermore, because the premine water quantity has returned to the spring thereby providing the same premine beneficial use to the area, any disturbance of the hydrologic balance is minimal. The proposed action will not affect the Cow Creek drainage basin.

9.2.4.2.2 East Fork Armells Creek

EFAC is divided into two segments for the purpose of issuing MPDES permits: an upper section that encompasses the headwaters down to the state highway and a lower section that includes the segment from the state highway to the confluence with West Fork Armells Creek. For analysis of surface water impacts in this CHIA, this division is important as the two segments of the creek behave differently and therefore have different applicable standards.

Upper EFAC is predominately ephemeral and is flanked by active mining activity along most of its length. Some channel segments of the upper section have defined channels while other segments have less defined channel bottoms. In many places in the upper section, the stream bottom has been widened by cattle (see **Appendix A**). Small reaches of flowing water exist, and these are associated with instream stock dams. While livestock grazing and channel use by livestock occurs in areas upstream of mined areas, coal mining activity (open pits, reclaimed lands, sediment ponds, roads, mining facilities, and associated infrastructure) dominates the potential anthropogenic pollutant sources in upper EFAC.

Lower EFAC has large reaches with intermittent to perennial flow. While no coal mining occurs adjacent to lower EFAC, the reach is influenced by coal mining activity upstream and in Area D. In addition to upstream coal mining, anthropogenic sources affecting water quality and quantity in lower EFAC include:

- runoff and infiltration from recreational and residential lands
- runoff from road and transportation infrastructure

- sewage treatment plant discharges
- runoff and infiltration from agricultural lands
- Infiltration from industrial treatment ponds

Mine pits adjacent to EFAC in areas A, B, and C were initiated close to the alluvium in the 1980's and 1990's and have progressed away from the creek. The dewatering of adjacent strata and the withholding of runoff in ponds and pits have contributed locally to lower water levels in the alluvium and reduced the volume of baseflow in EFAC where alluvial water contributed to streamflow. Spatially and temporally limited surface water flow data, however, precludes more meaningful analysis of past flow losses from alluvial depletions.

Pit water meeting the MPDES discharge standards has been discharged via MPDES outfalls directly into EFAC, and there has also been seepage from sediment ponds into the alluvium. Since a new and more reliable continuous flow monitor was installed in late 2011 at SW-55, located immediately upstream of the state highway crossing of EFAC, it has recorded the presence of water for almost all of 2012 (**Figure 9-2**), a relatively dry year. The upgrade in instrumentation is also coincident with a period of increased discharges to EFAC. Crest gauge data combined with the continuous recorder at SW-55 indicates that this area may routinely have flowing or ponded water for months out of the year. The flow data coupled with observations during regular mine inspections of EFAC indicate that the reach between the Area A facilities area and the Area A Tipple has intermittent to perennial water, at least since 2011. Sources of water in this reach may be from discharges and infiltration from sediment ponds up gradient and adjacent to this stream reach as well as baseflow from alluvial groundwater. This reach currently may be artificially enhanced by discharges and infiltration. Conversely, drawdown in the alluvium from mining may have greatly reduced the contribution of natural baseflow from the alluvium in this area in the past. The history of the presence and absence of water in this reach can only be speculated due to lack of surface water monitoring between the Area A facilities and the Area A Tipple after baseline data collection, long periods of poorly functioning instrumentation, and few water quality samples from SW-55.

Aquatic life surveys were conducted in the middle to late 1970's along EFAC and Rosebud Creek. Total counts of macroinvertebrates were low, and sampling methodologies differed between the 1976 and 1978 studies. Additionally, samples taken in November and December are outside of the range of months now accepted for macroinvertebrate studies. The 1970's surveys are only used as a general analysis of stream habitat conditions and are not used to determine specific stressors (e.g. inorganics, organics, metals, sediment, temperature, or water quantity). In general, taxa richness was similar at all the sites sampled along East Fork Armells Creek (**Table 6-3**). Of the three years sampled, the highest number of taxa was in 1978. As 1978 was one of the wettest years (**Figure 4-2**), the stream habitat was likely enlarged from the extra runoff and baseflow. The 1970's surveys provide an indication of the presence or absence of aquatic life but cannot be used to assess the quality of the habitat or stream water. The surveys indicate that, in the past, there has been sufficient water at the sites that were sampled to provide aquatic habitat and support a number of aquatic species.

The 1995 wetland assessment identified two reaches on EFAC between the Area A Tipple and SW-55 as wetlands (**Figure 6-3**). This section of EFAC has been observed in recent years to have larger stretches of intermittent to perennial water with wetland vegetation than was identified in 1995 (see **Appendix A**, photos 5 – 7 and 10 – 12). Since it is unlikely that the 1995 assessment missed wetland features that were present in this reach, it can be concluded that the extent of the 1995 wetland area has grown. This area was also chosen to be sampled in the 1970's as part of a macroinvertebrate inventory. The site

chosen was immediately upstream of the Area A mine entrance and has been observed to have at least intermittent water since 2011. In the 1981 report, the sampling location was described as having insufficient flow for macroinvertebrate sampling. “The site was located at a point above which streamflow seldom occurred. Standing or slow moving water is usually present below Station No. 3 and reflects the effects of groundwater contribution” (Schwehr, 1981).

In 2014, another macroinvertebrate survey was conducted in the stream reach between the Area A Tipple and SW-55. The sampling methodology, which followed DEQ’s WQPBWQM-009 (2012), differed from the methodologies used in the previous studies so that taxa richness may not be directly comparable. However, the survey demonstrated that a diverse community of macroinvertebrates was using the stream reach. Therefore, the reach currently meets the narrative standard of providing a beneficial use for aquatic life.

Figure 9-93 shows sulfate through time at various intermittent reaches on EFAC, and samples that would violate the guideline sulfate toxicity threshold listed in **Table 2-3** are circled in red. Sulfate limits for aquatic life are typically 2,000 mg/L due to the very high hardness of the stream water. Even in baseline samples, the sulfate thresholds for aquatic life were exceeded. Macroinvertebrate communities in Eastern Montana are likely adapted to high sulfate water.

In the 1980’s, when mining was closest to EFAC and many of the ponds next to EFAC were the most active, water quality samples from ponds near EFAC in the reach between the Area A Tipple and SW-55 routinely had chloride concentrations over 100 mg/L. Chloride concentration in mine pit water is not usually elevated above background levels, and consequently the chloride in these samples from the 1980’s is not attributed to natural groundwater or spoils. As mining moved away from the stream into the basin’s headwaters, the concentration of chloride in the ponds declined. The high chloride at this time was likely from operational activities, such as the use of magnesium chloride on active haul roads. Presently, high chloride concentrations are found in surface water and alluvial water samples in the reach between the Area A Tipple and SW-55. In 2012, chloride concentration in surface water in this reach was as high as 464 mg/L. From 2012 through 2014, 4 out of 5 samples from SW-55 had chloride concentrations above 100 mg/L. SW-55 receives flow from runoff events, MPDES discharges, and baseflow from alluvium (**Figure 9-2**). Groundwater infiltrating from ponds at the power plant flows towards the stream and mixes with alluvial water by SW-55. Bottom ash and flyash ponds within 0.7 miles of SW-55 have had chloride concentration that ranged from 181 mg/L to 807 mg/L (PPL Montana, 2014). The high chloride concentration at this site is likely from flushing of chloride in the soil and alluvium by the WECo Area A facilities in addition to chloride from the leaking power plant ponds. The current uses of the water in the vicinity of the intermittent reaches are for livestock, wildlife, and aquatic life. Further downstream on EFAC, the water is also used for irrigation. Because the stream still maintains its C-3 uses (primarily aquatic life, non-salmonid fishes, and agriculture) per ARM 17.30.629, the beneficial use of the stream is still maintained. The proposed mine plan is designed not to contribute additional chloride to the stream because lignin sulfonate will be used on roads instead of magnesium chloride.

While the reach of EFAC between the Area A tipple and SW-55 has seen an artificial increase in surface water due to mine operations, other reaches have experienced a reduction in intermittent and ephemeral flows. Capture and containment of water in sediment control ponds from ephemeral tributaries in mined areas can decrease the amount of runoff and/or flow delivered to EFAC. The sediment ponds cause a reduction in storm-driven flows in EFAC.

Baseflow in EFAC by SW-55 is predicted to experience a postmine increase in TDS of 13%, elevating the average concentration of TDS to almost 2,600 mg/L (Western Energy Company, 2015). The increase in TDS comes from spoil replacing the Rosebud coal as the aquifer feeding baseflow to the stream. This increase will not occur until the spoil has resaturated and groundwater flows from the spoils to the alluvium of EFAC. The proposed action will increase the volume of spoils generated by the mine, and groundwater from the recharged spoils may ultimately become baseflow in the creek. The postmine water quality should continue to support livestock use, although the water quality in the stream may be diminished from premine quality. Western Energy Company will continue to periodically conduct macroinvertebrate surveys to monitor the vitality of both aquatic life and habitat available in EFAC. Surface water quality and quantity sampling will continue at SW-55 on EFAC. Because the creek should be able to support its designated beneficial uses, even when spoil water contributes to baseflow, the proposed mine plan is designed to prevent material damage.

SP-28, located close to the EFAC channel, was listed as destroyed by mining in the 1986 baseline observations for the Rosebud Mine Area B permit. In November 1979 this spring was estimated to have between 5 and 10 gpm of discharge and was thought to originate from the overburden. The spring was likely destroyed in 1983 when a mine cut went through the area immediately upstream of the spring. While no data was collected on the spring's water quality or quantity (besides the one estimated flow), the discharge from the spring would have likely contributed to surface water flow in EFAC near the Area A tipple. The proposed action will not create additional disturbance to this area.

Two sections of upper EFAC (a reach in T1N R40E Section 8 and a reach in T1N R40E Section 15) were identified in the middle 1980's as possessing intermittent to perennial flow (**Figure 6-3**), and both of these reaches are currently observed as being ephemeral (see **Appendix A**, photos 3 and 17). The reach through T1N R40E, Section 8, is upstream of mining in Areas B and C and directly upstream of a large stock dam (PO-937) on EFAC. The reach through T1N R40E Section 15 is also upstream of an instream dam.

The Section 15 reach contains a premine stock pond built directly into the channel, and the approximately 20-foot thick alluvium. This portion of EFAC has a small segment of alluvium directly on top of the Rosebud Coal; upstream the alluvium sits on overburden and downstream the coal has been eroded away and the alluvium sits on top of interburden (**Figure 9-92**). The Section 15 reach was included in an aquatic and stream water quality survey done prior to mining in the area in 1970's. At this time, the reach was described as follows: "There has always been sufficient flow [below the small impoundment on the creek] to sample for water chemistry, however, flow is often too low to sample for invertebrates… This is one of the few locations on the creek upstream from Colstrip which has at least some flow through most of the year…" (Schwehr, 1981). In the Area B permit, the baseline description of the area was of "A short reach of East Fork Armells Creek in the northwest quarter of Section 15 hav[ing] flow throughout the year. A flow of 12 gpm at the west edge of Section 15 was measured in June of 1984. There was no flow at this point in August of 1984 although approximately 10 gpm was flowing into PO-929" (WECo, 1986). A 1995 wetlands survey identified the reach as having a segment of wetlands (MME, 1995), and water quality samples from this stretch were collected from approximately 1977 through 1983. In field visits in 2014, DEQ staff observed this area as a dry grassy channel bottom with some riparian trees (**Appendix A**, Photo 18 and 19).

Alluvial water levels in EFAC near the Section 15 reach started to steadily decline starting in the mid 1980's and continued to decline through the 1990's (**Figure 9-92**). Mining adjacent to the reach started in 1992 and was as close as 300 feet to the channel. The longest monitored alluvial well, WA-209,

started to decline in water levels in 1989 with the biggest decreases occurring in 1993 and 1995. Water levels in WA-209 dropped a total of approximately 10 feet before going dry in 1999, and the well has been dry ever since. The alluvial water levels indicate that this area experienced both natural (starting in the mid to late 1980's) and mine-related (steep declines in 1993 and 1995) drawdown. The nearest spoil well, WS-191, is located in the B Extension area (the B-extension pit was mined in 1999), and the well has been dry since installation in 2008. There are no spoil wells currently north of the Section 15 reach in the areas that were mined in the early to middle 1990's. No records exist on the historic status of the instream dam in this section through the years, but the dam is currently intact. The dam may have been the source of some of the water in the stream, but from the early descriptions of the reach, the reach may have been a gaining reach for at least some parts of the year during the 1970's and early 1980's. Mining activities such as cutting off tributaries to EFAC could have reduced the amount of runoff reaching the Section 15 instream pond and reach. This section may see a return of some instream ponding once the upstream sediment ponds are removed. The resaturation of the spoils and restoration of the premine groundwater gradient may also help to restore some baseflow. If flow returns, postmine water quality will depend on both runoff water quality from tributaries and possibly on spoil water quality. There are no surface water rights listed with the DNRC for East Fork Armells Creek through Section 15.

In summary, it is unknown whether there was premine baseflow in EFAC in Section 15, nor is the quantity of water known. Statements as to the nature of this section premine are anecdotal. Since the nature of this section was not well documented in the 1970's, past material damage to this section cannot be determined. While macroinvertebrates were documented using the water in Section 15 in the 1970's, it is unknown if water was present every year, only in wet years when runoff accumulated behind the instream dam, or only after years where the alluvium was saturated to the point of baseflow. Without knowing the true nature of the stream flow and the interaction between groundwater and surface water, a determination of material damage cannot be made.

Alluvial wells near the Section 8 reach measured a decline in water levels of approximately 5 feet from 1980 (the earliest measurement) through 1985. The years from 1983 through 1985 were below normal precipitation years (**Figure 4-2**). From 1985 until 2011, water levels were relatively stable and changed by less than 2 feet. After the large 2011 precipitation event, water levels have increased by 8 to 10 feet in the alluvial wells near Section 8. No observations were made of the presence or absence of surface water in the Section 8 reach after the 2011 recharge. The Section 8 reach may only be fed by baseflow after large recharge events and may be normally dry. Since this reach is also upstream of PO-937, the observed water in the 1980's may actually have been ponded water that was backed up into the reach from the instream dam. Alluvial water levels near the Section 8 and 15 reaches are discussed in **Section 9.2.5.1.1**.

Regardless of the nature of the reaches in Section 15 and Section 8, the proposed permitting action will have no effect on the reach. Therefore, DEQ finds that the proposed action is designed to prevent material damage to these reaches.

One spring has appeared in reclamation in Rosebud Mine Area C permit within the EFAC basin. Spring SP-46A has been monitored since 2001 (**Figure 9-3**), and is thought to be sourced from spoil water. TDS in the spring water has generally increased since monitoring began. The increase in TDS is mainly a result of increasing sulfate with minor contributions from small increases in calcium, magnesium, and sodium. In contrast, bicarbonate has decreased in concentration over time.

While changes to EFAC have been seen adjacent to the Rosebud Mine (areas A, B, and C), the magnitude and extent of surface mining impacts to EFAC downstream of mining (Colstrip and beyond) are difficult to quantify because of the contributions of additional industrial and municipal surface and groundwater water impacts in the Colstrip area. Proposed amendment AM4 would not significantly increase anticipated hydrologic impacts to surface water resources within and adjacent to the mine area or downstream in EFAC. Water quality of runoff in well vegetated postmine channels is expected to be similar to premine runoff water quality. During mining and while vegetation is re-establishing, sediment ponds and other best management practices would treat or retain runoff thus preventing excess sediment from entering EFAC. After the final stage of reclamation (phase IV bond release), surface water quality from the disturbed East Fork Armells Creek tributaries should be similar to premine water quality with no water quality changes expected for stock or wildlife use in the reclaimed drainages. Postmine baseflow in EFAC by SW-55 will be influenced by spoil water quality, and the baseflow will have increased TDS, mainly in the form of increased sulfates. The mining from AM4 will create increase the amount of spoils, but groundwater in these spoils will not move to EFAC.

9.2.4.2.3 Lee Coulee

The Lee Coulee drainage flows to the southeast into Rosebud Creek, and is predominantly ephemeral with some intermittent reaches. Mining in the Lee Coulee drainage began at the Big Sky Mine Area B in the early 1990's. The final pit at the Big Sky mine was mined in 2003. The Rosebud mine's Area B has cuts permitted within the Lee Coulee drainage basin along the drainage divide between EFAC and Lee Coulee.

Water quality in Lee Coulee is highly variable due to a mixture of runoff dominated flows and some reaches with groundwater dominated baseflows. The intermittent reach within the permit boundary experiences both types of flow regimes; at station BRTFL on the intermittent reach section, measured TDS (1984 through 1997) ranged from 220 mg/L during a February sampling event to 4,330 mg/L during an October sampling event. Median measured TDS was 2,700 mg/L.

Impacts to Lee Coulee surface water flow from mining are monitored at flume BS33FL which is located downstream of all mining in Lee Coulee (**Figure 9-4**). Starting in the 2000's, large flow events at BS33FL have become less frequent. Upstream of mining, at flume BPSFL, flows have become less frequent in general, although large flow events have become more frequent and larger. The changes in flows at both of these monitoring sites coincide with mining in the area and a climate period where annual precipitation varied widely. The change in flow characteristics in Lee Coulee downstream of mining are a combination of a shift in precipitation patterns as well as reduction in flow due to mining operations. The following paragraphs describe impacts from mining that have been observed in Lee Coulee.

Discharge of water to Lee Coulee from Big Sky ponds B-9 and B-22 began in late 1989 and in 1994, respectively, and ceased in June 1997. Monitoring wells below these discharge points experienced ground water level rises on the order of 10 to 15 feet, peaking in about 1995 to 1996 at wells closest to the discharge point. A 14-foot ground water level rise was observed downstream, outside the permit area, at well BAL2711. At this well, the peak occurred in about 1996 to 1997. The artificially recharged alluvial groundwater moved slowly down Lee Coulee. No significant changes to Rosebud Creek water quality were observed during this time (**Figure 9-5**).

The last of the sediment retention ponds were removed from Lee Coulee in 2013 allowing more runoff to leave the mine. The removal of the ponds will not likely degrade water quality leaving Lee Coulee and entering Rosebud Creek because the reclaimed mine area is well vegetated and flatter than premine.

The flatter and well vegetated reclamation area will result in less sediment and runoff leaving the site compared with premine.

Lee Coulee had a 'wet reach' through the Big Sky Mine Area B which was used by wildlife and was fed by baseflow from overburden and Rosebud coal aquifers from the north and northwest. The reach was intensively studied between 1989 and 1995 to determine the premine characteristics and to monitor impacts during the initial years of mining. This reach contains three dugout instream depressions which were likely created for livestock watering. Aquatic life and vegetation surveys focused on the three ponded areas where surface water would linger the longest throughout the year, although some samples were also collected in other segments of the creek. The aquatic life surveys concluded that the most upstream site had less diversity than the two sites downstream. The reduced diversity was theorized to be associated with increase stress on the ecosystem due to a more ephemeral setting with more sediment in the pond (BSCC, 1997). Overall, the taxa that were found had a high tolerance for poor water quality and stagnant water conditions. Taxa richness declined coincident with increased mining activities in the drainage (**Table 6-3**).

Pit dewatering and drawdown of coal, overburden, and adjacent alluvial aquifer water levels reduced and even eliminated intermittent flows in the Lee Coulee wet reach. The intermittent Randy Thomas site (BRTFL) is within the Lee Coulee wet reach, and flow monitoring recorded reduced baseflows beginning in 1994 after groundwater levels were drawn down by mining of adjacent pits (**Figure 9-4**). Mining drawdown appeared in alluvial wells in this area in 1993. Runoff events at the BRTFL site were also captured by upstream sediment ponds and mine pits. Stream baseflows are predicted to recover as backfilled spoil material saturates (see **Section 9.2.5.2.7**). The re-constructed portion of the wet reach of Lee Coulee has yet to exhibit persistent flowing water as of the end of the 2013 water year, but the unmined section of the wet reach has been observed to have water and riparian habitat (see **Appendix A**, photo 14). Monitoring stopped at the BRTFL site in 2001 and resumed at the same location in 2014 to determine if baseflow is recovering.

Two postmine end-pit ponds were created during reclamation in tributaries to the main Lee Coulee drainage (see **Appendix A**, photos 15 and 16). These ponds were left to provide postmine wetland and wildlife habitat as well as livestock drinking water, and the ponds are fed by up gradient unmined coal aquifers.

The quality and quantity of postmine spoils water entering Lee Coulee from the Big Sky Mine and its alluvium will largely dictate postmine surface water conditions in the coulee. As a result of mining and reclamation in Lee Coulee, there is a potential for change from premine conditions in the location and timing of groundwater flow from bedrock to the Lee Coulee wet reach. The quality of groundwater that will eventually discharge from spoils at the west end of the Big Sky Mine, adjacent to and within Lee Coulee will affect the restored wet reach. Both mining in Big Sky Area B and Rosebud's Area B could contribute spoil water to this reach. As this reach is entirely contained within Big Sky's permit boundary, changes to water quality will not result in material damage. Because Lee Coulee is ephemeral below the Big Sky mine permit boundary, this spoil water is unlikely to reach Rosebud Creek via surface water flows. **Figure 9-93** shows sulfate concentrations through time in the intermittent reach of Lee Coulee. Compared to EFAC, Lee coulee has fewer exceedances of the guideline sulfate criteria. Postmine baseflow from spoils could result in increased sulfate in this reach. The potential impact to the macroinvertebrate community is not known; the species found during premine studies are common in Eastern Montana and therefore they may be adapted to high sulfate water.

Springs within the Lee Coulee basin have been noted off the main drainage channel and toward the drainage divide. SP-78 is located immediately outside of the southern boundary of Rosebud Mine Area B. This spring was noted in the Rosebud Mine Area B baseline survey as discharging an estimated 4 gpm in May 1986 with an overburden source. This spring has not been observed since the initial baseline survey, but it was predicted by the mine to possibly experience a reduction in flow from mine-related drawdown. Further south in the Lee Coulee basin there are five springs that were monitored by the Big Sky Mine. These are Bailey Spring, Gumdrop Spring, Headwater Spring, P.P. Seep, and Section 29 Spring.

Water quality samples were collected from P.P. Seep from 1985 through 1995, and the median field conductivity during that period was 1,053 μS/cm. During baseline observations in 1985, it was noted that the seep dried up during the late summer and came back in the late fall. The seep has now been dry for years. Headwater Spring has been monitored for water quality since 1985 and is still actively monitored. This spring tends to have less than 1 gpm of flow at the time of monitoring (usually visited in March or April and again in August or September). A perched overburden aquifer on top of clinker is theorized as the aquifer source for the spring, and it was thought mining would not impact the spring. Field conductivity has remained consistently between 2,000 μS/cm and 3,000 μS/cm. Gumdrop Spring has consistently had water since the start of monitoring and usually has less than 1 gpm of flow during semiannual observation. The Section 29 Spring was sampled for water quality from 1989 through 1992, and in the early nineties it was mined through. It is unknown if another spring will return to the area. Median conductivity measured in the field was 1,706 μS/cm during the monitoring period. The land around Bailey Spring was undisturbed by mining, and the spring has never been monitored or sampled.

The proposed expansion of mining in Rosebud Area B in AM 4 is will not affect the water quality in the Lee Coulee drainage. Spoil water from Area B AM 4 cuts will not contribute to surface flow.

9.2.4.2.4 Miller Coulee

Little flow or water quality data has been collected in Miller Coulee due to the age of the mine disturbance. Mining at Big Sky Area A started before baseline hydrologic data was required, and consequently no baseline data exists for the drainage. Although the edges of the mined area are blended into the steeper topography, the middle of the mined area was reclaimed to a landscape of low relief with hay fields at the southern portion of the permit area. The mined area is also in the headwaters of the drainage. Due to these factors, flow in the area is ephemeral.

In Miller Coulee, a seep fed by spoil water has developed in the drainage bottom (see **Appendix A**, photo 13). Water quality samples were collected from the seep at 6 locations in May 2011 and May 2012. TDS ranged from 4,110 mg/L to 5,590 mg/L in 2011 and from 3,840 mg/L to 22,100 mg/L in 2012. In 2011, the full analytical suite in Big Sky Mine's monitoring plan was completed for the samples. Sulfate was the dominant ion in the samples with concentration ranging from 2,580 mg/L to 3,910 mg/L, and the second major component was bicarbonate with concentrations ranging from 455 mg/L to 823 mg/L. Despite the high sulfate concentration, pH measured in the field remained neutral to alkaline: 6.9 to 7.9. In this area, high TDS is not correlated with a notable increase in metals or trace element concentration.

In 2012, the year with the highest measured TDS concentrations, only TDS, conductivity, and pH were measured, and consequently it is unknown what cation, anion, or combination of analytes contributed to the extremely high TDS. In 2012, two samples taken from small pools of ponded water in the seep area had TDS concentrations over 10,000 mg/L. These sites had more than a 4-fold increase from 2011 to 2012. This large increase in one year is may be a result of evaporative concentration in the pooled

water and is not an indication of large changes in spoil water quality. TDS concentration in spoil up gradient of the seep has ranged from 3,510 mg/L to 4,510 mg/L, which is similar to the range of TDS concentration (3,840 mg/L to 5,590 mg/L) in the seep samples from 2011 and 2012 when the two samples over 10,000 mg/L are excluded. This area of Miller Coulee was mined prior to the enactment of SMCRA in 1978, and therefore material damage criteria do not apply. Furthermore, because the proposed mining in AM4 will not contribute water to Miller Coulee, the proposed action is designed to prevent material damage.

9.2.4.2.5 Pony Creek

The Pony Creek drainage is monitored by the Rosebud Mine for potential impacts from mining and by PPL as a reference creek in a program to monitor for power plant impacts to Cow Creek drainage. Consequently, a large data set has been created on water quality and quantity for the creek, springs, and alluvium in Pony Creek.

In their PHC analysis of hydrologic impacts from mining in Rosebud Area D, Rosebud Mine predicted that spring SP-24, located near the head of Pony Creek, could potentially experience significant impacts to quantity and quality from mining. Spring SP-24 has a source in Rosebud coal, and the spring feeds a pond, PO-917, created by the landowner for livestock use. The spring was expected to experience reduced flow during mining and increased dissolved solids concentrations after mining. The spring was not consistently monitored for water levels during mining and no flow measurements were taken. The spring was reported as dry for a number of years after 1992 and water level monitoring was subsequently abandoned. Water quality samples were taken through the middle 1990's at SP-24, indicating that the spring was not continuously dry. Three water quality samples from the middle 1990's are much higher in TDS than all of the other water quality samples (**Figure 9-6**). Ignoring the three outlier samples from the 1990's, starting in 2006, the TDS concentration has been elevated by approximately 200 mg/L to 500 mg/L. The cause for this increase is not known, and the change could be some combination of changes in precipitation patterns, evaporation at the sampling point, and changes to groundwater from mining operations (e.g. drawdown in the coal aquifer, artificial recharge from sediment ponds, etc.). TDS from spring GSP-7 is also shown in **Figure 9-6** for a comparison. GSP-7 is over 4.5 miles downstream from SP-24 in the Pony Creek drainage, and the source aquifer is unknown. This spring is outside of the influence of the Area D mine and shows variation in concentration from sources unrelated to mining. TDS concentration varies widely from a minimum of approximately 300 mg/L to a maximum of 3,300 mg/L. As demonstrated by GSP-7 and the middle 1990's data at SP-24, variation of water quality at springs unaffected by mining can be on the same order of magnitude or greater than increases that may be attributable to mine practices. The conditions in Pony Creek do not indicate the existence of material damage at this time because changes in water quality cannot be correlated with mining activities. The proposed mining in AM4 will not contribute water to Pony Creek, therefore the proposed action is designed to prevent material damage.

9.2.4.2.6 Rosebud Creek

Impacts to Rosebud Creek would come from changes in water quality and quantity in major tributaries including Lee Coulee, Miller Coulee, Cow Creek, Pony Creek, Hay Coulee, and Spring Creek. Because upstream mining disturbance is more extensive in Lee Coulee, Miller Coulee, Cow Creek, and to a lesser extent, Pony Creek, mining impacts are most likely in these drainages, but have been predicted to be insignificant below their junctions with the much larger Rosebud Creek drainage (**Table 9-2**). Because of more limited surface disturbance in Hay Coulee and Spring Creek, mining impacts to these surface water systems are expected to be limited to the upper reaches of the drainages within and near mined areas, and would be difficult to detect in the lower reaches near Rosebud Creek.

Two stations on Rosebud Creek upstream (BURCXS) and downstream (BUSGS) of Lee Coulee were used to determine if hydrologic impacts to Lee Coulee could be detected in Rosebud Creek. TDS is shown in **Figure 9-5** as a general indicator of changes in water quality. In general, the variation in TDS between the two stations is usually less than 100 mg/L, and the station downstream of Lee Coulee recorded higher TDS than the station upstream of the creek. Flow measurements were taken on the same day at the two stations from 1989 to 1993, and these measurements indicate that Rosebud Creek may be a losing reach around the confluence with Lee Coulee. Using the flow measurements in conjunction with water quality samples, a total dissolved solids load was calculated for these two monitoring stations. The salt load reveals that Rosebud Creek gains salt between these two monitoring points. The concentration of TDS measured at the downstream station has not increased over time, and similarly no trend can be seen in the difference in concentration between the upstream and downstream stations.

Figure 9-5 shows that most water quality samples collected since 1980 on Rosebud Creek near Lee Coulee have exceeded the water quality standard for specific conductance defined in ARM 17.30.670. While most samples exceed the standard for specific conductance, they also are mostly are below the standard for SAR. One sample collected in 1990 was excessively high for SAR, but analysis of the complete analytical data set indicates that this high SAR is likely due to a reporting error; the sample had an anomalously high sodium and low sulfate indicating that these two analytes may have been transposed during reporting.

The proposed action is designed to prevent material damage to Rosebud Creek because as of 2013, there has not been a change in water quality in Rosebud Creek that can be directly attributable to mining in Lee Coulee, Miller Coulee, Cow Creek, Pony Creek, Hay Coulee, and Spring Creek. The drainage area and volume of water carried by Rosebud Creek is much larger than the volume of water contributed by Lee Coulee, and consequently the water chemistry of Rosebud Creek is dominated by runoff and groundwater contributions upstream of Lee Coulee.

9.2.4.2.7 Spring Creek

The Spring Creek drainage immediately downstream of mining in Rosebud Area D contains seven springs and three stock ponds. Five springs and two stock ponds are currently sampled for water quality: SP-23, SP-43, PO-921 in one tributary and SP-44, SP-90, SP-91, and PO-808 in a more eastern tributary to Spring Creek. Baseline data on these surface water sites mainly consisted of one or two water quality samples before mining which is inadequate to characterize the range of water quality that would have been seen at the springs and ponds in the absence of mining. Flows have not been measured at the springs, but some water depth measurements have been taken.

Impact analysis by Western Energy Company for the Area D PHC focused on spring SP-23 in this drainage. Spring SP-23, in upper Spring Creek just north of Rosebud Area D mining disturbance, is in a narrow canyon bottom below the Rosebud coal outcrop at the base of a 10 foot to 15 foot Rosebud-McKay interburden sandstone headcut. The spring is within the permit boundary. The top of the McKay coal is exposed on an adjacent canyon wall. SP-23 was predicted to be potentially impacted during mining by disturbance of the source aquifer and by interception of upstream surface runoff by the mine. After mining, Spring SP-23 was predicted to possibly experience increases in total dissolved solids from up gradient mine spoils contributions, however, changes to water quality may take decades before they are realized due to the very slow recharge rate in the spoils aquifer. The impacts to SP-23 were predicted to be small because of limited mining impacts expected in the McKay aquifer, and smaller contributions assumed from up gradient Rosebud coal and overburden sources. To date, TDS

concentration from summer samples in SP-23 has increased over time from approximately 1,000 mg/L in 2000 to over 3,200 mg/L by 2013 (**Figure 9-6**). Potential changes to pond water quality downstream of SP-23 are less evident due to the variable mixing of spring water and runoff water. However, any changes in water quality or quantity would not be material damage because the spring is within the mine's permit boundary.

Spring SP-43 has also experienced an increase in TDS concentration, although the data set is limited to four samples. TDS has increased at SP-43 from approximately 2,000 mg/L to over 4,000 mg/L. Trends in water quality for other springs are more difficult to quantify due to the small number of samples and yearly variability in water quality.

Increasing TDS concentration in SP-23 and SP-43 are not correlated with changes in precipitation, and up gradient spoils are unlikely to have saturated to a level to cause discharge into the springs. The cause of the increase in TDS cannot be attributed to a single mechanism, and may be within the natural variation of the system. There are sediment retention ponds, ponds 80 and 80A, along the mine disturbance boundary up gradient of the springs. No discharge or pond water quality or quantity data have been collected at these ponds and outfalls, and therefore there is currently no evidence to link spring water quality changes to mining operations. If spring water quality is affected by sediment retention ponds at the margins of mining, water quality should return to near baseline water quality as reclamation progresses in Area D and ponds are removed. The proposed mining with AM4 will not affect the Spring Creek drainage, and therefore the proposed action is designed to prevent material damage.

9.2.4.2.8 Stocker Creek

Mining in Rosebud Mine's Area C permit has disturbed the headwaters of Stocker Creek. The Area C mine facilities is also located in the headwaters. The creek is mostly ephemeral, but intermittent flow has been observed in some sections, especially after the 2011 recharge event. Springs are found in the drainage basin's headwaters and provide water to stock ponds and short downstream reaches. Water quality can be naturally poor in some spring-fed ponds. For instance, pond PO-938 which is located immediately north of the Area C facilities, is sourced by spring SP-03 (see **Appendix A**, photo 1). Both the spring and pond have sulfate over 2,500 mg/L with one sample from SP-03 in 1986 having a sulfate concentration of 8,100 mg/L. These sulfate levels are not attributable to mining disturbance because operations did not start up gradient of the spring and pond until the 1990's. High chloride (over 20 mg/L) has also been found in surface water samples prior to mining. Many of the areas with high chloride were located next to the county road, which was unpaved at that time. High chloride was also detected on Stocker Creek all the way down to its confluence with EFAC and in springs far removed from mining impacts. High chloride in the late 2000's may be attributable to mine operations, agriculture, or county road maintenance, but a definitive source for the chloride has yet to be identified.

Stocker Creek flume SW-65 has been monitored since the early to middle 1980's and is one of the few sites with a continuous recorder located in an intermittent flow reach (see **Appendix A**, photo 2). The Stocker Creek flume is approximately 0.6 miles downstream of mining in Area C. Although there are a number of gaps in the record, the site has had stream flows in this reach of Stocker Creek that are variable in periodicity ranging from weeks in the spring snowmelt period to nearly perennial flow in wetter years (**Figure 9-7**). The Rosebud Mine has also discharged pit water into the stream at various times during mining, including in 2005 and 2006, which can be seen in **Figure 9-7**. Stocker Creek at SW-65 went through a prolonged period from 1999 through 2009 when no flows were recorded with the continuous recorder. However, crest gauge readings indicate that water did occasionally flow in the stream. If the continuous recorder was functioning properly, this drier period may only have had very

short ephemeral flows such that the daily flows averaged out to zero. In 2012, the site experienced a long period of flow for almost the entire year. The flow in 2012 is a result of the 2011 precipitation event which recharged the alluvium and possibly some shallow perched aquifers in the Stocker Creek drainage. Water quality samples taken in February and May of 2012 had TDS concentrations of 3,940 mg/L and 4,610 mg/L for daily average flows of 0.14 cfs and 0.08 cfs respectively.

The proposed mining with AM4 will not affect the Stocker Creek drainage, and therefore the proposed action is designed to prevent material damage.

9.2.4.2.9 West Fork Armells Creek

Impacts to WFAC surface water resources occur in the upper portion of the drainage. Mining along the drainage divide between WFAC and Stocker Creek occurred from 2001 through 2007, and mining in the Rosebud C West area started in 2008 (**Figure 9-8**).

Springs are prevalent in the WFAC drainage. Actively monitored springs SP-34, SP-35, SP-37, SP-63, SP-67, and SP-76 are part of the surface water monitoring network used to monitor for potential impacts to surface water resources from mining. These springs were monitored due to their potential to be impacted by mine-caused drawdown in their source aquifers. SP-34 and SP-67 are derived from an overburden aquifer, SP-35 and SP-37 are from the Rosebud aquifer, SP-76 is from a Rosebud and clinker aquifer, and SP-63 is from the McKay aquifer. All of the springs have seasonal changes in TDS and ponded water levels (**Figure 9-8**). TDS measured at these springs varies widely from around 800 mg/L (SP-37) to over 3,700 mg/L (SP-63). While some springs, such as SP-37 and SP-67 have relatively consistent TDS concentrations through time, other springs such as SP-63 and SP-34 have had large changes in TDS through time. SP-63 has had large changes in chloride concentration. The two highest concentrations, 40 mg/L and 43 mg/L, were in late 2005 and 2011 respectively. These years correspond with high precipitation years. SP-63 is downstream from a county road and the mine's haul road. The high chloride at this site may be related to runoff laden with magnesium chloride mixing with the spring water at the sampling point, however trends in magnesium concentrations were not correlated with trends in chloride concentrations at this spring. Even when mining was closest to the springs, in the early to middle 2000's, the springs were observed to produce similar water quantity to the baseline condition.

One small spring has appeared in reclamation in Rosebud Mine's Area C permit within the WFAC basin. Spring SP-112A is sourced from recharge in spoil water but is located on an unmined area north of the Area C pits. In contrast to SP-46A, the other newly emerged spring in Area C, there is no trend in water quality from 2011 through 2013 (**Figure 9-3**). Compared to the first sample collected in 2008, the concentration of TDS has decreased by over 1,000 mg/L.

The proposed mining with AM4 will not affect the West Fork Armells Creek drainage, and therefore the proposed action is designed to prevent material damage.

9.2.4.3 Postmine Topography

9.2.4.3.1 Disturbance Area & Basin Size

The main impact to surface water hydrology from open pit mining is the disturbance of drainage basins and channels and the subsequent changes in the timing and volume of sediment and runoff from disturbed areas. During mining, runoff from disturbed areas is routed to sediment ponds where the water is either discharged downstream, retained and used in mine operations, infiltrates, or evaporates. The amount of anticipated mine-impacted land is shown in **Table 9-2**. As seen in **Table 9-2**, the total life of mine disturbance area is a significant portion of some drainage basins such as Lee Coulee, EFAC

upstream of the junction with Stocker Creek, and Stocker Creek. The overall impacted area of the greater Armells Creek watershed is 8% and the area impacted in Rosebud Creek's watershed is 1%. Inclusion of pre-law mining would increase the total disturbance area due to coal mining.

The proposed postmine topography (PMT) and reclamation plan alters the shape of the sub-basins and drainage characteristics (**Table 9-3**; **Figure 9-9**). Alteration of drainage basins has already occurred because reclamation has been ongoing at the mines for decades. Most changes to major drainage divides have occurred from mining in Rosebud's Area D. Area D is located on top of drainage divides that separate four drainage basins: EFAC, Cow Creek, Pony Creek, and Spring Creek.

The proposed increase in mining in AM4 would result in an expansion of the life of mine disturbance area. The proposed mine cuts would be located near the drainage divide with Rosebud Creek and cut into small tributaries of EFAC. These tributaries have already been partially mined through, and many of the lower reaches of the tributary drainages have already been reclaimed. The existing haul roads that would be used to access the additional proposed mining areas were built along the premine drainage channels, and these roads are proposed to be reclaimed as the postmine tributary channels. Because the proposed expansion of mining would be within the EFAC drainage basin, the proposed expanded mining operations in Area B would not alter the size or shape of the EFAC drainage basin.

9.2.4.3.2 Aspect & Slope

Analysis of slope and aspect premine and postmine is done by comparing digital rasters derived from premine and postmine topographic contours provided by the mine. While an approved postmine topography (PMT) is required of the mine as a permit condition, the PMT is rarely built exactly as it is initially drawn. For example, changes in the location of spoil piles, haul roads, and volumes of spoil may lead to deviations from the approved PMT plan. The PMT provides a general plan for the postmine landscape, and therefore any analysis done with the PMT is only an estimate of what the reclaimed landscape will be.

The proposed AM4 mine plan would include mining into steeper, more diverse upland and ridge topography. These areas would be reclaimed to less steep terrain with fewer headwater tributaries and reduced topographic diversity. A comparison of the distribution of slope within the permit area from the premine topography and the proposed postmine topography indicates that the proposed postmine topography would decrease the area with less than 6% slope and increase the area with slopes between 6% and 14% (**Figure 9-10**). Slopes steeper than 14% would be reduced. Compared to the currently approved PMT, the proposed PMT would have less area of steeper slopes.

The increase in areas with slopes between 6% and 14% mainly comes from drainage bottom side slopes formed by reclamation of haul roads as incised drainages. The ephemeral tributary drainages would be reclaimed as wider, incised drainages than existed premine. The analysis of change in slope does not account for topography smaller than 30 square feet (the spatial resolution chosen by DEQ for the analysis of the topography), and small-scale topography may account for a large portion of Rosebud Mine Area B premine topographic diversity, particularly in the areas nearest the drainage divide. Narrative commitments in the permit commit the Rosebud Mine to adding topographic diversity beyond what is drawn on the PMT.

The compass orientation or aspect of slopes in Area B will also change in the proposed reclamation plan. In general, compared to the premine landscape, the AM4 PMT would reduce the premine north and northeast facing slopes in favor of more east and southeast facing slopes. Again, this change is largely a

result of the wide haul road drainages that will run mostly south to north and have east and west facing slopes. The changes in aspect and slope may result in less and shorter snow retention as well as affect the composition of vegetative communities that reestablish during reclamation. Postmine reductions in premine slope complexity, drainage density and topographic diversity would result in fewer leeward slopes for snow drift accumulation and storage and reduced soil moisture variability. Related hydrologic changes would include longer overland flow paths, greater infiltration losses from surface runoff, and reduced peak flows and runoff volumes.

The cumulative impact of mining on slope and aspect is shown by drainage in **Figure 9-11** and **Figure 9-12**. Most drainages will contain fewer steep slope areas as rugged areas are replaced by more gentle rolling topography. Steep areas within reclamation come mainly from high wall reduction areas where steeper topography may be permitted to replace premine features. Steep areas also may occur along new stream valleys that are usually along haul roads and final mine pits. Shallower slopes are predicted to lead to less runoff and erosion during storm events; shallower slopes result in lower runoff velocities which allow for more infiltration time and less energy for sediment transport. Changes to aspect in the drainage basins are mostly minor due to the size of the drainage basins compared to the area disturbed by mining. Most expanded mining, however, would occur in the headwaters of the drainages, and consequently changes to aspect, even if it is a minor percentage of the total drainage area, may have measurable impacts to the surface water hydrology. The headwater areas of drainages are the steepest and often the most topographically diverse areas of a drainage basin.

The proposed changes to the post mine topography do not indicate the existence or the possibility of material damage because the topography approximates the premine topography. Consequently, water retention and runoff is expected to be sufficiently similar that downstream water users will be able to receive a similar quantity of water after mining to the premine condition.

9.2.4.3.3 Runoff Modeling

Changes in theoretical runoff volume and flow are modeled using HEC-HMS and HEC-GeoHMS, a software program for modeling storm-driven runoff developed by the Army Corps of Engineers. For this analysis, a hydrograph from a single hypothetical storm event is modeled over ephemeral drainages, and consequently the model cannot give a seasonal or yearly average. The model simulates runoff from a summer storm event when the ground has low residual moisture and the drainages have no baseflow. All drainages are modeled as ephemeral because there is insufficient data to model intermittent reaches of Lee Coulee or East Fork Armells Creek or the contributions from springs to baseflow in some drainage reaches. Similarly, in stream stock ponds are not modeled due to a lack of data on the volume of the ponds and the amount of seepage through the dam and pond floor. Even with all of these limiting assumptions, the premine and postmine models allow for a comparison of changes in runoff flow from changes in topography.

The HEC-HMS model is a simplistic representation of the ephemeral drainages. The model results presented in this report are only meant to demonstrate the effect of changes to stream length, drainage basin size, and infiltration rates on the response of theoretical storm-driven runoff events and are not meant to be used for predicting actual premine or postmine channel flows. A detailed list of input parameters for the models is included in **Appendix B**.

Inputs for the HEC-HMS model are taken from the premine and postmine topography (**Figure 9-9**). All calculations of premine and postmine channels and basins are derived from a digital elevation model created from the premine and postmine contour lines submitted by the mines. While basin shapes do

not differ from those derived by the mine operators, channel lines differ because of different methodologies to derive channel lines from topographic models. For instance, in some areas the HEC-HMS model does not include subchannels to the detailed level drawn by the Rosebud Mine, while in other areas the HEC-HMS model may draw more channels than was included on the maps provided by the mine.

Curve numbers (CNs) are derived from national land use and soil maps as described in **Appendix B**. Curve numbers differ from the simplified estimates reported in the Rosebud Mine permit due to different methodologies used to estimate the curve number or the hydrologic condition, a qualitative assessment of vegetative density and establishment. Consequently, runoff estimates from the model presented in the CHIA will differ from those presented in the mine permits. Without intensive field measurements, the true curve numbers for the area cannot be known, and both DEQ and mine estimates are made with equally valid yet different assumptions. Postmine curve numbers are estimated from averaging premine soil properties within the life of mine disturbance boundary and recalculating the curve number within each mine permit area. This method of averaging assumes that the only postmine change in soil is a mixing of the premine condition and that no additional compaction occurs during reclamation. Premine and postmine vegetative communities are assumed to be similar.

As a consequence of these assumptions, the only differences between premine and postmine runoff models are a result of a change in the topography or curve number. Consequently, the models differ in drainage basin size and shape, stream lengths, basin slope, average basin curve number, and channel slope. Models are created for East Fork Armells Creek, Stocker Creek, West Fork Armells Creek, Cow Creek, Spring Creek, Pony Creek, Lee Coulee, Miller Coulee, and Hay Coulee. A series of storms are modeled to demonstrate the response of the basins to a variety of precipitation events. A 2-yr 24-hr (1.5 inches of rain), 10-yr 24-hr (2.45 inches of rain), 25-yr 24-hr (3.0 inches of rain), and 100-yr 24-hr (3.8 inches of rain) NRCS Type II storm was modeled. The resulting peak flow, time of peak flow from the start of the storm, and total runoff volume are presented in **Table 9-4**.

As shown in **Table 9-4**, East Fork Armells Creek, Stocker Creek, and Lee Coulee are modeled as experiencing measurable (more than a few percent change) decrease in runoff volume and peak discharge for at least some of the storm events. West Fork Armells Creek is modeled as experiencing a measurable decrease in runoff volume for the 2-yr 24-hr storm but an increase in runoff volume for the 10-yr 24-hr storm. Peak discharge is modeled as increasing for all of the modeled storm events. As would be expected, the drainages with the largest changes in modeled runoff characteristics are also the drainages with the greatest mine disturbance relative to their entire basin size (**Table 9-2**). Most changes to runoff characteristics are from changes in average curve numbers for the subbasins and not from changes in basin size or drainage reach characteristics. Many of the major drainage basin channels, such as EFAC, are outside of the permit boundary and do not change from the premine to the postmine model. Basin morphological characteristics such as overall slope and area are proposed to be reclaimed to similar premine conditions. As stated earlier, estimation of curve numbers is one of the most imprecise model properties and subject to the widest variation in possible valid postmine values.

Since the AM4 amendment area is upstream of current mining activities in Area B and would not disturb new drainage basins, the amendment would not result in any further decrease in natural runoff to drainages downstream of the mine during operations. Premine and proposed postmine drainage basin size, land use, and vegetation are similar enough that no significant change in the quantity of runoff or peak discharge is expected between the currently approved postmine reclamation plans and the proposed postmine reclamation plans. The proposed action is designed to prevent material damage to

the hydrologic balance because the difference between the premine and post mine drainage basin size, land use, and vegetation, should not result in an increase in total suspended solids from the premine condition, and the runoff volume and timing should be sufficiently similar that downstream users may receive similar quantities of water to the premine condition.

9.2.4.3.4 Effects of Ponding During Mining

Retention of runoff water in sediment control ponds and the discharge of water from these ponds change the natural surface water hydrology. Sediment ponds at the Rosebud and Big Sky mines are generally designed to retain runoff from storms up to 2.4 inches (10-yr, 24-h recurrence), and typically have additional storage volume for three or more years of projected sediment loss from disturbed drainages above them. Design requirements for sediment ponds result in at least temporary interception of all but the largest storm or snowmelt runoff events. Snowmelt runoff (usually in February or March) and successive spring storms (heaviest from April through June) can result in more frequent pond discharges from precipitation. Dewatering of mine pits into ponds can also result in planned discharges at any time of the year. Sediment control ponds are unlined and therefore pond water also infiltrates into shallow groundwater aquifers.

Multiple sediment ponds in drainages with significant mining activity can impact local hydrologic patterns during mining. The type and extent of impacts depend on site specific factors, including: number of active ponds, level of mining activity, amount of pit pumping, and the timing and magnitude of storm and snowmelt runoff. The cumulative effects of Rosebud Mine sediment ponds on EFAC surface flow and chemistry below the mine permit area are further complicated by the Colstrip power plant and municipal water uses within and adjacent to Colstrip.

Seepage losses and surface discharges of stored runoff or pit water from disturbance perimeter sediment ponds can affect flows in down gradient alluvial aquifers and streams. The effects of individual sediment ponds would generally be limited to adjacent streams and their alluvial aquifers, unless pond contributions are significant relative to those of the receiving channel or aquifer. For example, an intermittent to perennial flow reach was created in an ephemeral reach of Lee Coulee below Big Sky Mine pond B-9, which discharged nearly continuously from November 1989 through November 1991, and from April 1993 through September 1995. Big Sky Mine pond B-22 had similar discharges from September 1994 through July 1996 and from September 1996 through June 1997. Similar changes in surface flow regimes resulted from episodes of pit pumping from Rosebud Mine Area B pits with discharges to East Fork Armells Creek above Colstrip (most recently in October 1999 through April 2000 and March 2012 through June 2012).

Sediment pond discharges usually meet MPDES water quality effluent limitations. A list of exceedances of MPDES water quality limits since 2010 is given in **Table 9-5.** The two enforced violations were for exceeding total suspended solids limits: 70 mg/L (daily maximum). In typical discharges, water quality is similar or lower in suspended solids than storm runoff from local undisturbed drainages. In pond discharges with large amounts of groundwater from pit pumping, dissolved solids are usually higher than in ephemeral runoff from local undisturbed drainages. The 2012 MPDES discharges into EFAC shown in **Figure 9-2** were comprised mainly of pit water, and large discharges into EFAC can significantly increase flows in the creek.

Pond discharges are controlled and regulated under the MPDES permit, and adherence to the MPDES permit ensures that material damage will not happen outside of the mine permit.

9.2.4.4 Surface Water Quality: Analytes with Multiple Sources

Surface water quality impacts were analyzed by grouping large amounts of surface water data into five-year increments. **Figure 9-13** through **Figure 9-17** are spatial maps showing aggregated time frames. These maps show water quality for springs, ponds, and streams. Springs are sourced from a variety of aquifers ranging from alluvium to sub-McKay, and spring water is often ponded and may receive some runoff contributions.

9.2.4.4.1 Boron

Boron is a trace element naturally found in soils, sea water, and some rocks. Boron is essential for healthy plant and animal growth, but high concentrations can lead to boron toxicity in both plants and animals. As of 2014 there are no DEQ-7 human or aquatic health limits for boron (**Table 2-1**). However, livestock water quality guidelines and EPA long-term health advisory guidelines recommend boron to be less than 5 mg/L in water (**Table 2-2**). Boron concentrations in coal vary by depositional environment as coal deposited in brackish environments will have higher concentrations than coal deposited in freshwater environments. As a result, boron in some coalfields may be more concentrated than in others.

Median baseline concentrations of dissolved boron from 932 samples from stream, spring, and pond water is 0.2 mg/L with a 75th percentile at 0.38 mg/L and a 90th percentile at 0.91 mg/L. Fifteen of the 25 baseline monitoring sites with boron above the 90th percentile were east of the state highway in Cow Creek, Pony Creek, and Spring Creek with the other 10 monitoring sites in Lee Coulee, Stocker Creek, and EFAC (**Figure 9-13**). Baseline samples were collected in years ranging from 1972 to 2013 with the majority of samples taken in the 1980's and 1990's. Data collected from sites during non-baseline has a median concentration of 0.24 mg/L with a 75th percentile at 0.6 mg/L and a 90th percentile at 1.2 mg/L.

Bottom ash, which is known to contain elevated concentrations of boron, was approved to be used on haul roads in permit Areas A, B, C, and D in 2000 with the stipulation that visual vegetation monitoring be conducted along the haul roads and that samples be taken from the bottom ash stockpiles to analyze for boron. Bottom ash use on haul roads was reported in 2000, 2009, and 2012. Use of bottom ash on roads has not been correlated with high boron concentrations in downstream surface water sampling locations. High boron concentrations in Spring Creek, Pony Creek, and a tributary to Cow Creek downstream from Area D were measured before bottom ash was used along the haul roads, and elevated boron has not been detected in EFAC where haul roads adjacent to the creek were also approved for bottom ash application. High boron concentrations are also not associated with coal or spoil aquifers. Boron is almost always below 1 mg/L in spoil wells and is not found in spoil wells at concentrations above 1.4 mg/L.

Elevated concentrations of boron in EFAC are likely from water leaking from the power plant ash ponds and ponds at the power plant facilities mixing with EFAC surface water. Boron is part of a group of elements known as oxyanions (along with As, Mo, Sb, Se, and V) which are most mobile in the neutral to moderately alkaline pH range (Jones, 1995). Since groundwater in the Colstrip area is moderately alkaline, boron is expected to be very mobile. Boron oxides from ash become dissolved in water and are easily leached from the ash particles where it can then rapidly travel downstream or down gradient. Boron detected in tributaries in Cow Creek down gradient from the ash ponds and slurry pipelines is from the leaking ash ponds and former leaks in the pipelines. Boron in samples from the power plant's facilities ponds have ranged from 0.2 mg/L to 854 mg/L (PPL, 2014). The wide range of concentration is a result of various amounts of dilution in the ponds; some of the power plant ponds receive water from multiple sources.

An additional source of boron at some surface water sites may also be from air-borne sources. According to Finkelman (1995), boron is mostly bound to the organic constituents of coal. Boron is an element whose behavior is somewhere between a volatile element (becomes depleted in the solid phase and enters a gas phase during combustion) and a semi-volatile element (volatilizes but will condense onto ash particles). Meij (1995) reported on the concentration of trace elements from different phases of ash collection at coal power plants in the Netherlands. In the study boron was found to be successively concentrated from the original coal into the bottom ash and even more into the fly ash. Boron that is volatilized and emitted from the power plant may subsequently fall onto vegetation and open surface water down wind of the facility. Some of the monitoring sites with high boron are also downwind from the Colstrip power plant and/or the Colstrip Energy Limited Partnership (CELP) facility (**Figure 9-14**). The amount and concentration of boron leaving the power plant as gas from the emission stacks is unknown, and therefore the likelihood of an airborne source for high boron in surface water samples in Spring Creek, Pony Creek, and Cow Creek cannot be determined.

Spring Creek, Pony Creek, and some northern tributaries of Cow Creek are hydrologically disconnected from the power plant ponds and infrastructure yet also exhibit high boron in surface water samples. Since the early 1980's, when data was first collected in and around Rosebud Mine Area D permit, some springs, ponds, and alluvial wells have shown concentrations of boron routinely greater than 1 mg/L. Pond PO-917 is within the Area D permit, but it is on an undisturbed segment of Pony Creek (**Figure 9-13**). Since sampling started in 1981 the pond's water quality samples have routinely had boron concentrations above 5 mg/L with four samples above 10 mg/L. No increasing or decreasing trend is apparent in the pond's boron concentrations. Some springs, such as GSP-6 (also known as SP-25) and SP-23, have shown gradual increasing trends in dissolved boron through time. Other springs and ponds, especially within the Spring Creek drainage, do not have a long enough sampling history to indicate a long-term trend in concentrations. For instance, SP-90 has only been monitored since 2011 but the concentration of dissolved boron was above 8 mg/L for all four sampling events. Elevated boron in alluvial wells samples are found along Cow Creek, upstream of pond PO-917 in Area D and along East Fork Armells Creek as it passes through Colstrip (**Figure 9-13**; **Figure 9-14**).

The cause of the elevated boron in and around Area D is unknown, but the appearance of high boron is not correlated with mining events or operational practices. Analysis of overburden and interburden samples show that boron is occasionally present at high concentrations (> 5 mg/L). Soil samples have also been tested for boron prior to disturbance, but soil is not tested for chemical composition after reclamation. Some soil samples have been found to contain high boron concentrations. The mechanism (e.g. anthropogenic sources vs natural processes) that results in high boron in some soil sample is not known. It is unknown if the concentration of boron in Area D and Area E soils downwind of the power plant are higher than boron concentrations found in soils from areas upwind of the power plant. The surface water sampling sites in Area D are mainly along the burn line. Wells in this area that are completed in clinker, coal, and interburden layers also have high boron concentrations (> 1 mg/L). The burned and partially burned coal in this area may be releasing organically bound boron. Surface water at the monitoring locations may be mixing with groundwater sources high in boron.

Because there is no numeric standard, boron would cause material damage only if concentrations were sufficiently high to impair uses of the surface water. As indicated, coal mining does not appear to release boron into the environment; burning coal releases mobile boron into the environment. Therefore, while there are some areas within the mine permit boundary and near the permit boundary with elevated concentrations, there is no evidence to indicate that the mine has caused or exacerbated high boron

concentrations. The mine and the proposed action in AM4 is designed to prevent elevated boron that would hinder a use of the surface water.

9.2.4.4.2 Chloride

As of 2013 there are no DEQ-7 human or aquatic health limits for chloride (**Table 2-1**). Chloride occurs in coal in two main forms. First, it can be dissolved in pore water trapped inside of the coal. This mode is more likely to occur in coals that formed under brackish conditions. The second form can be as anions adsorbed onto the organic compounds and surfaces of coal (Finkleman, 1995). Weathered coal rapidly becomes depleted in chloride because chloride is highly mobile and will readily be transported (Goodarzi, 1995). Wet scrubbers, which are employed by the power plant, remove most of the chloride.

Figure 9-15 shows that surface water with high chloride concentration has been present since monitoring started. Median baseline chloride concentration from 876 baseline (premine) samples from streams, springs, and ponds is 7 mg/L with the 75th percentile at 12 mg/L and the 90th percentile at 21 mg/L. Data collected from sites during non-baseline has a median concentration of 10.9 mg/L with a 75th percentile at 25 mg/L and a 90th percentile at 60 mg/L. Some areas have seen an increase in chloride through time. The distribution and likely sources of high chloride concentrations can be divided into the following categories:

1) High concentrations in surface water downstream of the power plant ash ponds. Water samples from ash ponds suggest that the power plant captures a large amount of chloride. Since chloride is highly mobile, it readily infiltrates from the ponds into the groundwater whenever there is seepage from the ponds. Chloride concentration in power plant ponds ranges from 20 mg/L to 31,900 mg/L (PPL, 2014).

2) Moderately elevated concentrations in drainage reaches downwind of the power plant and far from county roads. Moderately high concentrations of chloride have been detected in Pony Creek and Cow Creek downwind of the power plant. The contribution of precipitated airborne emissions of chloride versus other sources cannot be discerned from the monitoring data. Monitoring sites next to the Area D permit boundary tend to have lower chloride than sites further downstream which indicates that the source of elevated chloride is not likely from the mine.

3) High concentrations in drainage reaches that cross county roads. Magnesium chloride may have been used along county roads, and the possibility of its usage is suggested by high concentrations of chloride in drainages near road crossings. For instance, high chloride has been found consistently in the Stocker Creek drainage, WFAC, and upstream EFAC before any mining occurred upstream of the sampling points in the 1980's. These creeks are crossed by unpaved county roads.

4) High concentrations in drainage reaches along haul roads, and near mine facilities. Magnesium chloride was used at the mines along unpaved haul roads and facility areas for dust control. It has also been applied to roads used by the power plant to access bottom ash and fly ash ponds. Bottom ash has also been used to a limited extent along haul roads and power plant roads. Some of the roads maintained by the power plant go near the permit boundaries for Rosebud Area D and Area E, and consequently surface water structures, such as sediment ponds, managed by the mine could have high chloride from mine and/or powerplant activities. An example of such a pond is PO-004. Chloride concentrations have been measured in Area E pond PO-004 as high as 366 mg/L in 1984. This pond still routinely has chloride concentrations above 100 mg/L. The location of this pond upstream of the roads used to access the power plant ash ponds precludes the association of high

chloride with the use of magnesium chloride on power plant roads. The chloride may be related to the movement of residual chloride left over from when mine haul roads crossed upstream of the pond. Salts may still be in the soil and may still be leaching into the pond.

An example of high chloride concentrations resulting from mine activities can also be found in Miller Coulee at the Big Sky Mine. High chloride concentration in Miller Coulee during mining is primarily a result of pond APD7400 (**Figure 9-15**). From 1990 through 2000, when monitoring of the pond ceased, chloride concentrations were at concentrations in the 100's mg/L to 1,000's mg/L. Prior to 1990, the chloride concentration in this pond was less than 10 mg/L. The source of the large increase in chloride is unknown but likely related to road maintenance use of magnesium chloride. During mining, the pond was adjacent to a main haul road.

Because there is no numeric standard in the DEQ-7, chloride would cause material damage only if concentrations were sufficiently high to impair uses of the surface water. As indicated, coal mining does not directly appear to release chloride into the environment; burning coal does release mobile chloride into the environment. Mine operations have and practices have contributed chloride to drainage ways, primarily through the use of magnesium chloride on the roads. However, current and future practices at the Rosebud Mine stop the use of magnesium chloride. Therefore, the proposed action in AM4 is designed to prevent elevated chloride that would hinder a use of the surface water.

9.2.4.4.3 Fluoride

As of 2013 fluoride is listed as a toxic pollutant for human health in DEQ-7 (**Table 2-1**). Median baseline fluoride concentration from 893 samples from stream, pond, and spring water is 0.25 mg/L with a 75th percentile at 0.54 mg/L and a 90th percentile at 0.61 mg/L. As seen in **Figure 9-16**, sites located east of the power plant have higher fluoride than monitoring sites west of the power plant and highway.

From 1985 to 1992, fluoride was included in the suite of analytes for power plant monitoring sites on Pony Creek and Cow Creek. From 1990 to 1992, abnormally high fluoride concentrations were detected in both of these drainages compared to the concentrations that were recorded in prior years. The only sampling sites downstream of the power plant facilities and ponds were on Cow Creek. The analytical suite for these sites does not currently include fluoride, which precludes the determination of current fluoride concentrations at the monitoring sites. Instead of being an indicator of anthropogenic pollution, the high fluoride concentrations from the power plant samples could be a result of changes in the resolution of the analytical method. However, higher than background fluoride concentrations have also been consistently seen in alluvial and spring water samples collected by the Rosebud Mine in the northern tributaries of Cow Creek. A contemporary comprehensive survey of surface water and alluvial water throughout Pony Creek and Cow Creek would be needed to determine if fluoride is still present in the basins at the concentrations seen in the early 1990's.

To date, elevated or increased concentrations of fluoride in drainage ways and springs have not been associated with mining in the Colstrip area. Like boron, fluoride is preferentially organically bound in coal, and fluoride can be release with the burning of coal. Because fluoride has not been linked to mining or operational activities, the mine is designed to prevent material damage from fluoride above the DEQ-7 human health limit.

9.2.4.4.4 Nitrate (as N)

Due to ambiguity in past methods used by the mines, nitrate plus nitrite as nitrogen and nitrate as nitrogen are shown together in **Figure 9-17**. High nitrogen may be in surface water samples due to residual chemicals from blasting materials, from agricultural activities, or from city runoff and municipal sources. In **Figure 9-17**, samples above the human health limit of 10 mg/L are shown as dark red. Many of the highest values have been detected downstream of active mining and in areas actively used by livestock. Recent samples (2000 - 2013) with the highest nitrate concentrations near mining activities were found in the Spring Creek drainage downstream from Rosebud Mine Area D. EFAC between Rosebud Mine Area A and B had high nitrate concentrations in the 1980's through middle 1990's. This is coincident with the time that mining was active adjacent to the drainage. The drainage bottom is also actively used and historically used by cattle. Most of the high concentrations in surface water have been below the nitrate-nitrite human health limit of 10 mg/L.

The additional mine cuts are along the EFAC and Miller Coulee drainage divide, over 6,000 feet from the nearest major stream channel, EFAC. From past observations in monitoring wells, this distance should be sufficient to prevent (through dilution) high concentrations of nitrate from blasting from entering the stream via spoil recharge and ultimately alluvial contributions to baseflow. Therefore, the proposed action is designed to prevent material damage to surface water resources from high nitrate concentrations.

9.2.4.5 Exceedances of Water Quality Standards

For intermittent and perennial waters, DEQ-7 numeric water quality standards must be met for aquatic life and human health. A summary of exceedances of the current DEQ-7 standards from the earliest sampling events to 2013 is presented in **Table 9-6**, **Table 9-7**, and **Table 9-8**. As stated in **Section 8.1.2**, MPDES currently considers SW-55 and SW-65 to be within an ephemeral stream segment, and consequently MPDES does not currently apply DEQ-7 aquatic life standards to the discharge water quality.

For the purposes of the material damage determination under MSUMRA, SW-55 and SW-65 are included in **Table 9-7** for the purpose of determining if there is material damage to aquatic life. As seen in **Table 9-6**, samples collected before (considered baseline) and after mining commenced upstream both had many exceedances of DEQ-7. Some metals with low DEQ-7 limits, such as cadmium, had a decrease in exceedances after mining started. This decrease is likely an artifact of later sample dates for the data collected after the start of mining. Cadmium detection limits have become progressively smaller, and the analysis results in many earlier samples with reporting concentrations at or near their reporting limit resolution exceeding the 2012 limit. The percentage of exceedances in water quality samples for nitrate plus nitrite in EFAC through Colstrip and total copper in Stocker Creek at SW-65 after the start of mining are both significantly higher than the number of exceedances in other drainages for these analytes. The high nitrate plus nitrite in EFAC through Colstrip is a result of municipal inputs and urban runoff which are not associated with mining. The high total copper in Stocker Creek is associated with high TSS in the water quality samples. The high TSS results in larger concentrations of all metals that were monitored. The baseline samples for Stocker Creek at SW-65 were low TSS samples and consequently had lower total metals. None of these exceedances are attributable to coal mining.

The exceedances listed in in **Table 9-6** are not persistent nor was any trend of increasing concentration through time found for the analytes with DEQ-7 standards. Aluminum and total iron standards were exceeded at higher rates than other metals, but these two metals are naturally occurring at high concentrations in the region, as evident by the high number of exceedances found in the 'baseline'

group. There is no evidence from the surface water monitoring program of systematic exceedances of DEQ-7 standards for surface water that can be attributed to coal mining that would result in a violation of a water quality standard.

The exceedances of DEQ-7 standards described in **Table 9-6** or **Table 9-7** do not directly indicate the existence or likelihood of material damage attributable to mining because there are many variables which change between the baseline and mining-affected data sets. There are differences in the seasonal distribution and consequently types of flows sampled, differences in the spatial distribution of sites, differences in the sampling frequency, and differences in the types of surface water that were sampled. There has been an increase in the rate of exceedances in some streams for some analytes with livestock thresholds. For instance, there was a higher rate of exceedances for sodium, magnesium, and manganese after the start of mining compared to baseline in Pony Creek. As with the exceedances of the DEQ-7 standards, increased exceedances of the livestock thresholds cannot be directly attributed to mining due to differences in sampling locations, surface water type (springs vs ponds vs streams), and seasonal variations. Water quality trends at long term monitoring sites, such as the sites discussed in **Section 9.2.4.2**, are a more appropriate indicator of potential changes in water quality from mining.

9.2.5 Groundwater

Open pit coal mining removes overburden and coal then backfills each successive pit with the broken overburden material (spoil) from the previous cut as mining progresses. As coal seams are shallow aquifers in the Colstrip area, there are impacts to groundwater and associated parts of the hydrologic system. Potential hydrologic changes include:

- Declines in water level or pressure head in mined aquifers
- Potential water level declines or changes in pressure head in stratigraphically adjacent aquifers
- Removal of alluvial material and/or interception of alluvial water adjacent to recoverable coal
- Changes in groundwater flow direction and gradient near the pit areas due to water level declines or changes in hydrologic head
- Removal of springs or diminished flow in springs
- Creation of localized recharge due to ponding in pits and sediment control structures
- Reduction in infiltration and recharge in disturbed clinker areas
- Increases in alluvial recharge and alluvial water levels due to discharge of pit water into tributaries
- Water quality decline in alluvial aquifers due to lowered water levels
- Water quality decline in alluvial aquifers due to pumping or seeping of impounded pit or sediment pond water into drainages
- Creation of a spoil aquifer with hydrologic properties different than the strata it replaced
- Poor spoil water quality due to dissolution of salts from overburden minerals
- Potential decline in water quality in adjacent aquifers and surface water due to movement of spoil water
- Potential water quality decline in springs adjacent to mining due to diminished flow or introduction of spoil water

The two main impact categories are changes in water level (or pressure head) and water quality. The evaluation of impacts to water levels is based on analysis of observed changes in monitoring well water levels as mining approaches and exits from an area. Observations include the amount of decline in water level (or pressure head) and the amount of time it takes for recovery. Variation in annual precipitation

affects water levels, especially in shallow aquifers, and thus climatic effects must be considered in the analysis of water level response.

Box and whisker plots show concentrations of the major water quality analytes by aquifer from baseline and recent samples at the Rosebud Mine (**Figure 8-9** and **Figure 9-18**) and the Big Sky Mine (**Figure 8-10** and **Figure 9-19**). The plots represent single, initial samples from baseline wells and the single most recent sample from each currently monitored well. The baseline and recent plots represent two snapshots in time and thus do not show the natural variability observed over time that often occurs at a monitoring site. For a number of reasons, the two populations (baseline and recent) are not directly comparable and differences in concentration between the two time periods should not be interpreted to construe changes attributable to mining. In the 20 to 30 years since baseline, many of the baseline wells have been lost to mining or another reason and thus the monitoring wells representing current water quality are not the same, or in the same location, as those representing baseline. Another problem in comparing the two populations is the affect that a change in detection limits can have on medians. For example, the recent detection limit for potassium at the Rosebud Mine is much higher than the one used in baseline. Thus, the statistics for baseline concentrations may have lower values.

The plots are useful for a general comparison of spoil water quality with that of baseline and current water quality from bedrock aquifers. Spoil is elevated in median as well as maximum concentrations of TDS, bicarbonate, sulfate, and calcium.

The best insight to changes in water quality attributable to mining comes from examining water quality at individual monitoring sites in the following sections. Water quality impacts are assessed by evaluating changes in analytical concentrations through time based on proximity to mining and other potential influences such as climate. TDS as an indicator of the degree of water mineralization is the primary indicator of a change in water quality and reflects changes in measured analytes, but largely reflects the change in sulfate concentration, and to a lesser degree, calcium and magnesium. Although conductivity is often used as an assessment of water quality, TDS is a better laboratory measurement of total mass in the sample. TDS concentration is the main water quality indicator used in several hydrologic studies in the area (Van Voast et al. 1977; Van Voast et al. 1988).

9.2.5.1 Rosebud Mine

9.2.5.1.1 Alluvium

Alluvial water levels and quality may be impacted by mining in a number of different ways as described in **Section 9.2.5**. Some monitoring well hydrographs indicate that climate, particularly rainfall and snow melt, dominates most alluvial water levels. In other cases, the data is insufficient to allow determination of whether water levels have responded to mining or climate. Observed and potential impacts to alluvial groundwater quantity and quality are discussed specifically below for each drainage in the CIA.

Area A, Area B, and Area C

In the west part of the Rosebud Mine (Area A, Area B, and Area C), alluvium is found in EFAC, Stocker Creek, the upper reaches of WFAC, and tributaries to these drainages. There are 27 active alluvial monitoring wells in this part of the mine (**Figure 9-20**). Many of the wells have been recording water level and water quality for three decades or more.

East Fork Armells Creek

EFAC is an ephemeral to intermittent stream located between Area A and Area B in the east part of the mine area, and Area B and Area C upstream to the west. Most of the creek bed upstream of Area A is

dry, however intermittent stretches have been identified (see surface water discussion for EFAC). Historically, small dams built to create instream ponds for livestock water have facilitated the intermittent stretches.

EFAC has eroded through stratigraphically lower units as it flows downstream; this is important to the evaluation of impacts in a given stretch of stream. Upstream of Area B, alluvium is bounded by overburden. Downstream, near the western edge of Area B and Area C, the alluvium comes into contact with the Rosebud coal (**Figure 9-21**). Further downstream the alluvium intersects Rosebud coal and then the interburden. Between Area A and Area B, the stream has eroded through the interburden and into the McKay coal. Thus, there is an increase in groundwater connection from the Rosebud coal and the McKay coal to the alluvium. However, the contribution of groundwater from the coal units to the alluvium is small compared to the up gradient alluvial source of groundwater (Western Energy Co., 2014, 2015).

Due to its location, EFAC has been subject to impacts from mining in Area A, Area B, and Area C. Mining was active at the easternmost end of Area B beginning in the middle 1970's. Mining has remained active in Area B almost continuously as the permit area extended to the south, away from EFAC. Initial mine pits in the east end of Area A were opened in the middle to late 1970's and were located relatively close to the north side of the stream. Mining in the 1980's and 1990's closely followed the coal crop line immediately adjacent to the stream in Area B. Although mining near the stream in Area A was active into the early to middle 1990's, it did not take place as close to the stream as mining in Area B. Area C pits near the stream were opened in the early 1990's and were active until 2010.

The greatest impacts to the stream and associated alluvium have been observed in the down gradient, east end of Area B. Alluvial wells record a marked decline in water levels here in the early to middle 1980's. There were implications for stream flow with the decline in EFAC alluvial water levels. As a mainly ephemeral stream dominated by runoff from snow melt and rainfall, EFAC would be expected to continue to have regular flows associated with runoff events. Thus, a decline in alluvial water levels does not mean the stream went dry. In ephemeral parts of the stream, alluvial water levels do not intercept the stream bottom and contribute to base flow. In areas where the alluvial water level does intercept the stream bottom intermittently, periods of flow may be shortened due to diminished base flow.

The extent of water level impacts to EFAC alluvium is difficult to assess from hydrographs (**Figure 9-22** and **Figure 9-23**) due to the influence of climate on water levels. Water levels recorded from alluvial wells along the entire length of EFAC reflect a period of drought in the late 1970's through the 1980's, with recovery beginning in the early 1990's. A shorter, less dramatic response to below average precipitation began again in the early 2000's, followed by a rise in water level in the late 2000's in response to above average precipitation. The introduction of water to the stream via MPDES discharges has tended to mitigate drawdown of alluvial water levels. The rising alluvial water levels observed in many monitoring wells between Area A and Area B reflects not only unusually high precipitation in 2011 and 2013, but also the release of water to the stream under the mine's MPDES permit from sediment ponds that intercepted increased runoff due to the precipitation events. Water levels are currently at or above premine levels in most alluvial wells. Other potential sources of water to the stream include leakage from sediment ponds, and wastewater in holding ponds and the leach field in the Area A facilities. The amount associated with these sources is thought to be insignificantly small (Western Energy Co., 2015).

As mining moved to the south, away from the stream in Area B, alluvial water levels began to recover. The interconnectedness of the alluvium and the reclaimed pit in the east end of Area B is evidenced by the rapid recharge of the spoil near the stream compared to the relatively poor water level recovery in spoil more distant (south) from the stream. Even though mining has been close to the stream in the more up gradient areas of EFAC, the hydrologic dynamic appears different than that seen down gradient. The drawdown effect of mining near the stream is recorded on the hydrographs of wells WA-114 and WA-209, suggesting a connection between Rosebud coal and alluvium. The precipitous water level drop in well WA-114 in 1984 is likely associated with nearby mining in Area B. Well WA-209 has been dry since 2000, likely in response to adjacent mining in Area C beginning in 1992. Well WA-114 has shown a recovery in water level while WA-209 remains dry. Recovery in WA-114 is likely a response to a number of factors: above average precipitation in 1993 and 1994, concurrent increase in the release of pit and pond water to the stream, and the movement of mining away from the stream. Although alluvial water is contributing to the recharge of spoil in the east part of Area B, the west (upstream) part of Area B spoil, like WA-209, remains dry to poorly saturated. However, up gradient of WA-209, water levels in Rosebud monitoring well WR-136 (see **Section 9.2.5.1.3**) suggest that the recovery of water levels from mining related drawdown in the middle 1990's was facilitated by recharge via EFAC alluvium beginning in 2011, coincident with a period of high precipitation.

Mining near WA-104 in the middle 1990's likely explains the decline in water level in this well at about the same time, although it is anomalous in its earlier water level character compared to other alluvial wells. It shows an increase in water level at the same time most other wells are showing a decline in response to drought. Wells WA-171 and WA-214, located up gradient of mining, show no effects from mining but record a strong effect from higher than normal precipitation in recent years. Due to their up gradient distance from mining, wells WA-215 and WA-118 also remain unaffected by mining. These wells serve as control wells to help determine the effects of climate verses mining on water level.

Water chemistry in EFAC alluvium varies widely, in both time and location. **Figure 9-22** and **Figure 9-23** show that water quality in the alluvial wells generally corresponds to water level. An increase in saturation results in an increase in TDS and a decline in saturation results in a decrease in TDS. This is notable in both up gradient and down gradient alluvial wells whether they are subject to mining influences or not. Potential sources contributing to the increase in TDS include spoil, MPDES discharges, leaking sediment ponds and/or pits, and infiltration from water used in the facilities area. Each of these potential sources was evaluated in the PHC (Western Energy Co., 2015).

Contributions to groundwater from the facilities area in Area A are evident from the concentration of chloride detected in surface water and alluvial groundwater samples. Magnesium chloride is used as a road surfacing material to control dust in the facilities area. As chloride occurs predominately as the highly mobile free chloride ion, it is chemically inert and passes easily through the unsaturated zone into groundwater. Although the use of magnesium chloride has been discontinued in the Area A facilities, chloride levels in EFAC will remain elevated until magnesium chloride remaining in the soil has been flushed from the system by precipitation and runoff. Contribution of water to the stream and alluvium from other facility uses (e.g. drain field serving the Area A office, lawn irrigation, and equipment cleaning ponds) was analyzed to be of such a comparatively low volume that it would not contribute measureable amounts of TDS to the system.

MPDES discharges were considered to be a potential contributor to the rise in TDS. However, TDS concentrations in discharges between 1999 to 2014, had an average and median of 1,589 mg/L and 1,210 mg/L, respectively. During the period of high precipitation and correspondingly high MPDES

discharges between 2011 and 2014, the average and median TDS of the (planned and unplanned) discharges was 1,724 mg/L and 1,780 mg/L, respectively. All of the discharges were below baseline (PHC average of 2,299 mg/L) and current alluvial well TDS concentrations, indicating that they are not directly responsible for the TDS increase observed in EFAC.

Saturating spoil near the stream in Area A and the northeast part of Area B was examined as a contributor to TDS. The Rosebud Mine PHC Addendum (Western Energy Co., 2015) indicates that, based on comparison of water levels in spoil and alluvium, Area A spoil water is moving toward EFAC alluvium but movement of Area B spoil water toward alluvium is unlikely. Based upon a simplified mass balance calculation, the current contribution of Area A spoil to the observed increase in TDS in EFAC alluvium is approximately three per cent.

Due to the widespread correlation of water quality and water level in alluvial wells, the reason for the increase in TDS is attributed to an increase in water level from natural recharge as well as MPDES discharges. Impacts to alluvial water from permitted operational discharges are expected to continue as long as there is mining in the EFAC basin although the volume will be dependent on weather patterns, with greater discharge occurring during periods of higher than normal precipitation. Alluvial TDS concentration is predicted to decline along with decreasing water levels after MPDES discharges to EFAC stop.

Flow from Area A spoil is predicted to impact water quality in downstream EFAC between Area A and Area B (Western Energy Co., 2015). Based on average TDS concentrations observed in spoil and alluvial baseline (in the wells used to develop the mass balance calculations at the east end of EFAC), post-mining alluvial TDS concentration is projected to be approximately 2,751 mg/L, equivalent to a 13% increase over the 2,299 mg/L baseline concentration (Western Energy Co., 2015). Due to the apparent connection between Rosebud coal and alluvium in the vicinity of WR-136 in Area C, resaturated spoil in this area may also contribute to an increase in TDS in EFAC alluvium. This estimation was conducted specifically for TDS, however because TDS and conductivity typically are linearly related, the results can be reasonably applied to conductivity. Average baseline conductivity in EFAC alluvial groundwater was 2,650 µS/cm, thus a 13% increase would result in an average postmine conductivity of 2,995 µS/cm, both Class III groundwater. The average conductivity at the most downgradient EFAC wells (P-01 through P-05) between Area A and Area B was 2,692 µS/cm when mining began nearby in 1975. This value falls within the conductivity range for Class III groundwater and a 13% increase in conductivity (to 3,042 µS/cm) would not change the groundwater class.

Current uses of EFAC alluvium are limited to drinking water for livestock and wildlife. Ionic water quality components of greatest concern for livestock include TDS and sulfate. Recommended upper concentration limits (**Table 2-2**) are 4,999 mg/L for TDS and 2,500 mg/L for sulfate. Initial sample analyses from each of 15 EFAC wells were chosen by DEQ to represent EFAC baseline throughout the stream length (**Appendix D**). TDS concentrations among these wells ranged from 1,300 mg/L to 4,680 mg/L (SC=1,720 µS/cm to 4,530 µS/cm) with an average and median of 2,302 mg/L (SC=2,650 µS/cm) and 1,900 mg/L (SC=2,390 µS/cm), respectively. Sulfate in these wells ranged from 640 mg/L to 3,010 mg/L with an average and median of 1,276 mg/L and 1,010 mg/L, respectively. Down gradient wells, which represent the area of greatest water quality decline, currently report concentrations of 2,300 mg/L (SC=2,620 µS/cm) (WA-101) to 4,220 mg/L (SC=4,330 µS/cm) (WA-131) for TDS (and conductivity), and 1,270 mg/L (WA-101) to 2,670 mg/L (WA-131) for sulfate. As discussed above the potential changes to water quality in EFAC alluvium are small in comparison to the observed variability and are unlikely to

impact livestock or wildlife drinking water use, or the listed uses for Class II or Class III groundwater, thus material damage to these uses is not indicated or predicted.

Private wells completed in EFAC alluvium may be affected by changes in water quality. A number of wells are located near EFAC between Rosebud Mine Area A and Area B, and Area B and Area C. Reported use of the wells in GWIC includes domestic and stock water. Many of the wells are completed in sub-McKay (underburden) units but some have shallow completions that suggest alluvium is the water source. Alluvial wells in and adjacent to the permit areas are at risk for changes in water quality. These include wells 17, 19, 20, and 79.

Private well 79 is located between Area B and Area C in Section 12 (T1N, R40E). Monitoring well WA-104 (**Figure 9-20**) is completed near well 79. The current water level in WA-104 is close to the original (1979) level and the current (2013) TDS concentration of 1,890 mg/L (SC = 2,380 µS/cm) is close to the earliest measurements (1979/1980) of 1,650 (SC = 1,950 µS/cm) and 1,840 mg/L (SC = 2,050 µS/cm). Assuming that WA-104 is representative of water in well 79, there are no changes to water quality from those observed at baseline and the water remains suitable for use as stock water. For the same reason no changes in water quality indicate possible harm, detriment, or injury to listed uses of water in this well. Contribution of spoil water from Area C is expected to be relatively small compared to the overall volume of alluvial groundwater flowing through EFAC and is not expected to elevate water quality components significantly to affect the use. Sulfate, as the critical groundwater component, would have to increase from the current level of 921 mg/L to 1,500 mg/L to meet the threshold limit for livestock water quality (**Table 2-2**). Even if the same magnitude of change occurred in this section of EFAC alluvium as was predicted for lower EFAC (13%), that water would remain within the conductivity range for Class II groundwater and would not be rendered harmful, detrimental, or injurious to a listed use for Class II water (ARM 17.30.1006) or unsuitable for a current or anticipated use. Furthermore, the proposed action will not exacerbate or intensify any adverse impacts from contributions of spoil water from Area C.

Private wells 17, 19, and 20 are located in Section 8 (T1N, R41E), between monitoring wells WA-114 and WA-128 and near WA-101 between Area A and Area B. The monitoring wells currently show increases in water level and TDS concentration as result of mining (**Figure 9-22**)(see **Section 9.2.5.1.1**). TDS concentration has increased due to increase in sulfate, magnesium, calcium, sodium, and chloride. The GWIC database indicates the private wells are listed for domestic use. Premine water quality was marginal Class II to Class III groundwater, with TDS (and conductivity) in monitoring wells ranging between 1,380 mg/L and 2,220 mg/L (1,770 µS/cm and 2,550 µS/cm). The most recent measurements in TDS (and conductivity) range from 1,890 mg/L to 2,890 mg/L (2,620 µS/cm and 3,330 µS/cm). There have been no increases in trace metals and no DEQ-7 human health standard has been exceeded. The residence where the wells are located is not occupied, is owned by Western Energy Company, and is within the permit boundary. According to Western Energy Company these wells are used only for livestock (Pers. comm., Western Energy Co. personnel, 2015). Sulfate, the most sensitive component of drinking water for livestock, remains within guideline recommendations. Initial calcium and magnesium concentrations were above the livestock guideline criteria. Calcium concentration has increased above the lower end of the initial concentration range (132 mg/L to 312 mg/L) but not at the upper end (153 mg/L to 264 mg/L). Magnesium concentration increased above the initial range (146 mg/L to 207 mg/L) at both the lower and upper ends of the range (201 mg/L to 307 mg/L). Current sulfate concentrations are 921 mg/L at WA-104, 1,270 mg/L at WA-101, and WA-114 at 1,660 mg/L. The alluvial water currently remains marginally suitable for domestic, livestock, and wildlife use. This change in conductivity from

the Class II to Class III groundwater range does not render the water harmful, detrimental, or injurious to a listed use for Class II groundwater.

Continued change to EFAC alluvial water quality is predicted post-mining due to infiltration of spoil water from the south part of Area A and the north part of Area B. Assuming postmine reestablishment of flow equilibrium, mass balance calculations estimate that average TDS in alluvium between areas Area A and Area B is expected to experience a 13% increase over the baseline TDS of 2,299 mg/L (SC = 2,650 µS/cm), yielding a TDS average concentration of approximately 2,751 mg/L (SC = 2,995 µS/cm)(Western Energy Co, 2015). Average alluvial water quality both premine and postmine indicates Class III groundwater is typical. At this concentration, water quality should remain suitable for livestock and wildlife use. This change in groundwater quality does not render the water harmful, detrimental, or injurious to a listed use for Class III water (ARM 17.30.1006), and no numeric standards are predicted to be exceeded, thus no material damage is expected.

As stated above, water chemistry in EFAC alluvium varies widely, in both time and location. Based on observed changes and predicted changes in water quality, conductivity at some, but not all, monitored sites has changed or may change from the conductivity range for Class II to the range for Class III groundwater. For all groundwater classes, concentrations of parameters for which human health standards are not listed in DEQ-7, there is to be no increase of a parameter to a level that renders the waters harmful, detrimental, or injurious to the beneficial uses listed for the class (ARM 17.30.1006). The primary difference between listed uses for Class II and Class III groundwater is that the listed use for "public and private water supplies" in Class II water is replaced by "drinking" in the listed uses for Class III water. Both "public and private water supplies" and "drinking" were at best marginally supported by EFAC alluvial groundwater in the baseline condition, and the predicted increases will not cause harm, detriment, or injury to this marginal support. After the observed and anticipated changes in water quality, EFAC alluvial groundwater will continue to be marginally suitable for the current and anticipated uses of EFAC alluvium as drinking water for livestock and wildlife.

Material damage to the EFAC alluvium is not indicated. Mining in the cuts proposed in AM4 is not expected to contribute to the decline in water quality in EFAC. Also, changes in water quality attributable to other permitted areas of the Rosebud Mine are not expected to result in material damage to the EFAC alluvium. Specific changes at individual wells are difficult to predict due to the variable nature of alluvial and spoil water quality, both spatially and temporally. It is likely that some wells which are just below the threshold of Class II/Class III water would change to fall within the conductivity rage of Class III, however this type of change also occurs naturally (see **Figure 9-23**, well WA-104) and in much larger magnitude than a 13% change. No material damage is indicated because any mine related water quality changes are not likely to be distinguishable from natural variations.

Stocker Creek

Stocker Creek is an ephemeral stream that drains the north parts of Area C and the northwest part of Area A, joining EFAC north of Colstrip. There are seven active alluvial monitoring wells (**Figure 9-24**) in Stocker Creek and its tributaries. Most of these wells have been active since baseline in the late 1970's and early 1980's. Mining in the Stocker Creek watershed in Area C took place as early as 1984 and continued through 2007. Mining in the part of Area A that drains to Stocker Creek began in 1988 and continued through 1994. Stocker Creek also drains the mine office and facilities in Area C.

Alluvial thickness ranges from 13 feet (WA-217 and WA-160) to 34 feet (WA-109) and saturated thickness has ranged up to 20 feet. Most wells have maintained some level of saturation even during

periods of low precipitation. The hydrographs of most of the wells show a similar water level response. They also reflect the climate effects observed in EFAC wells. Mining does not appear to have affected water levels in Stocker Creek alluvium.

As noted in EFAC alluvial wells, water quality in some Stocker Creek wells appears to correspond to water level, with TDS increasing with increasing water level as observed in WA-160, WA-164, WA-169, and WA-217. Current water levels in these wells are at or above baseline. Other wells have a relatively constant TDS through time (e.g. WA-168) or do not correlate closely with water level (WA-109). Poorest water quality is associated with wells WA-164, WA-168, and WA-169, located in the middle to upper section of the drainage. Initial samples from wells except WA-217 represent baseline. Baseline TDS concentrations range from 2,006 mg/L to 5,360 mg/L, with a median of 2,545 mg/L and an average of 3,024 mg/L. Average TDS concentrations in the wells during mining ranged from 2,096 mg/L to 4,045 mg/L, with an average TDS concentration of 3,922 mg/L. The lack of increasing TDS concentration through time suggests there have been no impacts to water quality attributable to mining operations in the Stocker Creek drainage.

The proposed AM4 mining in Area B will not affect water quality and water quantity in Stocker Creek. Only a small part of Area C is drained by Stocker Creek and no measurable impacts to water level or quality are anticipated with the recovery of the groundwater system. No material damage has been observed or is expected in the Stocker Creek alluvial groundwater.

Upper West Fork Armells Creek

The west and northwestern most part of Area C drains to West Fork Armells Creek (WFAC). There are five active alluvial wells in the upper reaches of the ephemeral drainage and its tributaries (**Figure 9-25**); all but one has been active since the early 1980's and all have collected baseline data. Baseline measurements began in the early to middle 1980's in most wells and in 2003 for well WA-218. Mining began in 2001 in the north part of Area C and in 2008 for the west part of Area C. Reclamation of the north part of Area C is complete; the west and central parts are actively mined.

Alluvial wells are shallow in Upper WFAC, with depths ranging from nine to 19 feet deep. Saturated thickness ranges as high as 20 feet in WA-190, but is less (nine to 15 feet) in the other wells. The water levels from WA-199, WA-218 and WA-186 have the same trends seen in alluvial wells throughout the mine area that reflects a response to climatic changes (discussed above in the section on EFAC). There are numerous springs in many of the tributary drainages; many supply water to nearby livestock ponds. The hydrograph from WA-204 has a "flashy" signature that likely reflects the influence of upstream spring SP-55 and associated ponds. Wells WA-186, WA-190, WA-218, and WA-199 are downstream from springs that may influence water level. Water seeping from ponds may also affect water quality. Based on monitoring data, it does not appear that water levels in alluvial wells have been affected by mining.

Average TDS concentrations during baseline ranged from 2,318 mg/L to 3,800 mg/L, with medians from 2,150 mg/L to 3,770 mg/L. The average TDS concentrations subsequent to mining ranged from 2,115 mg/L to 5,255 mg/L with medians from 1,840 mg/L to 5,255 mg/L. Wells WA-218, WA-204, WA-186 and WA-199 have shown increases in TDS associated with a recent rise in water level. This is a common response in alluvial wells throughout the mine and is not a result of mining but rather additional ions that come into solution with an increase in precipitation and subsequent rise in water levels. WA-190 is the exception to this trend, as it has maintained a relatively steady TDS concentration as water levels have risen.

There is no indication that water quality changes in Upper WFAC are the result of mining. The proposed AM4 mining in Area B would not affect water quality and water quantity in WFAC. No material damage has been observed or is expected in the WFAC alluvial groundwater.

Area D and Area E

Pony and Cow Creeks

In the east part of the Rosebud Mine, Area D and Area E are drained by Pony Creek, Cow Creek and South Fork Cow Creek. Cow Creek, South Fork Cow Creek and Pony Creek are ephemeral tributaries to Rosebud Creek. Although there is a considerable history of groundwater monitoring in the alluvium of these drainages, mining and associated disturbance was active in the Cow Creek and South Fork Cow Creek drainages prior to requirement for baseline data. There are currently ten wells monitored in these drainages (**Figure 9-26**).

Pacific Northwest National Laboratory/Battelle-Pacific Northwest Division (PNNL) oversees monitoring and reports on surface and groundwater monitoring results in Cow Creek and Pony Creek under contract with the Colstrip Power Plant (PNNL, 2014). A power plant effluent holding pond complex is near the headwaters of Cow Creek. The ponds receive scrubber slurry pumped via pipeline from power plant units 3 and 4. Monitoring in the Cow Creek drainage documents impacts from the slurry ponds. For comparison with measurements in Cow Creek, Pony Creek is used as a "control" drainage as it is similar geologically to but hydrologically isolated from Cow Creek.

Pony Creek flows east from Area D. Baseline and subsequent measurements in Pony Creek by the Rosebud Mine were taken from a two-foot deep alluvial monitoring well (WA-178) near the head of the drainage. As the well was often dry, monitoring was discontinued in 2007. Western Energy Company and PNNL actively monitor wells in other stratigraphic units in Pony Creek but there are no active monitoring wells completed in alluvium.

Cow Creek and South Fork Cow Creek flow eastward to Rosebud Creek. There are eight alluvial wells monitored in the headwaters of Cow Creek and two wells are monitored near the head of South Fork Cow Creek (**Figure 9-27**). As there was premine disturbance up gradient of these drainages, there is no baseline data. Most alluvial monitoring began in 1981.

Cow Creek alluvial wells are mainly in the upland tributaries of the drainage. Water levels in WA-142, WA-145, WA-146 and WA-147 are influenced by stock ponds. The other Cow Creek wells have hydrographs that mainly reflect the same climatic conditions commonly seen in alluvial well levels throughout the mine area. Well WA-132 is the most down gradient well. It typically contains between four feet and seven feet of water and is intermittently dry. Likewise, WA-133 most commonly contains from less than one foot to four feet of water. Wells WA-136 and WA-137 are in South Fork Cow Creek. The hydrograph of WA-136 suggests that an up gradient pond periodically influences the water level response in this well. There is no evidence that alluvial water levels have been affected by mining.

The TDS concentration in some wells has varied over a significant range, whereas other wells have remained relatively steady in water quality. Current (2011-2014) TDS concentrations range from 3,010 mg/L (WA-134) to 6,040 mg/L (WA-142), with an average and median of 3,893 mg/L and 3,380 mg/L, respectively. The highest concentrations are in adjacent wells WA-142 and WA-145, both located less than a mile north of the ash ponds. TDS concentrations in WA-145 have ranged as high as 15,400 mg/L.

All of the wells have water quality affected by activity associated with management of the Colstrip power plant ash. Repeated breaks and leaks in the pipeline moving the ash slurry from the power plant to the ponds has affected monitoring wells in tributaries upslope and up gradient of the ash ponds. The ash ponds are also leaking effluent to the area. The slurry and water from the ash ponds are typically high in TDS but also has higher than normal concentrations of boron, chloride and fluoride that distinguish it from alluvial, bedrock or spoil aquifers. All of the alluvial wells in Cow Creek and South Fork Cow Creek have elevated boron and fluoride concentrations, and many have high chloride concentrations. An unexplained increase in potassium concentration occurred in the wells beginning in approximately 1995. No elevated concentrations in other analytes, including trace metals, are reported in alluvial well analyses.

As Pony and Cow Creek exhibit impacts attributable to operation of the power plant, there is no evidence that the mining has or will materially impact the water quality in these creeks. The proposed AM4 mining in Area B would not affect water quality and water quantity in Pony or Cow Creek alluvium. No material damage has been observed or is expected in the Pony or Cow Creek alluvial groundwater.

Spring Creek

Spring Creek flows to the north of Area D, opposite the direction of groundwater flow. Five alluvial wells were installed in Spring Creek or its tributaries in 1982 to 1984. Most of the wells were dry during the monitoring period that lasted through 1997. Wells that infrequently contained scant water were monitored until 2007 before monitoring was discontinued. Due to the direction of groundwater movement and the lack of water in the alluvium, it is unlikely that impacts from spoil will affect the drainage. The proposed AM4 mining in Area B would not affect water quality and water quantity in Spring Creek alluvium. No material damage has been observed or is expected in the Spring Creek alluvial groundwater.

9.2.5.1.2 Overburden

Overburden wells generally do not show a response to mining until active mining is nearby. The lack of responsiveness in the wells is attributable to the discontinuity and low permeability of the strata, which is characterized by claystones and siltstones. The lack of response in overburden wells demonstrates that most of the overburden strata are hydraulically isolated from the underlying Rosebud coal and water in the overburden is often perched. Even though overburden wells locally may contain 30 feet or more of water, poor yield and the lack of horizontal continuity of water bearing zones in the overburden makes it a poor source for reliable production. Few overburden monitoring wells are currently active as most have been removed by mining.

Overburden will continue to be removed and spoiled into the pit as mining continues in Area A, Area B and Area C. As discussed below, proposed mining in AM4 will remove additional overburden in the east part of Area B but will not affect overburden water levels or water quality in other permit areas of the Rosebud Mine. No material damage has been indicted in overburden groundwater and none is expected to occur.

Area A

Mining in Area A has taken advantage of low cover coal near the crop lines, leaving an undisturbed area ringed by pits. Well WO-105 is the only active overburden well in Area A and has been monitored since 1981 (**Figure 9-28**). Mining in the area began as early as 1975 and continued through 2000. The continuous decline in water level since approximately 1990 is likely in response to mining **(Figure 9-29)**. Water level has declined from approximately 13 feet to seven feet of water currently in the well.

Water quality in the well was consistent until the most recent sample, when it went from a TDS near 2,100 mg/L to 10,000 mg/L. The reason for the increase is likely associated with reported surface damage to the well or activity in preparation of the area for impending mining.

Area B

Four overburden wells are active in Area B (**Figure 9-30** and **Figure 9-31**). With a head of approximately 46 feet, WO-160 lies at the southeast edge of mining and has shown a slight decline of less than two feet in water level with the nearby approach of mining (**Figure 9-29**). WO-162 is located near the last cut in the west part of Area B. It experienced a drop in water level in 1998 when mining moved close to the well and has continued a slow downward trend for a total decline of approximately six feet. Approximately 104 feet of head remains in the well. WO-171 is located more than a mile west of mining in Area B and Area C and while it shows two abrupt declines in water level, the declines are not readily explained by changes in mining operations. The relatively steady decline in WO-173 began long before mining reached the area in late 1999. The punctuated rate of decline in 2000 may be in response to nearby mining. Mining persisted through 2007, shortly before decline in this well ended. At the most, a decline of between 12 feet and 14 feet is attributable to mining.

Water quality in the overburden wells is highly variable, ranging from a TDS of less than 500 mg/L in WO-160, to an isolated maximum of 3,350 mg/L in WO-173, although average TDS in this well is closer to 1,500 mg/L. WO-162 has shown an increase in TDS concentration from 1,100 mg/L to 1,900 mg/L as the well declined in water level. The increase in TDS in recent samples is most likely a direct response to the approach of mining.

Mining associated with AM4 will remove additional overburden in the proposed mine cuts area at the east part of Area B. This will increase the disturbance and volume of spoil but is not anticipated to interrupt overburden groundwater resources outside the mine area because the overburden wells are hydraulically isolated from the underlying Rosebud coal and because the water bearing zones in the overburden demonstrate poor yield and a lack of horizontal continuity. Based on the private well inventory, there is no indication that the overburden groundwater is used as a resource in this area. AM4 mining is not expected to cause material damage to the overburden groundwater.

Area C

Four overburden wells have remained active in Area C since the early to middle 1980's (**Figure 9-32**). WO-168, located near the edge of mining in the south part of Area C, was in decline when mining began to influence the well, causing a sharper drop between 2005 and 2006 (**Figure 9-29**). Due to distance from mining (approximately 3,000 feet) well WO-172 remains unaffected by mining and reflects changes in water level attributable to climate or other influence. Despite the close proximity of mining to WO-178, it has not shown a water level response. WO-181, located in the west part of Area C, south of mining, responded to nearby mining with approximately two feet of decline in water level between 2011 and 2012.

Water quality is closely correlated with changes in water level in WO-172. The remaining overburden wells do not appear to have TDS concentrations strongly correlated with water level. TDS concentrations among the wells are highly variable, ranging from less than 500 mg/L to over 6,000 mg/L. There is no change in water quality in wells that show a change in water level precipitated by mining. Due to its location upgradient, proposed mining in Area B will have no impact on water quality or quantity in Area C overburden.

Area D
Seven overburden wells were completed in Area D (F**igure 9-33**). Four wells located in the east fingers of Area D were dry when installed. The remaining three wells (WO-104, WO-106, and WO-175) were located more interior to the permit area and recorded drawdown associated with mining before they were mined-out (**Figure 9-34**). WO-104 had as much as 38 feet of water when installed and was already in decline, likely in response to climate as mining in the area was not active until late 1980's. WO-106 measured up to 20 feet of saturation and WO-175, located near the crop line, had 18 feet. The sharp decline in WO-175 beginning in 1999 is attributed to mining.

Even as mining neared the wells, TDS concentrations in the wells remained low, ranging from 306 mg/L to 819 mg/L, likely reflecting local recharge via clinker, which is typically lower in TDS. As mining removed most of the coal resource in Area D, there are no currently active Area D wells for comparison. Due to its location, proposed mining in Area B will have no impact on water quality or quantity in Area D overburden.

Area E
Overburden well WO-174 remains active in Area E (**Figure 9-33**). Located at the west margin of mining, monitoring at this well began in 1983. Recent measurement indicates that the well contains 67 feet of water. Compared to hydrographs in adjacent areas of the Rosebud Mine, including wells not affected by mining, the hydrograph for WO-174 has a characteristic trend that suggests a water level response to climate effects rather than mining (**Figure 9-34**). Changes in water level do not correspond with the conclusion of mining (1986) or completion of reclamation (1996) although these events may contribute to water level changes reflected by the hydrograph.

Generally, water quality in WO-174 appears to respond to water level, with increasing TDS concentration corresponding to increasing water level. TDS rose from 1,070 mg/L to 1,610 mg/L with an 11-foot increase in water level. The increase in TDS is not attributable to spoil. The direction of groundwater flow places WO-174 up gradient of the area mined in Area E; thus it is up gradient of spoil. Additionally, spoil saturation remains below the elevation of the overburden. Due to its location, proposed mining in Area B will have no impact on water quality or quantity in Area E overburden.

9.2.5.1.3 Rosebud Coal
The Rosebud coal is the aquifer most directly affected by mining as it is the target of coal removal. Locally the aquifer is dewatered as each mine cut is sequentially developed. Monitoring wells indicate that drawdown near the pit areas can be substantial, but the close proximity of the crop line to the pits limits the extent of drawdown north and east of the permit areas. Therefore, the greatest extent of drawdown in Rosebud coal outside the mine area is to the south of the Rosebud Mine.

Area A
There are three active Rosebud coal wells in Area A (**Figure 9-28**) and they have been monitored for more than 30 years. All have recorded the effects of mining on water level with observed declines in the early 1980's through the early 1990's, depending on the location of mining in proximity to a given well (**Figure 9-35**). Drawdown was also observed in wells WR-110 and WR-105, two wells that were removed by mining. A few years (1979 - 1981) of steady water level in WR-105 prior to mining associated decline represents background water level and water quality. Approximately 30 feet of water level decline was measured in this well. The 10-foot recovery of water level in WR-127 is likely due to infiltration of adjacent ponded surface water. Rising water level that began in 1993 in WR-104 is likely due to recharge

resulting from the collection of pit water immediately south of the well while mining was in hiatus. The recent decline in water level in this well beginning in 2012 is likely due to pit pumping in preparation for resumption of mining. At this time, active Rosebud monitoring wells indicate that the unmined Rosebud coal remains under confining pressure.

As represented by TDS concentration, water quality in the Area A Rosebud monitoring wells is highly variable. Initial measurements range from 494 mg/L (WR-110) to 2,780 mg/L (WR-105). WR-104 and WR-127, both show increases in TDS concentration over the life of the well. The rising TDS concentration in WR-104 likely has been influenced by pit water which had concentrated dissolved salts due to evaporation during a 14 year mining hiatus in Area A. The rising trend in WR-127 may be due to influences from nearby spoil (e.g. WS-113), but most likely this well is strongly affected by infiltration of surface water from ponds and ditches in the mine facilities area. High chloride (64 mg/L) and magnesium (339 mg/L) concentrations in this well (9/21/2011 sample) is characteristic of dissolved magnesium chloride that was applied to road surfaces in the facilities area. WR-130 shows water level with a repeated response to mining during the times it was active in adjacent (east) pits, although water quality has not shown a significant change. Water level and water quality have been relatively static since the last mine cut in 2000. TDS concentration has declined somewhat since the initial sample and currently is close to 1,000 mg/L.

Mining resumed in the east pit of Area A in 2014. Continued mining will increase the drawdown in the Rosebud coal, increase the volume of spoil, and the recovery time of water levels. The drawdown model predicts a maximum of 20 feet of Rosebud coal drawdown in the southwest part of Area A in 2011 and 2020 (see **Section 9.2.7**). The remainder of the area is predicted to have 10 feet of drawdown. By 2026 drawdown is expected to have recovered to approximately 10 feet.

As the Rosebud coal crop line defines the extent of the pit, there will be no lateral up gradient movement of Rosebud coal groundwater into Area A spoil from the normal flow direction (from the west) to provide recharge. Recharge will depend on surface sources such as infiltration from precipitation events and ponds.

Area A spoil is dry except for the south part of the mined area adjacent to EFAC. The movement of spoil water to EFAC is discussed in **Section 9.2.5.1.1**, under EFAC and in **Section 9.2.8**. The mining proposed in Area B in AM4 will not influence the groundwater water level or water quality in Rosebud Mine Area A due to the discontinuity of Rosebud coal between Area A and Area B. Because the Rosebud coal in Area A does not extend beyond the permit boundaries there is no potential for material damage to the Rosebud coal groundwater in Area A.

Area B

Seven active Rosebud coal wells in Area B have been monitored since the early 1980's (**Figure 9-30** and **Figure 9-31**). Many of the wells at the west end of Area B (WR-124, WR-125, WR-164, WR-162, and WR-173) experienced a water level decline in the 1980's, prior to the approach of mining in areas adjacent to the wells (**Figure 9-36**). This widespread drawdown response was likely due to climate. However, mining effects are suggested by the abrupt change in water levels observed from the late 1990's to early 2000's in WR-164, WR-162, and WR-173. Total water level decline ranged from approximately six feet to 14 feet and is, at least in part, attributable to mining. Thirty to 35 feet of head remains in these wells, indicating that they remain confined aquifers. Only WR-173 has begun to show recovery.

Due to its location over a mile from mining, it is unlikely that the decline in water level in well WR-125 reflects mining activity. Well WR-124 is close to mining. The decline beginning in approximately 2000 may reflect activity in Area C; however, the steep recovery has brought water levels to within three feet of the initial measurement in 1980.

Wells WR-205, WR-160, WR-101, and WR-161 record the response of the Rosebud coal in the east part of Area B. Mining affected drawdown was underway when WR-205 and WR-160 were installed. Recovery and then renewed decline in WR-160 corresponds to the timing of nearby mining activity. Ten feet of recovery in this well was observed when nearby mining ended in 2007. Resumption of mining nearby caused a subsequent decline. The Rosebud coal in this area is has a head of approximately 40 feet. WR-205, located immediately adjacent to EFAC alluvium, has recovered to a steady water level since middle 2007 and has a head of 34 feet. The early measurements of WR-101 and WR-161 reflect baseline. WR-101 and WR-161 recorded approximately 60 feet of head decline prior to being mined out. Rosebud coal and clinker monitoring wells ("WX" wells) adjacent to the coal outcrop along EFAC (**Figure 9-37**) measured an abrupt decline in head between seven feet and 35 feet when mining began at the east end of Area B. An equally abrupt recovery began shortly thereafter, likely due to infiltration of water from EFAC alluvium.

Wells in the west part of Area B had baseline TDS concentrations ranging from 758 mg/L (WR-162) to 2,390 mg/L (WR-125). These wells have shown variability in TDS concentration; change in water level and water quality response are not strongly correlated. The most recent (2013) sample from well WR-173 had a reported TDS concentration of 6,460 mg/L. This is a reporting error as confirmed by the fact that the conductivity and all analytes in the analysis do not reflect a dramatic increase but remain near previous concentrations typical of this well.

Baseline water quality in the east part of Area B is represented by early measurements in WR-101 and WR-161 and in monitoring wells installed in 1983 ("WX" wells), prior to the beginning of mining adjacent to EFAC. A single water quality sample was taken from most of these wells. Water quality as represented by TDS concentrations ranges from 520 mg/L to 1,880 mg/L. WR-160 has shown a mostly steady increase in TDS from 626 mg/L to 2,730 mg/L. WR-205 has had a variable TDS throughout the life of the well ranging from 1,990 mg/L to 2,850 mg/L TDS. Based on distance from EFAC, WR-205 is the only well likely to be affected by alluvial water quality. WR-205 and WR-124 are the only two wells experiencing increasing water levels and the only two wells close enough to EFAC to be influenced by alluvial water levels and water quality. As WR-124 is up gradient of mining, alluvium adjacent to the area (west end of Area B) is not likely to have been impacted by mining. Down gradient, at well WR-205, the rise in water level is assumed associated with the rise in alluvial water level. The rise in down gradient EFAC alluvial water level is attributed to both increase in precipitation during recent "wet years" and to MPDES discharges from the Rosebud Mine which has in turn caused on increase in alluvial TDS concentration (see discussion on EFAC alluvium).

Drawdown, including pressure head, associated with currently approved mining in Area B was modeled (see **Section 9.2.7**) to be 90 feet at the end of 2011. Removal of additional coal proposed in AM4 will extend the mining period in Area B and cause additional drawdown in the Rosebud coal. The increased drawdown from mining AM4 is expected to be 40 feet over that expected to occur in currently approved mining. This is discussed in greater detail in **Section 9.2.7**, Groundwater Flow Models. No private wells are located in the Rosebud coal in the area of increased drawdown, thus there is no potential for material damage to water quantity. An increased volume of spoil would also be created in mining AM4 resulting in a longer period for recovery of water levels and water quality. The potential effects of this

additional spoil on water quality in the Rosebud coal southeast of Area B is discussed in **Section 9.2.5.1.7**, under Area B.

Area C

There are six active Rosebud coal monitoring wells in Area C (**Figure 9-32).** These wells have been collecting data for three decades or more (WR-103, WR-121, WR-126, WR-136, WR-168, and WR-181) **(Figure 9-38**). They are located at various distances outside the pit areas and thus record the response of groundwater outside the immediately affected area. Numerous other wells removed during mining record the response of the system within the mine pit area. Hydrographs from three of these wells are shown on **Figure 9-38**. Many of the wells outside of mining in the south and west part of Area C (e.g. WR-103, WR-121, WR-168, and WR-136) record a water level response similar to the one seen in the west part of Area B (discussed above). Specifically, there was marked water level decline in the 1980's to middle 1990's, prior to mining near these wells. The hydrograph during this period indicates a response to climatic conditions throughout the mine area.

The response of groundwater levels to mining overprinted on climate-initiated water level changes makes it difficult to interpret and assess the extent of each source of change. Based on timing of mining and water levels, well WR-103, located approximately a half-mile up gradient from the nearest pit area, does not appear to have been influenced by mining but shows an abrupt rise in water level in response to above average precipitation in 2011. The steepened decline in well WR-121 in 2007 was likely a response to mining, although the well was in decline in response to climatic conditions prior to commencement of nearby mining. It currently contains approximately seven feet of water. Well WR-126 is located near the Rosebud outcrop, is shallow (20 feet) and is responsive to surface infiltration. This well contained less than six feet of water when installed and maintained saturation during mining. It went dry in 2002 during a time of below normal precipitation but resaturated to premine level when precipitation returned to near normal amounts. Well WR-136 probably was affected by mining as early as 1995 due do its close proximity to mining in both Area A and Area B. However, it was already declining by this time in response to climate or another influence. This well has recently recovered to higher than its initial (1985) water level and has 54 feet of head. Due to its location adjacent to EFAC and downstream from a stock pond, this well is also sensitive to infiltration of shallow groundwater. Mining likely affected water levels in WR-168 in 2006 or later, creating up to six feet of drawdown. Approximately seven feet of water remains in this well. The drawdown response to mining is distinctive in WR-181, resulting in a decrease of approximately 28 feet of head. Forty feet of head remains in this well. West of WR-181, monitoring well WR-231 located a mile and a half west of WR-181 and outside of Area C, has recorded 11 feet of head loss, with a remaining head of 85 feet. By comparison, WR-238 located approximately a mile northwest of the pit lies near the outcrop and has shown no drawdown response and maintains 59 feet of head.

Wells removed by mining (WR-112, WR-117, and WR-169) that were chosen to represent the response to mining in various parts of the Area C pits, show a baseline period followed by a decline as mining approached. WR-112 in the north part of Area C records a response to climate conditions until mining encroached in approximately 2003, causing a brief decline before the well was removed. The well contained between five feet and seven feet of water prior to removal by mining. Well WR-117 located in the east part of Area C, shows an abrupt decline in 1985 when mining came within 800 feet of the well. Prior to its removal, there was approximately 35 feet of head in the well indicating that the Rosebud coal at this location was confined. Well WR-169 in the central part of Area C was confined with 42 feet of head before mining moved within 1,500 feet of the well, causing it to drop 18 feet.

Water quality in Area C is highly variable with background TDS concentrations ranging from less than 500 mg/L (WR-117) to more than 5,000 mg/L (WR-103). Some wells have shown a change in TDS concentration with a change in water level, whereas others have not. WR-121 decreased in TDS concentration when head declined. Well WR-126 experienced a marked changed in water quality from as low of 2,100 mg/L in baseline to a peak of over 8,000 mg/L. When WR-126 went dry and recovered three years later, TDS concentration rose from 3,190 mg/L to over 8,000 mg/L. As a result of its shallow depth (20 feet) and a location immediately adjacent to the county road, this well has been subject to surface influences on water quality. This is evidenced by high concentrations of chloride and magnesium from road stabilization compounds, and higher than normal boron concentrations that suggest the use of coal ash as a road stabilizer. High concentrations of nitrite-nitrate suggest influence from agricultural practices or other local source. The water quality changes are not attributed to spoil water as nearby spoil well WS-122 contains only four feet of water and is down gradient of WR-126. The last sample (12/2013) from well WR-136 spiked approximately 800 mg/L in TDS concentration. This coincides with rising water levels and may be influenced by proximity to EFAC alluvium. The remaining wells (WR-103, WR-121, WR-168, WR-181) have not shown significant water quality changes.

Due to the direction of groundwater flow, Area B mining, including that proposed in AM4, is not expected to increase drawdown or otherwise impact the Rosebud coal groundwater in or near Area C. In 2011, maximum drawdown in Area C was modeled to be 60 feet (see **Section 9.2.7**, Ground Models). By 2020 drawdown is modeled to be 70 feet. By 2026 drawdown is expected to recover to 60 feet. Currently, Area C spoil has experienced little recharge. Saturation of spoil in the north part of Area C will depend on vertical infiltration as the mine area is defined on three sides by the coal crop line, including to the west, which is the up gradient direction of lateral groundwater flow. This means there is no up gradient recharge from the Rosebud coal into the north part of Area C. Although the drawdown here was relatively small (modeled at 10 feet) because of the scant amount of water here in the Rosebud coal, it is anticipated that it will take a substantial amount of time to saturate the spoil in this area. The remainder of Area C will receive lateral recharge to coal and spoil. Upon saturation, migration of spoil water in the direction of natural groundwater flow will be limited by the coal crop line, which defines the down gradient margins of mining in Area C. No material damage to Rosebud coal groundwater has been observed or is expected. Drawdown in the Rosebud coal will not impact any groundwater users and the coal crop line location immediately downgradient of the mine pits limits migration of spoil water into the Rosebud coal groundwater. A possible connection of the Rosebud coal with alluvium in the southwest part of Area C (as suggested by the response of WR-136) suggests EFAC may be subject to spoil water from Area C assuming a local hydrologic connection with the alluvium. Based on the response of monitoring wells (discussed above), connection between the Rosebud coal (or spoil) and the stream appears limited. The impacts of Area C mining on EFAC alluvium is discussed in **Section 9.2.5.1.1**.

Area D

There is one active Rosebud coal monitoring well in Area D (**Figure 9-33**). This well (WR-134) is at the outcrop margin, less than four feet deep and intermittently dry (**Figure 9-39**). It rarely contains more than two feet to three feet of water. Fifteen monitoring wells installed to monitor the Rosebud coal were removed during mining. The limited extent of saturated Rosebud coal remaining in Area D precludes well installation adjacent to the pit areas post-mining. Monitoring wells removed during mining record the response of the Rosebud aquifer as mining took place. Prior to mining, the Rosebud coal in Area D was unconfined. Groundwater on the north side was scant, ranging from less than one foot to four feet. Up to 25 feet of water was measured in more centrally located wells. Well WR-107 was located in the southwest part of the permit area and had a saturated thickness of 16 feet to 20 feet. Most water level fluctuations in this well reflect responses to climate with mining likely responsible for

the dip in level in 1991. Well WR-118 represents conditions in the southeast arm of the permit area. It contained 12 feet of water prior to being affect by mining in 1987. Well WR-123, with between 16 feet and 25 feet of water, recorded water level response to climate before being affected by mining in 1989. Wells WR-131 and WR-132 were located at the north edge and northeast arm of the permit area, respectively. With between a foot and three feet of water in these two wells, they showed little response to mining when it encroached in middle 2000.

A wide range of TDS concentration characterized Area D Rosebud coal water quality. TDS concentration ranged between 476 mg/L and 6,645 mg/L, with an average of 2,406 mg/L and a median of 1,577 mg/L, respectively. As commonly observed in other permit areas, TDS concentrations often declined coincident with declines in water level. Elevated boron concentrations ranging from 2 mg/L to 3.1 mg/L in well WR-107 suggest influence by power plant ponds located approximately a mile south. Anomalous but less concentrated boron (0.7 mg/L to 2.7 mg/L) was found in samples from WR-118, WR-131, and WR-183. The source of the boron in these wells is undetermined.

Area D is geologically isolated from impacts associated with proposed AM4 mining. Because of this geological isolation, there is also no potential for material damage to groundwater in the Rosebud coal from Area D mining.

Area E

Four Rosebud coal monitoring wells in Area E have been active since the early 1980's (**Figure 9-33**). The east part of Area E, including part of the area on which the Colstrip power plant facilities are located, was mined pre-law, prior to passage and implementation of MSUMRA in 1978. Thus, the wells do not represent a baseline period.

WR-174, located at the west margin of mining, shows the greatest fluctuation in water level and appears to be in a confined part of the Rosebud aquifer at this location, with a total head of 53 feet (**Figure 9-40**). The water level decline in the middle to late 1980's likely represents a combination of drawdown associated with mining, which ended in late 1986, as well as an extended period of low precipitation. Water levels in this well began to rise coincident with the completion of reclamation in 1996. Return to initial water levels in this well took place with above average precipitation in recent years. By contrast, well WR-108 located a short distance up gradient of mining, has a relatively small water level fluctuation of two feet or less most of the time. The total head in this well is 41 feet. As this well was drilled two feet into McKay coal, it may be influenced to some extent by the head and water quality in the McKay coal.

Wells WR-128 and WR-129 are located in an erosional remnant of coal, near the margins of the Colstrip power plant effluent pond for Units 3 and 4. The pond was built in the middle 1980's. As evidenced by water quality, well WR-129 has been affected by the pond. However, well WR-128 has also been affected by the pond. Due to the small area of Rosebud coal in which these wells are located, they contain little water, generally between seven and 11 feet. Rosebud coal in WR-129 is only five feet thick and is overlain by 72 feet of highly permeable clinker.

Water quality in the Rosebud coal wells in Area E is highly variable, ranging from less than 1,000 mg/L in WR-128 and WR-174, to slightly over 6,000 mg/L in WR-129. Water quality in WR-174 appears correlated somewhat with water level, with TDS increasing with increasing water level. Elevated concentrations of boron and chloride, two analytes used to characterize water quality affected by coal ash, are in samples taken from WR-128 and WR-129. Increased potassium concentrations in samples

taken in 1996 and later from wells WR-108, WR-128, and WR-129 also characterizes these wells. The source of the potassium has not been identified. Potassium does not represent a hazard or concern.

Drawdown in Area B overlaps that of Rosebud Mine Area E. Drawdown from additional mining in Area B as proposed in AM4 is not expected to extend into Area E by the time mining in AM4 would be completed in 2026 (see **Section 9.2.7**). However, recovery of water levels and water quality in Area E may be extended somewhat, as Area B is up gradient of Area E and a source of lateral recharge to Area E. Upon saturation of Area B spoil, groundwater is anticipated to move beyond the permit boundary to the east southeast, toward the down gradient crop line in Area E, the former Pit 6 mine area, and Big Sky Area A and Area B. With the exception of Area B spoil well WS-158, which has a higher TDS, spoil water quality in Area B and Area E (including Pit 6) is within the same range (see **Figure 9-56**). Area B spoil is not expected to cause decline in water quality in Area E. As discussed above, no material damage has been indicated in Rosebud coal groundwater as a result of Area E mining and none is predicted to occur as a result of current or future Area B mining.

9.2.5.1.4 Interburden

The interburden, like the overburden, is composed of thin, discontinuous beds of low conductivity sedimentary rock. Locally, water in the interburden may be in communication with underlying McKay coal where there is sufficient pressure head. The interburden is of low yield and not utilized as a water resource.

Area A

Two active interburden wells remain in Area A (**Figure 9-28**). Well WI-111 (**Figure 9-41**) is located in the east part of Area A, immediately west of mining. Mining recently resumed at this location after a hiatus of 14 years. The pit remained open since mining of the last cut in 2000 and held water for much of the time the area was in hiatus. Early mining (1978) south of well WI-111 may have caused water levels to decline prior to well installation and the upward trend characteristic of this well may represent recovery. However, the well maintained a gaining water level trend, as did the McKay well (WM-129) at the same location, when mining was nearby in the 1990's, suggesting that it was insulated from mining effects. Well WI-111 now has a head of 65 feet and the McKay has a 70-foot head. The water level measurements from these two wells are similar enough to infer that the McKay coal and overlying interburden are in communication.

Well WI-102 is located in the southeast part of Area A near the margin of early (1979) mining. The earliest water level measured in this well was 1980, indicating that it was installed after mining and therefore likely records the recovery of the interburden water levels. It currently contains more than 80 feet of water. Adjacent wells in the McKay coal (WM-130) and spoil (WS-106) show the same increasing water level trend as WI-102. Similar water levels suggest that these wells are in communication. Location of these wells adjacent to a pond is a likely source of the recharge.

Interburden wells removed during mining include WI-101 and WI-112. WI-101 was located in the northwest part of Area A and contained approximately 62 feet of water at initial measurement. A declining trend characterized this well from the first measurement even though mining in the area did not begin until the middle to late 1980's. The abrupt rise in water level near the end of well life likely reflects well failure as mining approached. By contrast, well WI-112 never contained more than a foot of water and gives no clear indication of being impacted prior to removal.

Water quality in Area A interburden wells is variable within a given well and between wells. Well WI-111 showed a decline and then an increase in TDS, dropping from 1,840 mg/L (SC = 2,350 μS/cm) to 877 mg/L (SC = 1,370 μS/cm) and later returned to initial TDS concentration range. The reason for the variation is not clear and there is no clear correlation with mining activity other than the possible effect of standing water in the pit contributing to the decline in water quality. McKay well WM-129 is in likely communication with WI-111, has also shown a decline and subsequent rise in TDS concentration, and is now at 1,740 mg/L (SC = 2,310 μS/cm). TDS is slightly higher in the McKay coal well. TDS in well WI-102 climbed from 1,980 mg/L (SC = 2,130 μS/cm) to as high as 3,480 mg/L (SC = 3,460 μS/cm), but is now at 2,850 mg/L (SC = 2,800 μS/cm). The spoil well at this location has lower TDS concentrations (3,440 mg/L) than found in WI-102 at the time of its highest TDS concentration although it could influence water quality given the fact that water levels suggest it is in communication with the interburden.

Area B mining proposed in AM4 is not expected to affect interburden in Area A. No material damage has been observed in the interburden groundwater in or near Area A and none is expected. Well WI-102 may show a water quality impact from mining, but this well is located within the permit boundary and migration of water in the interburden is limited by the low permeability of this unit.

Area B

There are eight active interburden monitoring wells in Area B (**Figure 9-30** and **Figure 9-31**). The wells at the east end of Area B (WI-157, WI-159, WI-184, and WI-185) show a rising water level trend that represents a recovery subsequent to drawdown associated with mining (**Figure 9-42**). These wells were installed within the mined area after reclamation was complete. The strength of the rising trend, particularly at the far east end of Area B, is due to hydrologic connection between water in EFAC alluvium and spoil and bedrock units that experienced drawdown during mining. McKay coal, spoil and interburden in this area have nearly identical water levels suggesting that they are in hydrologic communication.

Interburden wells in the southwest part of Area B (WI-162 and WI-164) recorded drawdown associated with mining. Mining in this part of Area B began more than a decade after mining in the east part of Area B. Within the past few years, these wells have begun to show a slight recovery. McKay wells WM-162 and WM-164 show the same water levels and response as the interburden wells at the same location. Recovery to the wells is laterally from the west but is limited by their location near the active pit.

Wells WI-157, WI-159, and WI-184 have shown increases in TDS coincident with increasing water level. Among the interburden wells in Area B, WI-159 has the highest TDS concentration at 4,390 mg/L. The adjacent spoil well, WS-159, at the same water level as WI-159, has a TDS of 4,220 mg/L, suggesting that it may be contributing to interburden water quality at this location. WI-157 and WI-184 remain below a TDS concentration of 2,400 mg/L at this time. Nearby spoil well WS-157 has a TDS concentration at 2,670 mg/L (SC = 2,830 μS/cm). Well WI-184 lies adjacent to spoil well WS-184 with a nearly identical water level. They have TDS concentrations of 2,360 mg/L (SC = 2,480 μS/cm) and 2,350 mg/L (SC = 2,490 μS/cm), respectively. Nearby alluvial wells WA-126 and WA-128 have TDS concentrations of 3,070 mg/L (SC = 3,890 μS/cm) and 2,890 mg/L (SC = 3,330 μS/cm), respectively. Alluvial water is currently the main source of recharge to spoil and interburden at this location and generally shares a similar chemistry and quality.

WI-160 is in the east part of Area B but lies in an undisturbed area, south of pits mined as recently as 2007. TDS concentration in this well has increased from 418 mg/L (SC = 718 μS/cm) to as high as 1,360 mg/L (SC = 1,780 μS/cm) and now measures 1,180 mg/L (SC = 1,570 μS/cm). Similar increases occurred in the adjacent Rosebud coal well, WR-160. The most likely cause of water quality change is associated with changing water levels due to mining.

WI-185 has shown a decline in TDS concentration during a rise in water level. The TDS concentration in this well currently is below 1,000 mg/L and is similar to TDS in interburden wells WI-162 and WI-164. WI-162, WI-164, and WI-173 have shown a decline in TDS concentration with decline in water level. These wells have a TDS concentration of between 1,100 mg/L and 1,300 mg/L.

Interburden in the east part of Area B is relatively thin and appears to be hydrologically connected with the Rosebud coal and McKay coal. Based on the response of interburden wells in the east part of Area B, the proposed mining in AM4 is expected to cause additional interburden drawdown in the immediate vicinity of the mined area. This will result in longer water level recovery of depressed water levels in interburden. No physical disturbance of the interburden is expected. Upon saturation, the overlying spoil may diminish interburden water quality in the area of the AM4 pits where the interburden water level is near the base of the spoil. This change in interburden water quality is not expected to render the interburden groundwater: 1) unsuitable for existing and anticipated uses; 2) harmful, detrimental, or injurious to beneficial uses; or 3) cause exceedances of narrative or DEQ-7 standards outside the Area B permit boundary. Thus, no material damage is expected.

Area C

Seven interburden wells remain active on the periphery of mining in Area C **(Figure 9-32**). Wells impacted by mining typically have an abrupt decline in water level, as exhibited by WI-181, located adjacent to mining in the west part of Area C (**Figure 9-43**). Wells WI-171 and WI-172 remain approximately a mile and a half-mile, respectively, from the limits of mining at Area C and have not been affected by mining. The persistent, long-term decline in these wells was in progress when these wells were installed, long before the nearest mining began in 2006 and 2010. Although located immediately adjacent to mining that took place in 1984, WI-153 had a relatively small response and quick recovery and has maintained approximately 20 feet to 24 feet of water. A nearby well, WI-186, installed after mining, appears to record a recovery, although what appear to be errors in measurement cast doubt on data from this well. Well WI-168 would have been affected by nearby mining between the late 1990's and 2011 and the relatively small decline during this period may be associated with mining. Although immediately adjacent to mining in 2003 through 2008, well WI-178 appears minimally affected.

Water quality among the wells is variable, with TDS ranging from 500 mg/L to 5,000 mg/L. Most wells range between 2,000 mg/L and 3,500 mg/L and have shown declines and increases in TDS concentrations. Wells WI-171 and WI-172 are outside areas impacted by mining and changes in the wells are not attributable to mining. Well WI-178 is outside but immediately adjacent to mining and may be experiencing an increase in TDS associated with drawdown. A slight upward trend in TDS concentration had begun before WI-181 became affected by mining. The well with the most significant change in water quality is well WI-186, with a rise from an initial measurement of 504 mg/L to 4,670 mg/L, before dropping to a current concentration of 3,380 mg/L. The rise correlates with an initial increase in water level. Spoil well WS-186 is located near WI-186 but has been intermittently dry and has not had sufficient water to sample. Because it has been dry to scantly saturated, the spoil well is not suspected as the source of the increased TDS. This well is relatively shallow at a completion depth of 65 feet. Atypical increases in chloride (from 5 mg/L to 32 mg/L) and in nitrite-nitrate (from 0.05 mg/L to as

high as 13.9 mg/L) are associated with the water quality changes at this well. Its location in a hayfield and adjacent to a county road subjects this well to anthropogenic sources of contamination associated with agriculture and road maintenance and may explain the observed water quality changes.

Due to the direction of groundwater flow, Area B mining, including mining proposed in AM4, is not expected to impact Area C interburden. No material damage is indicted to the interburden groundwater near Area C and none is expected to occur.

Area D

Only one active interburden monitoring well remains in Area D (**Figure 9-33**). WI-110 is a shallow well with a water level that varies between three and 10 feet (**Figure 9-44**). The "flashy" water level on the hydrograph is due to the shallow depth and tendency of the well to be affected by infiltration from runoff and precipitation. The well has variable water quality but generally has a trend of increasing TDS over time. The source of change in water quality is not clear. An adjacent McKay coal well (WM-128, located stratigraphically below WI-110) shows no trend of increasing TDS and is somewhat lower in concentration at 2,210 mg/L than WM-128 at 2,800 mg/L. Adjacent spoil well WS-129 (located stratigraphically above well WI-110) is dry and thus is not the source of declining water quality in WI-110.

Interburden wells removed during mining generally showed a water level decline as mining approached. Some wells showed an abrupt increase in water level before being removed that was likely due to well failure from blasting as mining drew near. The amount of water in the interburden measured in the wells ranged from 18 feet to 55 feet. Water quality as represented by TDS was highly variable, ranging from 700 mg/L TDS in well WI-183 to 7,000 mg/L in well WI-114. Interburden thickness ranged between 18 feet and 30 feet, and water levels between the interburden and McKay coal maintained a downward vertical gradient.

Area D is geologically isolated from impacts associated with proposed AM4 mining. No material damage to the interburden groundwater is expected near Area D or has been observed to date.

Area E

There are eight active interburden monitoring wells in Area E (**Figure 9-33**). All of them have been active since the early 1980's and most record increases in water level since installation. The 10-foot decline in WI-174 through 1988 reflects drawdown associated with the final stages of mining (**Figure 9-45**). As drawdown was active at the time measurements in the well began, the original water level is unknown. Water level recovery in this well appears to be continuing based on the upward trend on the hydrograph. WI-106 and WI-117 record the end of the water level decline followed by decades of recovery. WI-182 is also likely recovering from drawdown associated with mining. The steady climb in water level observed in WI-116 may be associated with recovery of postmine water level but is also heavily influenced by its location immediately adjacent to the Talen Energy ponds, as are the other monitoring wells in this location (e.g. WM-135, WS-116). WI-107, WI-108 and WI-109 water levels are influenced by their proximity to the power plant ash ponds in the Cow Creek drainage. The amount of water in the interburden wells varies from 11 feet (WI-109) to 55 feet (WI-116). Most wells contain less than 25 feet of water.

Water quality, as represented by TDS concentration, is variable in Area E interburden wells, ranging from less than 1,000 mg/L to greater than 4,000 mg/L. WI-108 has a high variability but no trend of increasing concentration. This well is located at the southeast corner of the ash pond in the Cow Creek

drainage and has been affected by leaks from the pond as well as pumping wells (as exhibited by the water level hydrograph for this well) designed to capture affected groundwater. Most of the interburden wells in Area E appear to be affected by poor quality water from the plant area or ash ponds, based on the presence of higher than background boron concentrations. Background boron concentrations in Rosebud Mine aquifers typically contain no more than 0.5 mg/L. Area E interburden wells consistently in the initial boron concentration range are WI-107 and WI-174 (**Figure 9-46**). Boron concentrations in the remainder of the wells have shown increases in concentration and range from 0.6 mg/L to 1.3 mg/L. A single analysis from WI-108 ranges to almost 10.0 mg/L. Water quality in well WI-174 improved coincident with drawdown (TDS concentration declined from 2,430 mg/L to 1,140 mg/L currently) and has maintained this quality as water levels recovered.

AM4 proposed mining in Area B is not expected to affect interburden in Area E. For the reasons stated above, Area E interburden groundwater has shown no evidence of material damage and none is expected. Water quality impacts noted above are all attributable to the Talen Energy plant area and ash disposal ponds.

9.2.5.1.5 McKay Coal

The McKay coal ranges between eight and 23 feet thick and averages approximately 18 feet thick. It is not physically disturbed by mining and lies below the Rosebud coal a few feet to tens of feet, depending on the thickness of the interburden. The McKay coal typically is confined and generally has a pressure head of tens of feet except near outcrop limits, where the aquifer becomes unconfined. Most McKay coal within the mined areas has experienced a slight decrease in head due to mining.

Area A

Five McKay coal monitoring wells have been active in Area A for more than 30 years (**Figure 9-28**). Well WM-105 lies the farthest from mining, northwest and just outside the permit boundary, approximately a half-mile from mining. The hydrograph for WM-105 generally shows three feet to four feet of variation in water level during the monitoring period that subtly reflects climatic changes rather than the effects of mining (**Figure 9-47**). Thus, WM-105 represents background conditions at this location. The total head at this well is currently 104 feet.

Based on proximity to and timing of mining, well WM-104, located interior of mining, likely experienced drawdown associated with mining during 1993-1994, although the amount is uncertain due to climate influences suggested by the hydrograph trend. Water levels have shown at least 10 feet of recovery from a low in 1994 and have remained approximately steady since 1999. The temporary five-foot increase in water level during higher than normal precipitation in 2011 illustrates the susceptibility of this well to climate effects. The water elevation (total head of 124 feet) in this well is the same measured in adjacent Rosebud well WR-104, suggesting that they are hydraulically connected. The interburden between the two coal units at this location is 54 feet. McKay coal wells in Area A have a head between 72 feet and 124 feet.

Wells WM-103, WM-129, and WM-130 show increasing head through time, although the setting of WM-103 and WM-130 is substantially different from WM-129. WM-130 is located at the south margin of early reclamation near a perennial pond. The increasing head in this well likely reflects recovery of head lost during early mining. However, the pond likely contributed to the 13-foot rise in water level. Interburden well WI-102 is located adjacent to this well and shows the same increase in water level. WM-103 is located adjacent to a cut off loop meander of EFAC that is used as a pond to capture runoff from the tipple area. The close proximity of this pond affects the water level in the monitoring well.

WM-129 is located in the eastern interior of Area A, close to the last mining cut (taken in 2000). It has also shown an increase in water level of approximately 13 feet with a nearly constant upward trend since the middle 1980's. Adjacent interburden well, WI-111, also showed an increase in water level of the same magnitude. The increase may reflect a recovery of earlier drawdown but is likely also affected by water that has collected and ponded in the adjacent idle pit.

With the exception of WM-129, TDS concentration does not vary much within a given well. WM-129 has varied from 984 mg/L to 1,990 mg/L without a consistent trend. Average water quality among the wells varies from 1,723 mg/L (WM-103) to 3,036 mg/L (WM-105). There is no indication that water quality in these wells has been influenced by mining.

Mining resumed in the east pit of Area A in 2014. Continued mining will increase the decline of head in the McKay coal although it will not physically disturb it. The interburden separation between spoil and McKay coal is sufficient to protect it from effects of spoil water quality. The drawdown model (see **Section 9.2.7**) predicts drawdown of between 10 feet and 15 feet in the McKay coal in 2011 and 2020, with the greatest drawdown in the southwest part of Area A. Approximately 15 feet of drawdown, limited to the south edge of the permit area, is projected to remain in 2026 at the end of mining in AM4.

Because the TDS concentrations in McKay wells in Area A show no variability attributable to mining operations, no material damage has been observed or is expected to occur in groundwater in the McKay coal near Area A.

Area B

McKay coal monitoring wells (**Figure 30** and **Figure 31**) abandoned or removed during mining record loss of head in the aquifer (**Figure 9-48**) as mining approached. Wells in the southwest part of Area B (WM-100, WM-113, and WM-163) showed the least amount of head loss, with declines between four feet and nine feet. Remaining head ranged between 67 feet and 90 feet in these wells. McKay wells removed from the east end of Area B (WM-161, WM-106) experienced head declines of 44 feet and 57 feet, with 58 feet and 106 feet of remaining head. Baseline TDS ranged from 426 mg/L to 1,830 mg/L (average of 1,011 mg/L). After mining began to affect water levels in the wells some of them experienced changes in TDS, both increases and decreases, with a range from less than 100 mg/L to 1,833 mg/L. Increase in TDS concentrations due to infiltration from spoil is not a likely cause for increasing TDS as the spoil in this area remained dry to scantly saturated at the time these wells were in place. Interburden water quality generally has a lower TDS than the McKay wells and is not a likely source of increase in McKay water quality. The source of the change remains undetermined.

Eight active McKay coal wells have water level observations that date from the early to middle 1980's **(Figure 9-49**). The four active wells in the northeast part of Area B (WM-158, WM-159, WM-184, and WM-185) record head gains of between 12 feet and 20 feet. The gain appears ongoing as of the last measurements. As these four wells were installed in reclamation, the trend of increasing water level reflects recovering pressure head lost during mining. Current head in these wells ranges from 54 feet (WM-159) to 81 feet (WM-184).

The four active McKay wells to the southwest (WM-139, WM-162, WM-164, and WM-173) record declines in head of between nine feet and 26 feet and have a remaining head of between 87 feet (WM-173 and WM-139) and 110 feet (WM-164). These wells were in place during mining and are located outside mine disturbance. A gently declining trend observed in most of these wells at the time monitoring began is likely climatic in origin. A sharp drop in head on the hydrographs point to the time

the well responded to mining. The decline in these wells appears to have ended and a slight recovery begun.

Well WM-139 records a continuous gentle decline beginning in 1984, lasting until 2008. The nearest mining (in Area C) is located approximately 1,200 feet from this well and was not active until 2005. It does not appear that this well has been affected by mining.

Along with a decline in water level, well WM-162 shows a trend of declining TDS, from a high concentration near 3,000 mg/L to a concentration hovering consistently above 1,000 mg/L in the last decade. WM-184 has a trend of increasing TDS from 902 mg/L to 1,530 mg/L which may be the result of water quality changes attributable to infiltration from overlying interburden (TDS = 2,360 mg/L) and spoil (TDS = 2,350 mg/L) water. The remaining wells do not exhibit strong trends or significant changes in TDS. The average TDS among the wells ranges from 1,109 mg/L to 2,550 mg/L.

Modeled drawdown in 2011 (see **Section 9.2.7**) estimated a maximum of approximately 30 feet of decline in McKay coal head, centered in the east central part of Area B. At the end of currently approved mining in Area B (2020), drawdown is expected to remain approximately the same. Mining proposed in AM4 would increase the amount of drawdown in the McKay coal to 35 feet but would not measurably increase the extent. Due to the substantial confining pressure in the McKay coal, significant head is expected to remain even with the predicted drawdown. As the McKay aquifer will remain intact and connected to up gradient flow, recovery is expected to reach former water levels but may take longer with the additional AM4 mining. The separation between the base of spoil and the top of the McKay coal is approximately 10 feet in the vicinity of the cuts proposed in AM4. The narrow separation makes it more likely that McKay coal water quality may be affected by spoil water quality. In the east part of Area B where water level recovery is underway in all units, only one well (WM-184) has shown a marked increase in TDS concentration (from 902 mg/L to 1,530 mg/L). This suggests that if there is substantial decline in McKay coal water quality, it will be local in extent. Any local decreases in water quality in the McKay coal groundwater in Area B are not expected to spread beyond the permit boundary and constitute material damage.

Area C

The drill logs of the eight active McKay monitoring wells in Area C (**Figure 9-32**) show much of the McKay coal is less than 10 feet thick. Only one well (WM-181) monitors McKay coal as thick as 12 feet. All of the water levels measured in the McKay coal aquifer indicate that it is under confining pressure with heads as great as 104 feet (WM-107)(**Figure 9-50**).

WM-181, located approximately 1,500 feet southwest of the active pits had a 16-foot drop in water level after 2007 that is likely associated with mining. The period between the early abrupt increase in water level followed by an abrupt decrease some three years later likely represents measurement or calculation errors. Last measurement shows a slight increase in water level that may indicate the beginning of water level recovery.

WM-153 and WM-186 are both located along the north edge of mining in the east part of Area C. Mining in the area began near the outcrop in 1984 and continued through the early 1990's. The hydrograph for both of these wells shows a period of variable water level during this time with a loss of head between 2 feet and 6 feet. Both wells have recovered to premine levels. The irregularity of the water level measurements in WM-107 between 1988 and 2003 suggest a problem with the well or in the measurements taken at this well. WM-107, like WR-103 (discussed above), is located outside the permit

area, southwest of mining. The period of decline in this well occurred prior to the time that it could have been influenced by mining.

The drop in water level in well WM-178 in 2007 reflects the beginning of a four-foot head loss in response to mining. Current water levels have returned to premine levels.

The decline observed in monitoring in well WM-191 is not likely associated with mining. Monitoring in this well did not begin until late 2002 and it remains over a mile from nearest mining. WM-201 was installed in reclamation in the north part of Area C and reflects rising head associated with recovery after mining.

Water quality in the Area C McKay coal wells has been relatively consistent in some wells and more variable in others. TDS concentrations have ranged between 2,000 mg/L and 3,500 mg/L with the exception of concentrations in WM-107 and WM-186. WM-107 reached a concentration as high as 4,740 mg/L before returning to a concentration that is currently 2,760 mg/L. WM-186 has shown an increase from a concentration of approximately 500 mg/L to a current concentration of 2,250 mg/L. Adjacent interburden well WI-186 has also experienced a substantial increase in TDS concentration, suggesting that both wells are influenced by a similar source. Nearby spoil wells WS-122 and WS-186 contain five feet and 16 feet of water, respectively. Historically these wells have been dry to intermittently dry and have not been sampled for water quality. The thickness of the interburden ranges from 23 feet (WI-153) to 57 feet (WI-186) and is generally considered protective of the McKay coal water quality as the vertical conductivity of the interburden siltstones and mudstones is low.

Maximum drawdown in McKay coal in Area C was modeled to be 25 feet by 2011 (see **Section 9.2.7**). Further decline in head is predicted to be 30 feet in 2020 and to remain at 30 feet in 2026. Given the amount of potentiometric head in the McKay coal, the decline in head is not expected to be significant. As the McKay coal is not physically disturbed and remains laterally continuous up gradient, recovery of head is expected. Changes to the McKay coal water quality are not expected to result from mining and no material damage is expected to occur.

Area D

Five active McKay monitoring wells remain in Area D (**Figure 9-33**). Thickness of the McKay coal in Area D averages approximately eight feet but increases to 12 feet in the center of the permit area, where the McKay is at a greater depth. The McKay coal was confined throughout Area D except near the outcrop, with heads of up to 24 feet. Heads are lower in the north part than the central and south part of Area D. Drawdown ranged from none to as much as 13 feet during mining. Many hydrographs from the active wells indicate that an increase in water level is taking place, as evidenced by the water level in well WM-189 (**Figure 9-51**). Well WM-189 was installed to replace well WM-110 that was removed by mining in 1991. Current water levels are equivalent to premine levels with approximately 34 feet of head in the well.

The poorest water quality (TDS = 3,300 mg/L - 5,400 mg/L) was measured in historic wells along the north edge of Area D, whereas the best water quality is found in the southeast leg (e.g. active well WM-125, TDS = 1,500 mg/L) where clinker is common. Water quality is variable among the active wells, ranging from 1,500 mg/L (WM-125) to as high as 4,150 mg/L (WM-188). The TDS concentration in well WM-188 is higher than the spoil well (WS-188) at the same location (TDS = 1,700 mg/L). There is no indication that water quality in the McKay coal is being affected by spoil or has otherwise changed due to mining.

The McKay crop line is exposed around the north, west, and east sides of Area D, meaning that it is not connected to up gradient lateral flow. Additional recharge to the McKay coal will come from infiltration through the Rosebud/spoil or directly from precipitation when the McKay coal is near the surface. An interburden thickness of 18 feet to 30 feet offers protection to the McKay coal from infiltration of spoil water. No material damage to groundwater in the McKay coal has been noted near Area D. Area D is geologically isolated from impacts associated with proposed AM4 mining, thus precluding the potential for material damage.

Area E

There are 12 active McKay coal monitoring wells in Area E, including three that were installed in the former Pit 6 permit area (**Figure 9-33)**. The average McKay coal thickness in Area E is nine feet. As much of the mining in Area E was pre-mining there were no baseline data gathered to compare to current data. However, the active wells have more than 30 years of data. All of the wells indicate a confined aquifer and most have a head of 30 feet or more. A number of the wells have rising water levels that represent recovery subsequent to mining drawdown (**Figure 9-52**). Wells WM-127, WM-136, and WM-138 have variable water levels that reflect power plant ash pond water management. Pumping wells have been installed along the periphery of the pond to control movement of groundwater away from the pond.

Most of the mine monitoring wells were installed after mining concluded, including areas along the east margin of Area E and Pit 6 that were mined pre-law. However, well WM-174 located near the last mine cut was installed in time to record drawdown at the end of mining and subsequent water level recovery. Well WM-135 began a marked upward trend in 1988 and steadily gained 30 feet over a period of 10 years. This well is located immediately adjacent to ponds at Colstrip power plant that have likely contributed to the water level and water quality of this well. Well WM-124 has also gained approximately 30 feet of water, likely due to its location on the southeast side of the ash ponds in Cow Creek drainage.

Water quality in the Area E McKay wells is highly variable. The wells (WM-121, WM-122, and WM-123) south of the Area E permit, in the former Pit 6, have TDS concentrations that average 500 mg/L or less. With the exception of wells WM-127, WM-135, and WM-182, TDS concentration in the Area E McKay wells typically is 2,500 mg/L or less. Boron concentrations greater than background (background = 0.5 mg/L or less) in a number of the wells suggests nearby ash ponds have influenced their water quality (**Figure 9-46**). These include WM-126, WM-127, and WM-138. As discussed above, the water level and chemistry of WM-124 is influenced by the nearby ponds at the power plant. The greatest water quality anomaly in the area is the stable, long-term TDS concentration of 7,500 mg/L to 8,000 mg/L in well WM-127 (WR-129 at this location also has a relatively high TDS concentration). At 11 feet of saturation, WM-127 contains the least amount of water of any well in Area E. It contains anomalous amounts of dissolved iron, chloride, magnesium, and sulfate. The concentrations of all analytical components are higher in this well than any other Area E spoil well. For this well and all other McKay wells in Area E, there is no indication that spoil water is influencing water chemistry.

Mining in Area A and Area B has created drawdown in the McKay coal that extends into Area E and adds to the drawdown created by mining in Area E (see **Section 9.2.7**). Modeling for 2026, the year AM4 mining is to conclude, shows water level recovery underway with the eastern extent of the drawdown cone lessening in Area E. Except for areas under the influence of power plant activities (e.g. WM-127 and WM-138), hydrographs indicate that water levels in the McKay coal are recovering and are expected

to continue this trend. Due to activity associated with the power plant it is difficult to tell if mining has impacted or will impact the water quality in Area E. The unusually low TDS that characterizes McKay coal groundwater in former Pit 6 indicates no mining or power plant impacts at this location. As described above, no material damage has been indicated to McKay groundwater in or around Area E and none is expected to occur.

9.2.5.1.6 Underburden

Underburden monitoring wells are completed in water bearing strata below the McKay coal in every permit area of the Rosebud Mine. Well depth varies from 130 feet to over 400 feet and usually represents the first water bearing zone below the McKay coal. The variation in depth results in different water elevations and water quality. Underburden wells monitor mining associated drawdown and water quality changes, including potential downward migration of water from the spoil.

Examination of water levels and water quality in the underburden wells through time indicates that the underburden remains largely unaffected by mining in much of the Rosebud Mine. Although water levels in some areas appear to show a response to mining, there is no indication that spoils water is affecting the underburden aquifer water quality. Mining proposed in AM4 is not expected to cause water level or water quality changes in underburden groundwater. No material damage has been observed to underburden groundwater at the Rosebud Mine and none is anticipated.

Area A

Rosebud Mine Area A has one active underburden well (WD-107) located approximately 500 feet west and up gradient of mining (**Figure 9-28** and **Figure 9-53**). It is 203 feet deep. Monitored since 1981, this well predates the beginning of local mining in 1987 and has shown no significant changes in water level or water quality since mining began. Another well (WD-109) located two miles northwest of Area A and over a mile from mining in Area C, has been monitored since 1982 and remains unaffected by mining

Area B

Rosebud Mine Area B has six active underburden wells (**Figure 9-30** and **Figure 9-31**). They range in depth from 147 feet to 425 feet. Except for the deepest well (WD-195), the wells appear to have an upward gradient with more than 100 feet of head. Except for the deepest well (WD-195), wells have a head of more than 100 feet, suggesting there is an upward gradient between the underburden and overlying units in some areas (**Figure 9-53**).

Mining in Area B began in the late 1970's at the far east end and followed the crop line southwest along EFAC through the middle 1980's to the line between section 7 (T1N, R40E) and section 12 (T1N, R41E). Mining further to the southwest began in the middle 1990's. Well WD-100, completed some 130 feet below the Rosebud coal, monitored water level and water quality in the northeast part of Area B from 1979 until removed ahead of mining in 1986. By early 1981, the well was showing a decline in water level although mining was a mile away. The final measurement in 1986 indicates a total water level decline of almost 50 feet. The decline in water level closely mimics hydrographs of adjacent wells WR-101 and WM-106, suggesting the cause for the decline was mining related.

Wells installed in 1982 and later in northeast Area B (WD-159, WD-160, and WD-184) have a hydrograph that shows an initial short, sharp decline that was in progress at the time of installation (1982-1985), likely representing a response to mining that was already in progress. It was followed by a gain in head of between 12 feet and 20 feet until approximately 2002-2003. The persistent, relatively steep rise in head into the late 1990's in these deep wells is observed in every stratigraphic interval monitored in this

part of Area B. The rise most likely represents recovery from an earlier decline in head like the decline observed in WD-100. Subsequent, short-lived declines like the ones seen in WD-184 likely reflect renewed mining near the well. Recent water level fluctuations are in response to climate.

Two underburden wells located farther to the southwest were installed in 2008-2009. WD-195 is a mile west and up gradient of mining and appears to have had no response to mining. WD-196 is in reclamation and shows a slight increase in water level, but whether the increase is due to recovery or a response to climate is uncertain.

Except for WD-160 and WD-196, the wells have maintained relatively consistent water quality, suggesting they have remained isolated from other water sources during changes in water level. TDS concentration currently ranges from 221 mg/L to 3,090 mg/L. WD-160 showed a strong increase in TDS concentration after the first sample and then a precipitous decline in 1998, to an uncharacteristically low TDS range of less than or equal to 200 mg/L, where it has remained. A possible explanation is that a different, secondary water source reached the well. However, surface water or groundwater in the vicinity with this low of a TDS concentration has not been identified. WD-196 experienced a slight increase in TDS concentration with increased water level.

The decline in underburden head in the east part of Area B appears to be a response to the unloading of overlying units removed during mining, rather than a direct hydrologic connection to the shallower units. Underburden will likely continue to have this response as mining continues in Area B. With the lack of direct hydrologic connection and a significant thickness of low conductivity material between underburden and the overlying McKay coal, no change in water quality from spoil water is expected.

Area C

Area C has 10 active underburden wells (**Figure 9-32** and **Figure 9-54**). Wells with a long record outside or on the periphery of mining (WD-178, WD-181, WD-187, and WD-194) span baseline, mining and post-mining monitoring. They show no significant changes in water level or water quality**.**

Well WD-186 was installed in 1986, soon after mining in the area was finished, and is completed 150 feet below the base of spoil. Well WD-186 showed a slight increase in water level in 1991 and has shown a trend of increasing TDS, from 694 mg/L to 2,660 mg/L that began shortly after installation. The increase in TDS is mainly due to increases in sulfate, but includes increases in calcium, magnesium, chloride, iron, and manganese. Well WD-153, located approximately a mile to the west and up gradient of WD-186, was installed after reclamation and a few years later than WD-186. Samples from WD-153 have somewhat variable concentrations of TDS, ranging from 2,710 mg/L to 3,250 mg/L, but also unusually elevated concentrations of iron and chloride. The water quality in WD-186 is within the range of that in WD-153. Spoil in this area is dry (e.g. WS-120 and WS-186) and therefore could not be contributing to the water quality change in the underburden. The location of WD-186 adjacent to the county road may influence water quality (e.g. chloride and magnesium increases) as identified in other monitoring wells located adjacent to the road.

New underburden wells (WD-198, WD-199, WD-200, and WD-201) were installed within the last few years in the former pit area. These wells have only a few measurements to date. Well WD-200 was installed in 2012 in the same location and approximate depth as WD-179, which was removed by mining in 2008. Plotting the two on the same graph (**Figure 9-54**) shows the water level has remained the same, but TDS is slightly higher. The remaining new wells have water quality that is comparable to background measurements from underburden wells.

Area D

There are four active underburden wells in Area D (**Figure 9-33** and **Figure 9-55**). The active wells are located outside the margins of mining (WD-105, WD-106) or in reclamation in the "fingers" that extend northeast (WD-202) and southeast (WD-197) of Pony Creek. Active wells and wells that were removed during mining recorded water level changes over decades. Some water level changes may be in response to mining but others appear to be responses to unidentified stresses. Well WD-103, completed some 140 feet below the Rosebud coal, appears to respond to mining that took place in 1987, approximately a half-mile to the east, but an earlier, less dramatic decline beginning in 1980 is likely in response to a period of below average precipitation. The substantial and persistent drop in water level in well WD-152 and coincident increase in TDS concentration that began in 1982 is in response to a stress other than mining, as mining was not active in the area until 2002. Water level decline was underway in WD-105 when it was installed in 1981, prior to any mining in Area D. A decline of approximately 13 feet in WD-105 that began in 2002 may have been, at least in part, associated with mining. The earlier drawdown suggests that the response of the well may be limited to climate related factors. WD-106 shows no evidence of being influenced by mining. Wells WD-197 and WD-202 are in reclamation and fall within water level and water quality range of background underburden measurements.

Recent TDS concentrations in the wells range from 1,460 mg/L to 2,700 mg/L. Water quality has remained stable in most of the wells. TDS concentration in WD-106 declined in the first 10 years after installation but has remained stable since 1990. There are no water quality impacts from mining.

Area E

There are three active underburden wells in Area E that were completed in or at the margins of reclamation (**Figure 9-33** and **Figure 9-55)**. Completion depths range from 160 feet (WD-104) to 500 feet (WD-174, WD-182). All wells show steadily increasing water levels and declining to steady TDS concentrations. Water level increases range from approximately seven feet to 13 feet. The water level response in WD-104, the well with the shallowest completion, did not begin until eight to 10 years later than the other two underburden wells. The increasing water level trend in WD-174 and WD-182 began at about the same time that mining concluded in Area E, suggesting that the increasing trend represents a recovery, although these two wells were completed some 250 feet below the Rosebud coal. Current TDS ranges from 1,040 mg/L to 1,470 mg/L. None of these wells have water quality that suggests they have been impacted by mining.

9.2.5.1.7 Spoil

Water saturates the broken overburden material spoiled into each previously mined out cut as the next cut is opened. Most water entering the spoil is from laterally adjacent Rosebud coal, although ponds and other surface water sources contribute to recharge where available. Thickness of the spoil varies from as shallow as 15 feet to 150 feet, although most spoil wells are completed at less than 100 feet.

Water levels in spoil vary widely and depend upon a number of hydrologic factors. Proximity to recharge has the greatest influence on spoil saturation. Areas where mining is active restricts recharge and promotes drawdown, thus slowing spoil saturation. Recharge from up gradient Rosebud coal is often intercepted by active or open pits from reaching down gradient reclamation. However, in some instances, standing pit water and ponds contribute locally to spoil recharge, as do streams and alluvium. In some permit areas, such as Rosebud Area A and Area D, vertical recharge increases in importance due to the erosion of laterally up gradient water bearing units (e.g. overburden, Rosebud coal). Vertical

recharge in the Colstrip area occurs slowly due to low precipitation. Spoil water recovery throughout much of the mine areas remains depressed at this time and will remain strongly influenced by mining activities until final reclamation is completed.

Aquifer tests in spoil wells indicate that spoil has the ability to recharge and the flow system to recover. Eleven tests of mine spoil hydraulic conductivity in the Colstrip mines were completed using a bailer recovery method (Van Voast et al., 1977). The values generated were in the same general range as those for undisturbed coal-bed aquifers. Eight spoil wells at the Rosebud Mine were tested and found to have transmissivity ranges from 28 gpd/ft to 2,955 gpd/ft (Western Energy Co., 1984). This implies that spoil has the ability to conduct groundwater similar to the Rosebud coal prior to mining and will not restrict post-mining groundwater flow. Due to the increased porosity or void spaces created by the broken overburden material that forms the spoil aquifer, vertical conductivity and storage coefficient for spoil is expected to be somewhat greater than that of the Rosebud coal it replaced.

Prediction of spoil water quality is complex and has been approached in numerous ways. Van Voast and Reiten (1988) observed that southeast Montana mines averaged an increase in mine spoil of 50 to 200 percent over that of undisturbed aquifers. Geochemical conditions simulated in the laboratory with bench scale column-leach and paste-extract leaching tests using overburden materials suggest that the dissolved-solids concentrations in the backfill water reach a maximum during initial saturation and then decrease to an equilibrium level after one or more pore volumes of water pass through the backfill (Van Voast and Reiten, 1988).

The water chemistry of spoil water in future mine areas is anticipated to be comparable to that currently observed, although water quality in spoil can be highly variable, even within a local area. The timing for improved spoil water quality will vary from location to location and is dependent on spoil mineralogy, local hydrologic character of the disturbed areas including recharge rate and flow rate, timing of reclamation of up gradient areas, extent of up gradient mining, restoration of hydraulic gradients and source and quality of recharge. In general, spoil water quality is expected to recover to near premine water quality as salts are flushed through the spoil.

Forty-four spoil wells are active in the Rosebud Mine. Many wells show some level of recovery but others remain dry or have insufficient water for sampling. Twenty-five spoil wells from throughout the permit areas have a history of water quality sampling (**Figure 9-56**).

The greatest chemical changes in spoil water compared to Rosebud coal water chemistry are increases in TDS concentrations driven by increases in sulfate, calcium, magnesium and bicarbonate (**Figure 9-18**). Comparisons among the latest samples (2012-2014, one sample from each currently monitored well) show spoil TDS concentrations ranging from 1,830 mg/L to 7,690 mg/L (median = 3,690 mg/L; average = 3,963 mg/L). Current Rosebud coal TDS concentrations range from 594 mg/L to 6,460 mg/L (median = 2,620 mg/L; average = 2,674 mg/L); overburden ranges from 359 mg/L to 7,720 mg/L (median = 3,610 mg/L; average = 3,799 mg/L). Currently, spoil TDS concentration represents an increase of 2% of the median and 4% of the average TDS concentration in overburden water, and an increase of 41% of the median and 48% of the average TDS concentration in the Rosebud coal aquifer at the Rosebud Mine. Given the fact that overburden composes the spoil, it is no surprise that spoil water quality most closely resembles that of overburden.

Area A

Ten spoil wells are active in Area A although only seven have sufficient water to monitor (**Figure 9-28** and **Figure 9-57**). Many of them were installed in the early 1980's in the south and east part of the permit area, where the earliest mining took place. Wells along the south edge of Area A, near EFAC, have 21 feet to 46 feet of water. Many of these wells are located near ponds which are contributing to the local recharge. Wells adjacent to EFAC are also the shallowest wells as they are located near the Rosebud coal outcrop. Spoil wells along the east margin of Area A (WS-100, WS-101) contain 13 feet to 20 feet of water, but wells immediately to the west (WS-102, WS-103) are dry. WS-107 is in close proximity (1,000 feet) to an open pit that collects water and may have contributed to rising water levels. Water levels remain depressed in the west part of the permit area and spoil is dry (e.g. WS-123). As coal is removed to near the crop margins, there is no lateral up gradient source of groundwater to the west, which will slow spoil saturation.

Six active spoil wells in Area A have decades-long histories of regular water quality analyses. Some wells show increases in TDS through time coincident with rising water levels (WS-100, WS-113, and WS-115). The highly variable water quality in WS-114 is the result of infiltration of surface water (with lower TDS concentration) due to the location of this well in a ponded drainage. Most of the spoil wells have relatively high TDS concentrations, but WS-107, with 22 feet of water, remains in the range of background Rosebud coal water quality. Many of the spoil wells have high chloride concentrations (>20 mg/L), especially in more recent analyses. This reflects the susceptibility of the wells to surface infiltration from runoff from roads where magnesium chloride is used. Higher than normal iron (1 mg/L - 13 mg/L) in some of the wells (WS-106, WS-113,WS-114, and WS-115) and high nitrate (up to 34 mg/L) in wells WS-100 and WS-107 may be due to surface infiltration.

Average TDS for Area A spoil wells is 3,299 mg/L, with a range of 2,045 mg/L to 4,122 mg/L. TDS concentrations from the most recent samples range from 1,880 mg/L (WS-107) to 4,530 mg/L (WS-115). Wells WS-100 and WS-113 continue to show increasing concentrations of TDS.

Trace elements from Area A spoil well samples that exceed human health standards (HHS) established in DEQ-7 include nitrate (nitrite-nitrate as NO_3), cadmium, and zinc. With the exception of nitrate, the exceedances are represented by single analyses from a given well and none are recent (see **Section 9.2.6**). Nitrate concentrations above the HHS of 10 mg/L are persistent in well WS-100, ranging as high as 34 mg/L in 2012 and 24 mg/L in 2014. Well WS-100 has not shown significant changes in recent water levels or other analyte concentrations. Nitrate as high as 19 mg/L was analyzed from a sample of well WS-107 as recently as 2005, but currently is at 1.5 mg/L in this well.

Residual nitrate from blasting explosives used in mining is one source of nitrate in mine spoil, but the appearance of nitrate from explosives more than 30 years after reclamation is unusual. Well WS-107 is in a hay field, although the farmers reportedly do not use fertilizer (Western Energy Co., 2014, personal communication). Well WS-100 is located in a field used for cattle grazing. See **Section 9.2.6.10** for further discussion of nitrate HHS exceedances in mine groundwater.

The Rosebud coal crop line defines the extent of mining in Area A. As there is no lateral up gradient recharge, precipitation and surface flow will be the source of recharge for spoil. Upon saturation, flow direction will be to the east-southeast toward the coal crop. Prior to mining the coal crop was dry and is expected to remain dry on the north, west and east sides of the permit area as the hydraulic properties of spoil are expected to be the same as the Rosebud coal. The Rosebud Mine PHC Addendum (Western Energy Co., 2015) indicates that, based on comparison of water levels in spoil and alluvium, Area A spoil

water is moving toward EFAC alluvium. Based upon a simplified mass balance calculation, the contribution of Area A spoil to the observed increase in TDS in EFAC alluvium currently is approximately three percent. Impacts to EFAC discussed in **Section 9.2.4.2.2**, **Section 9.2.5.1.1**, and **Section 9.2.8** indicate that the contribution from Area A spoil to EFAC alluvium water quality is estimated to reach 13 percent. As described in the sections referenced above, no numerical standards are expected to be exceeded and water quality of the alluvium and stream are expected to meet the requirements of beneficial uses, thus no material damage is expected.

Area B

Nine spoil wells are currently active in Area B although only eight contain water (**Figure 9-30** and **Figure 9-31**)**.** Spoil in the northeast part of Area B has shown a strong water level recovery over a period of approximately 30 years. Saturated thickness ranges between 21 feet and 63 feet (WS-118, WS-157, WS-158, WS-159, and WS-184) (**Figure 9-58**). As water levels are highest in the four wells closest to EFAC, surface and alluvial water are the most likely sources of recharge. As the stream has eroded through the Rosebud coal in this area, the coal outcrop is close to the stream and associated alluvium.

By contrast, the spoil wells in the southwest part of Area B (WS-185, WS, 189, WS-190, and WS-191) contain three feet or less of water or remain dry (WS-190, WS-191). Mining is more recent in this part of Area B and wells were installed after 2000. Factors contributing to less recovery in this area include the relatively recent completion of reclamation, the existence of open pits and active mining south of reclamation, and, unlike the northeast part of Area B, Rosebud coal in this area was deeper and did not crop out as close to the stream. Also, intermittent stretches of EFAC are at the northeast end of Area B and thus more water is available for recharge.

Water quality samples are currently collected from the five spoil wells in the northeast part of Area B. Most wells have increased in TDS concentration since installation. The average TDS concentration of the wells with current water quality analyses is 3,686 mg/L, with the average TDS of individual wells ranging from 1,827 mg/L (WS-184) to 7,332 mg/L (WS-158). TDS concentrations of the most recent samples range from 2,350 mg/L (WS-118, WS-184) to 8,030 mg/L (WS-158). WS-158 is notably higher in all major analytes and is more variable in TDS concentration than other Area B spoil wells, although water levels in this well are stable. This well has the highest average TDS of all spoil wells monitored at the Rosebud Mine.

Trace elements reported from Area B spoil wells that exceed human health standards (HHS) established in Circular DEQ-7 include nitrate, cadmium, and lead. The exceedances are represented by single analyses in a given well and none are more recent than 1982 for nitrate, 1991 for cadmium, and 1993 for lead. The appearance of lead above the standard in three wells during a single sampling event in 1993 suggests a problem in quality control during sample collection or lab analysis (see **Section 9.2.6**).

Mining proposed in AM4 would increase the amount of drawdown in Area B and would increase the recovery time of water levels. As more coal is removed with proposed mining, the volume of spoil would be increased. An increase in spoil volume would result in additional dissolved solids with concentrations similar to that observed in existing Area B spoil wells.

Upon saturation, movement of water from some of the Area B spoil is anticipated to be to the southeast rather than toward EFAC (Western Energy Co., 2015). Movement of Area B spoil water toward EFAC alluvium is likely to be limited to the northeast portion of Area B, and these impacts are discussed in **Section 9.2.5.1.1**. Spoil water from the southern and western parts of Area B will be directed to the area

between the Rosebud Mine and the Big Sky Mine, and eventually to the Big Sky Mine permit areas. The distance between the Rosebud Mine and Big Sky Mine ranges between approximately a half-mile and two miles. Rosebud coal water quality in the area between the two mines (outside the permit areas of both mines) is variable and is currently unaffected by spoil. North of mining in Big Sky Mine Area A, Rosebud coal ranges in TDS concentration from 611 mg/L (SC = 881 µS/cm) in ARCM67 (reported from a single sample in 1996) to an average of 2,056 mg/L (SC = 2,400 µS/cm) in well ARC53. North of Big Sky Area B, Rosebud coal well BRC513 reported a TDS concentration of 4,300 mg/L (SC = 4,100 µS/cm) and BRC1313 has a TDS concentration that has declined with declining water level, from a high of 2,460 mg/L (SC = 2,540 µS/cm) to low of 770 mg/L (SC = 1,100 µS/cm).

Area B spoil water quality, described above, averages 3,686 mg/L and, in general, exceeds the quality of Rosebud coal between the two mines. Mixing of spoil with the background Rosebud coal water will take place as groundwater from the spoil moves to the south. There are no wells identified in the private well inventory that are completed in the Rosebud coal in the area between the Rosebud Mine and Big Sky Mine. No uses are expected to be impacted and numeric water quality standards are not expected to be exceeded based on spoil water quality. Due to the natural spatial and temporal variability of water quality in Area B spoils, the unmined coal between Area B and the Big Sky Mine, and Big Sky Area A spoils there is no generally accepted methodology to predict impacts with any certainty. Due to a large deposit of clinker throughout much of the area between the two mines, enhanced aquifer recharge will serve to dilute spoil water quality impacts in this area, therefore it does not appear that a parameter will increase to a level that renders the water unsuitable for domestic use or livestock and wildlife watering, or harmful, detrimental, or injurious to the beneficial uses listed for Class II and Class III groundwater. As such, no material damage is expected.

Area C

There are eight active spoil wells in Area C (**Figure 9-32**). Most are dry or have little water and, therefore, water quality samples are limited. Area C has been the focus of mining in recent years and has numerous open pits that impair saturation of spoil. Well WS-121 was installed in 1997 and has had a slow but steadily rising trend (**Figure 9-59**). With 14 feet of water, it records the greatest amount of recharge of any well in the central part of Area C. Three other nearby spoil wells register three feet (WS-120), four feet (WS-122) and six feet (WS-186) of water, with most of the recharge taking place since 2011. Well WS-197 is in the west part of Area C and records approximately 18 feet of water.

Only two wells monitor spoil water quality at this time, WS-121 and WS-197; the remaining wells have insufficient water for sampling. TDS concentration in WS-121 has increased with rising water level from 2,150 mg/L to as high as 7,360 mg/L. The most recent TDS concentration in this well is 6,420 mg/L. Average TDS of well WS-121 is 5,722 mg/L and average TDS concentration in WS-197 is 3,733 mg/L. This well also has relatively high concentrations of chloride (up to 58 mg/L). High chloride is typically attributed to use of magnesium chloride on roads. There has been no exceedance of an HHS in any Area C spoil water quality analysis.

Currently, Area C spoil has experienced little recharge. Saturation of spoil in the north part of Area C will depend on vertical infiltration as the mine area is defined on three sides by the coal crop line, including the west, which is the up gradient direction of lateral groundwater flow. This means there is no up gradient recharge from the Rosebud coal into the north part of Area C. Although the drawdown here was relatively small (modeled at 10 feet, see **Section 9.2.7**) because of the small amount of water in the Rosebud coal, it is anticipated that it will take a substantial amount of time to saturate the spoil in this area. The remainder of Area C will receive lateral recharge to coal and spoil. Upon saturation, migration

of spoil water in the central part of Area C will be toward the coal crop line, which defines the down gradient margins of mining. The coal crop line was generally dry prior to mining. The saturated thickness of the coal thins toward the crop line due to evapotranspiration as a result of the slow movement of Rosebud coal groundwater.

A possible connection of the Rosebud coal with alluvium in the southwest part of Area C (as suggested by the response of WR-136) suggests that up to a half-mile stretch of EFAC may be subject to spoil water from Area C if there is substantial hydrologic connection with the alluvium. Based on the analysis of contributions from Area A to EFAC alluvium, input from Area C spoil into the stream is expected to be small but may contribute to diminished water quality in EFAC. This migration of spoil water from Area C is not expected to render any down gradient water unsuitable for domestic use or livestock and wildlife watering, or harmful, detrimental, or injurious to listed beneficial uses or cause the violation of any DEQ-7 numeric standard, as discussed in **Section 9.2.5.1.1**. As such, material damage is not expected.

Area D

There are 10 active spoil wells in Area D (**Figure 9-33**). Mining in Area D was completed in early 2013 and reclamation continues in 2014. Most spoil wells were installed between the late 1990's and early 2000's in the older, south permit area. These wells (WS-125, WS-126, WS-127) have the most recharge with 20 feet to 32 feet of water (**Figure 9-60)**. Pond 151, a permanent pond in reclamation, is likely providing recharge to this area. The west part of Area D (WS-128) has recovered 12 feet of water. The remaining wells are thinly saturated and contain less than one foot to eight feet of water.

The shallow aquifers in Area D were only thinly saturated prior to mining due to lack of up gradient recharge, creating a "high and dry" setting for Area D. Therefore, water in Area D spoil will depend upon infiltration and is expected to be slow in forming an aquifer.

Six wells are sampled for water quality. Water type in Area D spoil is unusually variable and includes calcium-magnesium sulfate, sodium sulfate, and calcium-magnesium bicarbonate. The average TDS concentration for the wells ranges from 1,853 mg/L (WS-188) to 7,882 mg/L (WS-127). The current average TDS concentration for spoil wells in Area D is 4,492 mg/L with a median of 4,500 mg/L. There are anomalously high levels of chloride (56 mg/L, average) and magnesium (1,092 mg/L, average) in analyses from well WS-127 that are assumed to be from the use of magnesium chloride on the haul road adjacent to the well. This well also contains elevated nitrate levels that have consistently exceeded the human health standard. Since the initial sample from this well (1999), nitrate concentrations have been as high as 50 mg/L. The most recent sample (2011) had a concentration of 7.6 mg/L. Nitrate from blasting explosives used in mining is one source of nitrate in mine spoil. The well is located in a reclamation field that supports grazing and is less than 500 feet from a permanent pond used for cattle drinking water.

Other exceedances of human health standards have been identified for cadmium (two samples), and zinc (one sample). The exceedances are represented by single analyses from different wells and are only slightly above the standard. None of the exceedances are from recent samples.

The isolation of Area D from laterally up gradient and down gradient groundwater sources limits spoil recharge, but also limits the effects of spoil to groundwater. Saturated thickness of Rosebud coal groundwater thins as it approaches the coal crop. At the crop line, Rosebud coal is typically dry. The low conductivity and slow movement of Rosebud coal groundwater results in evaporation as groundwater moves toward the coal crop. There is a possibility that spoil water may cause springs at the down

gradient crop line but no Rosebud coal springs were noted in baseline. Migration of spoil water from Area D is not expected to render any down gradient water unsuitable for domestic use or livestock and wildlife watering, or harmful, detrimental, or injurious to listed beneficial uses, or cause the violation of any DEQ-7 numeric standard. Therefore, material damage is not expected.

Area E

There are eight active spoil wells in Area E, including three wells in the former Pit 6, a premine area located immediately south of Area E that was released from bond in 2006 (**Figure 9-33)**. A few of the spoil wells in Area E remain poorly saturated to unsaturated (WS-130, WS-109)(**Figure 9-61**). WS-116 is recording the greatest saturation. It has seen a steady climb of more than 30 feet in water level since installation in 1981 and now has 37 feet of saturation. It is located immediately south of the Colstrip power plant and likely receives recharge from adjacent power plant ponds. Wells at the south end of the permit area (WS-124, WS-117) and in former Pit 6 (WS-110, WS-111, and WS-112) have had a slow rise in water level and currently contain 10 feet to 21 feet of water.

Average TDS concentrations in these wells range from 1,491 mg/L to 4,575 mg/L. The average TDS of these wells is the lowest average for all permit area spoil wells. Most of the spoil wells have seen a rise in TDS concentration since monitoring began but the increase is greater in some wells than others. The exceptions are WS-111 and WS-112 in the former Pit 6 area, which have seen slight declines in TDS concentrations even as water levels rose. The three Pit 6 wells (WS-110, WS-111, WS-112) have a water type that is characterized by calcium-magnesium bicarbonate or magnesium bicarbonate and lower TDS and sodium concentrations than most spoil wells throughout the mine. This suggests better spoil quality or better quality (lower TDS) recharge to the Pit 6 area than is characteristic of the larger mine area.

Well WS-116 had two consecutive analyses of lead above the human health standard of 0.015 mg/L. Samples in 1993 and 1995 had lead concentrations of 0.05 mg/L and 0.02 mg/L, respectively. Six subsequent samples, from 1998 – 2013, have reported non-detect or very low (0.00021 mg/L) concentrations of lead. No other samples from Area E spoil wells have reported analyte concentrations that exceed human health standards.

Upon sufficient saturation, Area E spoil groundwater will move east toward the down gradient crop line. The crop line marks the extent of mining and approximates the Area E permit boundary. As discussed previously, the Rosebud crop line is generally dry. Migration of spoil water from Area E is not expected to render any down gradient water unsuitable for domestic use or livestock and wildlife watering, or harmful, detrimental, or injurious to listed beneficial uses or cause the violation of any DEQ-7 numeric standard and material damage is not expected.

9.2.5.2 Big Sky Mine

9.2.5.2.1 Alluvium

Area A

Four alluvial wells remain active in Area A (**Figure 9-62**). They are located below the extents of mining in Miller Coulee (AAL51) and Emile Coulee (AAL12, AAL14, and AALM70) (**Figure 9-63**). All of the wells have relatively shallow completions (12 feet to 31 feet) and have been continuously monitored for three to four decades. Current water levels are among the highest levels measured in the wells, with between 11 feet (AALM70) and 24 feet (AAL51) of saturation.

The three closely spaced wells in Emile Coulee are located among cultivated fields. They currently have TDS concentrations that range from 1,950 mg/L (AAL12) to slightly greater than 4,000 mg/L (AAL14,

AALM70). Well AAL14 temporarily reached TDS concentrations as high as 8,080mg/L, mainly due to significant increases in sodium and sulfate. These increases may have been caused by mining, but have not impacted beneficial uses and no numerical standards (except for nitrate-nitrite, discussed below) have been violated, thus material damage has not occurred. Current water quality trend are stable to improving, thus material damage is not expected in the future. All three of the wells in Emile Coulee have reported nitrate-nitrite nitrogen concentrations as high as 20 mg/L. Due to the shallowness of the wells and the absence of significant nitrate-nitrate nitrogen in spoil water quality analyses, the high nitrate-nitrite concentrations in the alluvial wells are attributed to agricultural sources rather than mining, thus the nitrate-nitrite exceedance are no considered material damage.

Miller Coulee well AAL51 currently has a TDS concentration of 4,270 mg/L. TDS concentration in this well has not varied significantly. All reported nitrate-nitrite nitrogen concentrations are less than one mg/L. The proposed AM4 mining will not affect alluvial water quality in Area A.

Area B

Eighteen alluvial wells **(Figure 9-64**) monitor alluvium in Lee Coulee, both up gradient and down gradient of mining. In the upland well (BAL2011), almost 28 feet of alluvium is holding approximately three feet of water. Alluvial thickness in the downstream area ranges to almost 40 feet with 30 feet of water at the confluence of Rosebud Creek (BAL3511). Measurements from wells in the more central part of the permit area indicate that the alluvium generally holds six to 12 feet of water.

By their nature, alluvial wells have variable water levels reflecting seasonal and climatic changes. Most of the wells in Area B have hydrographs that indicate a return to baseline or higher water levels. Exceptions are three wells (BAL2011, BAL2321, and BAL2361) at the upstream extent of the mine area. The wells currently show a loss of five feet to 13 feet. Decline in these wells began before mining encroached on the adjacent area. Down gradient mining likely would not affect the availability of groundwater in well BAL2011 and mining upstream in the west part of Rosebud Area B was not active until after 2000. Coal removal took place immediately adjacent to BAL2321 and BAL2361 and may have disrupted water to the alluvium. Wells further down gradient (BAL9031, BAL9041) have either recovered to premine levels or were not affected. A feature common to alluvial wells in the central part of the permit area and extending to wells more than a mile south of the permit boundary is a rise in water level of between six and ten feet that began in 1993, peaked in 1996 and subsequently fell to previous levels. Although some water level rise during this period may be attributable to above average precipitation, MPDES discharge from sediment ponds was the source for most of this temporary increase in water level. Water quality changes marked by an increase in TDS commonly accompanied the rise in water level. TDS concentrations have remained somewhat elevated even though water levels decreased to or near levels that existed in 1992, prior to the increase from MPDES releases (e.g. BAL2521, BAL2711, and BAL3511).

TDS concentration appears to vary with changes in water level in a number of wells, increasing with increases in water level and decreasing when water levels decrease. This may be explained by increased dissolution of minerals in the alluvium with increased volume of water. Baseline TDS concentrations varied from 615 mg/L (BAL2011) to 3,920 mg/L (BAL9031). Current TDS concentrations range from 460 mg/L to 4,230 mg/L. TDS remains higher than baseline in many of the wells, coincident with higher water levels in many cases, but not all. Flow of spoil water into the alluvium at this time is unlikely, as the spoil remains thinly saturated. As spoil saturation increases it is likely that it will influence alluvial water quality, but is not expected to impact uses outside the permit area of the Big Sky Mine.

Wells BAL9081 and BAL2611, located in a tributary on the north side of Lee Coulee, have an upward trend in TDS concentration due to releases or infiltration of water from an upstream sediment pond. Water from the pond is of higher salinity than alluvial water due to the concentration of salts in the pond. As this pond was recently reclaimed, the TDS concentration is expected to attenuate with time. Downstream wells in Lee Coulee that have increased TDS concentrations (e.g. BAL2521) may also be affected by water from the sediment pond, although these wells have had a relatively consistent TDS concentration of approximately 2,500 mg/L for five or more years. Water from stock ponds upstream of wells located further north in the permit area (e.g. BAL9031 and BAL2411) may have caused increases in TDS concentrations in these wells.

Private wells potentially affected by mining include alluvial wells in lower Lee Coulee below the Big Sky Mine permit boundary. These are designated as wells number 2 and 3 (**Table 6-1**). Alluvial monitoring wells in lower Lee Coulee (**Figure 9-67**) recorded increases in water level and TDS resulting from MPDES permitted releases of water from sediment ponds and Big Sky mine pits (see **Section 9.2.7.2.1**). Water levels declined but remain above premine levels, which may be due to precipitation. TDS remains elevated above premine levels but may decline if water levels further decline, as the water level and TDS appear closely correlated in alluvial wells. TDS concentration in monitoring well BAL2711 varied from 1,630 mg/L to 1,800 mg/L before the rise in water level. TDS in this well now varies between 2,350 mg/L to 2,520 mg/L after reaching a peak of 3,010 mg/L. Monitoring well BAL3111 recorded similar TDS concentrations. Increases in TDS resulted mainly from increases in calcium (originally 159 mg/L, now 208 mg/L), magnesium (originally 167 mg/L, now 238 mg/L), sodium (originally 118 mg/L, now 152 mg/L), and sulfate (originally 955 mg/L, now 1,340 mg/L). There were no increases in trace metals, most of which remain below analytical detection. The use of wells 2 and 3 is stock water. Calcium and magnesium concentrations in pre-mining samples from Lee Coulee alluvial monitoring wells were above the suggested upper limit guideline concentrations for livestock water quality (**Table 2-2**) and are now higher. Although the water quality in these wells is above guideline levels for calcium and magnesium, the critical component, sulfate, remains below the guideline threshold limit. The alluvial water remains suitable for livestock at current concentrations. The change in water quality should not render water unsuitable for domestic use or livestock and wildlife watering, or be harmful, detrimental, or injurious to a listed use for Class II groundwater. The proposed AM4 mining will not affect alluvial water quality in Area B.

9.2.5.2.2 Overburden

Area A

One overburden well, AOVM73, remains active in Area A (**Figure 9-65**). It is located immediately northwest of the permit boundary. The well experienced more than 20 feet of drawdown and has shown almost no recovery since water levels reached the end of a precipitous decline in late 1984 (**Figure 9-66**). Decline attributable to mining began after 1982, as mining did not approach this well until that time. There are 26 feet of water remaining in the well. The few historic overburden wells that were in the mined area indicate there was little water in the overburden, ranging from a foot or less (AOV23) to 18 feet (AOV24).

Well AOVM73 is the only overburden monitoring site with water quality data. TDS concentration increased slightly, from 3,070 mg/L to 3,360 mg/L, during the 14 years that it was measured. No impacts are anticipated on Area A groundwater from the proposed AM4 mining. Material damage has not been observed and is not expected.

Area B

The eight remaining overburden wells (**Figure 9-67**) are located at elevations above the pit areas, near or outside Area B permit boundaries. Initial heads in these wells ranged from 13 feet to 68 feet, with the lowest head in the southwest permit area. All wells showed decline during mining and most have begun to recover as evidenced by increasing water levels (**Figure 9-68**). Residual drawdown currently ranges from zero (BOV1012, BOV412, and BOV512) to almost 13 feet (BOV612).

Water quality in the overburden wells has shown no significant changes with the change in water level. Premine TDS concentrations ranged from as low as 360 mg/L (BOV2012, inactive) to as high as 4,720 mg/L (BOV1012). Currently active wells have TDS concentrations that range from 960 mg/L (BOV612) to 3,880 mg/L (BOV1012). No impacts are anticipated on Area B groundwater from the proposed AM4 mining. Material damage has not been observed and is not expected.

9.2.5.2.3 Rosebud coal

Drawdown created by mining in Rosebud Mine Area B overlaps that created by mining in Big Sky Mine Area A and Area B. Mining proposed in AM4 does not significantly increase the amount or extent of drawdown in the Big Sky Mine and is not expected to significantly delay saturation of spoil water. Currently, spoil water quality in both permit areas of the Big Sky Mine is of poorer quality than spoil water in Rosebud Mine Area B. Rosebud Mine Area B spoil water is not expected to further lower the quality in Big Sky Mine spoil.

Area A

The six remaining Rosebud monitoring wells (**Figure 9-65**) are located near the reclaimed pit margins. Water level response to mining in the west part of the permit area is documented in wells ARC30 and ARC66, which have shown 10 feet and seven feet, respectively, of water level increase (**Figure 9-66**). This may be because ARC30 was not installed until 1977, after pre-law mining to the east, and ARC66 was installed in 1984 after nearby mining was complete. Therefore, these wells likely are recording recovery of Rosebud coal water levels. The amount of head currently measured in the wells is approximately 36 feet. The remaining four wells (ARC52, ARC53, ARCM63, and ARCM67) were installed prior to mining and all recorded a loss in head that currently ranges from 51 feet (ARCM67) to nine feet (ARC52). All but one well (ARCM67) has shown a recovery in pressure head. The amount of head measured in these wells ranges from to 41 feet to 43 feet in the wells north of mining (ARC52, ARCM63, and ARCM67) to 22 feet in ARCM63, northwest of mining. Recharge of the Rosebud coal appears to occur in the highlands between the two mines, but recovery of water levels near Big Sky Area A will likely be slower because some of this water is diverted to the Rosebud Area B mine pits.

Well ARC30 has a lengthy record of water quality measurements with a TDS concentration that remained near 4,500 mg/L for decades. The current TDS concentration of 3,930 mg/L is approximately the same as the initial concentration in 1982. The three wells (ARC52, ARC53, and ARCM67) north and up gradient of the pit area have TDS concentrations that range between 511 mg/L and 742 mg/L. The two wells to the west of the pit area have remained relatively unchanged with TDS concentrations of 3,260 mg/L to 3,550 mg/L (ARCM63) and 1,830 mg/L to 2,160 mg/L (ARC66). Water quality in the Rosebud coal in Area A is not expected to be affected by the proposed AM4 mining. No material damage in the Rosebud coal groundwater has been indicated or is anticipated.

Area B

There are eleven active or recently active Rosebud coal monitoring wells in Area B, all of which recorded premine water levels and quality (**Figure 9-67**). Premine heads in Area B Rosebud coal indicate that

some areas of the aquifer were unconfined and others were confined. East of the pit, between Area A and Area B, premine heads ranged between 80 feet (BRC613) and 50 feet (BRC1713). In the upland area northeast of mining, immediately adjacent to the permit boundary, the head measured 172 feet (BRC513) (**Figure 9-69**). In the upland area between Rosebud Mine Area B and Big Sky Mine Area B (BRC 1313 and BRC113), heads ranged between 45 feet and 71 feet. West of the mine, heads were as high as 84 feet (BRC213). In contrast, heads in the southwest pit area were as low as nine feet near the crop line (BRC1213) and much of the area is unconfined (BRC9163, BRC413, and BRC713).

All of the Area B Rosebud monitoring wells showed a decline in head in response to mining. However, most wells record at least a slightly recovering water level. At this time, remaining head declines range from zero (complete recovery) to 24 feet, with an average of approximately 10 feet. The advance of mining in Rosebud Mine Area B appears to have stalled recovery of Rosebud coal levels between the two mines (BRC1313). The proposed AM4 mining is expected to continue to delay recovery of Rosebud coal water levels north of Big Sky Area B.

Changes in up gradient water quality vary from declines in TDS (BRC1313) to variable TDS (BRC613, BRC1713) to stable water quality (BRC1013, BRC1513). In the currently active wells, premine TDS ranged from 4,450 mg/L (BRC1013) to 1,370 mg/L (BRC213, BRC413). Recent measurement from the active wells ranged from 4,080 mg/L (BRC1013) to 380 mg/L (BRC1713). The poorest water quality, both premine and currently, is located in the east part of the permit between Area B and Area A (BRC1013, BRC1513, and BRC1713). Water quality in the Rosebud coal in Area A is not expected to be affected by the proposed AM4 mining. No material damage in the Rosebud coal groundwater has been indicated or is anticipated.

9.2.5.2.4 Interburden

Area A

No interburden wells were installed in Area A.

Area B

The eight remaining interburden wells lie near or outside of the permit boundary (**Figure 9-67**). Most of the wells experienced a decline in head associated with mining at either Big Sky Mine Area B or Rosebud Mine Area B (**Figure 9-70**). Most of the declines began in or soon after 1989, the year mining began in Big Sky Area B, or in the middle 1990's, when mining in the west part of Rosebud Mine Area B began. Head declines in the interburden wells ranged from 2 feet to 20 feet and many wells have recently begun to show a slight recovery. Current heads range from 48 feet to 128 feet. In wells BIN117, BIN517, and BIN1317 the interburden head is almost equivalent to that in the Rosebud coal and an upward gradient exists between interburden and Rosebud coal at well BIN217.

Wells with a history of water quality measurements indicate that TDS concentrations have remained consistent or have declined. Baseline TDS concentrations ranged from 1,850 mg/L to 3,800 mg/L. Current TDS concentrations range from 510 mg/L to 4,150 mg/L. The proposed AM4 mining is not expected to have an impact on interburden water quantity or quality in Area B. No material damage has been noted or is expected to occur.

9.2.5.2.5 McKay coal

Area A

One McKay coal well, located in the southwest permit area, remains active (**Figure 9-65)**. The water level response of this well (AMC20) is similar to that of nearby historic wells (AMC25, AMC32) (**Figure 9-71**).

The wells are adjacent to pre-law mine areas that, along with mining inside the permit area in the middle 1970's, may have caused or contributed to the drawdown recorded in 1975-1977. A rise in water levels suggesting post mining recovery began shortly thereafter. Water level has been relatively steady in AMC20 since the late 1970's and is assumed to have fully recovered. The total head in this well is currently almost 62 feet. The McKay coal at this location was confined prior to mining and has remained confined. Historic wells near the east margin of mining indicate that the McKay coal was confined in locations away from the crop line (AMC59) and unconfined near the crop line (AMCS25). The increase in water level between 1975 and 1983 in these two wells suggests a response to above average precipitation during this period.

TDS concentration in the wells in the southwest corner of the permit area appears to have remained relatively steady during the monitoring period. TDS concentration in the currently active well, AMC20, varies between 2,770 mg/L and 3,180 mg/L. Adjacent historic wells were slightly higher in TDS concentration and increased slightly from 3,850 mg/L to 4,210 mg/L during the monitoring period. The proposed AM4 mining is not expected to affect water quantity or quality in the McKay coal at Area A. No material damage to McKay coal groundwater is indicated or is expected to occur.

Area B

Eleven McKay coal monitoring wells remain active in Area B (**Figure 9-67**). They are located outside of the mine pit areas. Water levels in the currently active wells indicate that much of the McKay coal outside the mine area was confined prior to mining and remained confined after mining. The exceptions are wells BMC1614, located over a mile east of mining, and BMC714 located in the southwest part of the permit area where saturation in the overlying aquifers was also comparatively sparse (**Figure 9-72**). Many of the historic McKay coal wells that were located in the pit areas indicate that much of the McKay coal in this area was unconfined prior to mining, particularly at lower elevations near the McKay coal outcrop. As with the overlying aquifers discussed above, most of the active wells show a recovering water level. Residual drawdown in the active wells ranges from zero (BMC1514) to 16 feet (BMC214), with current heads ranging as high as 152 feet (BMC114). Upland wells subject to impacts from Rosebud Mine Area B (BMC1314, BMC 514, and BMC114) show only a slight recovery. Three of the currently monitored McKay wells (BMC714, BMC1014, and BMC1614) have water levels that have increased since baseline, gaining rather than losing water during active mining. Hydrographs throughout the Colstrip area show similar water level responses that are assumed to be climate related.

TDS during baseline ranged between 1,630 mg/L and 3,700 mg/L with an average of approximately 2,200 mg/L. Most of the McKay coal wells measured throughout the life of the mine indicate that TDS has varied somewhat with varying water levels, but generally, recent TDS concentrations are not significantly different from baseline. The proposed AM4 mining is not predicted to cause impacts to McKay groundwater at Area B. Material damage has not been observed and is not expected.

9.2.5.2.6 Underburden

Area A

The nine active underburden monitoring wells (**Figure 9-65**) are located south of the Rosebud and McKay coal crop and are relatively shallow, ranging from 40 feet to 116 feet deep. Five of the wells (ASM2, ASMTW1, ASMTW2, ASMTW3, and ASMTW4) are within a few hundred feet of one another in the south part of Area A, near the former facilities area (**Figure 9-73**). Wells ASMTW1 through ASMTW4 were located around the "truck wash" area. Equipment was washed on a graded area and runoff was retained in an adjacent pond. These wells show a steep initial increase in water level followed by a steep decrease and then somewhat variable levels since 2002. The wells in the central part of the permit area

(ASMM27, ASMM32, ASMM69) have water levels three to eight feet greater than initial measurements in the mid 1970's, likely in response to recent above normal precipitation.

Initial TDS concentrations varied from 2,190 mg/L to 5,930 mg/L with an average of 3,202 mg/L and a median of 2,530 mg/L. TDS concentration has remained relatively steady in some wells (ASM2, ASMM27), decreased in conjunction with water level changes in others (ASMM32, ASMM69), and increased in the ASMTW wells. Increases in TDS concentration in the ASMTW wells was immediate and remains higher (3,590 mg/L to 4,650 mg/L) than baseline (2,390 mg/L to 2,680 mg/L). The ASMTW wells show notable increases in analytes associated with road stabilizing and cleaning products, including increases in boron, chloride, magnesium, sulfate, and sodium. No increases in other trace metals were observed and all analytes have declined from high concentrations. Well ASM2, located 700 feet to the southwest of the ASMTW wells, has not shown a change in TDS that indicates interception of water moving from the ASMTW wells. Because the impacts to water quality observed at the truck wash have not migrated beyond the permit boundary, no material damage has occurred. Current water quality trends are generally improving at the truck wash wells and well ASM2 has not indicated migration of the lower quality water, therefore future material damage is not expected.

Area B

There are 20 active underburden wells in Big Sky Area B (**Figure 9-67**). The wells can be divided into "shallow" and "deep" underburden wells depending upon their location. Underburden wells above the Rosebud coal crop line are referred to as "deep" wells (**Figure 9-74**), and many are located in upland areas near or outside the permit boundary. The wells located below the crop line in the eroded drainage of Lee Coulee are referred to as the "shallow" wells (**Figure 9-75**). The deeper wells have heads between 45 feet and 171 feet and the shallower wells have heads between 16 feet and 107 feet. Many of the "shallow" wells have hydrographs characteristic of alluvial wells with seasonal variations in level over a relatively narrow range.

Most of the well hydrographs suggest water levels are subject to influence by climate. Most show a rise in water level of varying amounts between 1993 and 1997, a period of average to above average precipitation that ended the drought of the prior decade. Many of the hydrographs show a return to lower water levels with the advent of a period of below average precipitation that followed. A period of generally above average precipitation influenced the subsequent water level rise seen in many wells. Although a similar water level response is observed in many wells regardless of location, the "shallow" wells located in Lee Coulee and side tributaries were heavily influenced by MPDES discharges to the drainage and this likely is the reason for the rise in water level in these wells. Unlike other wells with a variable water level, a steady and significant water level decline is observed in wells BSM115 and BSM515 for a head loss of 14 feet and 8 feet, respectively. Both of these wells are located in the north permit area, between Rosebud Mine Area B and Big Sky Mine Area B. Activity at Rosebud Mine may have influenced the response of these wells. A head of 171 feet remains in BSM115 and 99 feet remains in BSM515. The spike in water levels in BSM9035 and BSM215 likely represents well failure. Both are now recording water levels close to those of the McKay coal.

Water quality in the "deep" wells appears to have changed little from baseline. TDS concentrations in most wells range from slightly below 2,000 mg/L to 2,500 mg/L. Two wells (BSM915/915R and BSM1715) have TDS concentrations between 3,300 mg/L and 3,500 mg/L that have not changed significantly since baseline. Baseline TDS concentrations in the "shallow" wells ranged from 4,500 mg/L to as low as 1,520 mg/L. Four of the wells (BSM2535, BSM2615, BSM9085, and BSM9095) have shown increases in TDS and one (BSM2415) has shown a decline. Despite the difference in depth (102 feet vs.

25 feet), two of the wells (BSM9085 and BSM2615) located in a drainage south of the pit area began to experience an increase in concentration in 1994 characterized by increases in chloride, sodium, calcium, magnesium and sulfate, causing TDS concentration to rise from a premine concentration of approximately 1,500 mg/L to 3,240 mg/L. These wells likely have been influenced by an upstream pond that has concentrated salts due to evaporation and periodically discharged or allowed water to infiltrate downstream. This pond has been recently reclaimed and water quality should return to lower concentrations with time. Well BSM2535 approximately a mile downstream from BSM2615, may also have been affected by the upstream pond, showing increases in TDS beginning at about the same time. Water quality at this well has remained stable with a TDS of approximately 2,300 mg/L since 1998. Well BSM9095, located in the center of the permit area near the coal crop, has increased approximately 1,000 mg/L to 3,710 mg/L in TDS concentration and appears to be on a continuing upward trend. Most of the increase in TDS concentration is attributable to an increase in sulfate. The source of this increase has not been identified and will continue to be monitored.

The proposed mining in AM4 is not anticipated to affect underburden water quantity or quality near Area B. Although some impacts to shallow underburden wells are noted above, all are within the permit boundary and these impacts are not expected to spread outside the permit boundary. No material damage has been observed and none is expected.

9.2.5.2.7 Spoil

Area A

Ten spoil wells are active in Area A (**Figure 9-65)**. They contain water columns of between 10 feet and 76 feet, with the least water in wells near the location of the Rosebud coal crop. All of the wells are showing continued increases in saturation (**Figure 9-76**).

Current TDS concentrations range from 2,250 mg/L (ASP61) to 14,100 mg/L (ASP22). The average concentration is 5,346 mg/L and the median is 3,990 mg/L. In comparison, TDS concentrations in the Rosebud coal ranged from 711 mg/L to 3,820 mg/L, with an average of 2,362 mg/L and median of 2,110 mg/L. Currently, the highest concentration in a spoil well is in ASP22, which contains approximately 18 feet of water and lies in a pre-law mining area. TDS concentrations at this well have been as high as 19,200 mg/L, measured in 1987. A slightly declining trend over the past 22 years has brought current concentrations to 14,100 mg/L. Chloride concentration has been extremely high (156 mg/L - 430 mg/L), along with magnesium (849 mg/L to 1,740 mg/L), sodium (980 mg/L to 2,400 mg/L), and sulfate (4,830 mg/L to 11,400 mg/L). Trace elements and metals that are unusually and persistently high include boron (up to 1.9 mg/L), copper (up to 0.178 mg/L), manganese (up to 5.59 mg/L), and molybdenum (up to 1.3 mg/L). The chemical signature of water from this well suggests that that it is affected by road stabilization materials (magnesium chloride), cleaning compounds (boron, sodium and sulfate) and unknown sources of trace metals such as copper and molybdenum. There is no record of the mining activity in this pre-law area. Spoil well ASPP18 located approximately 30 feet to the southwest has approximately the same completion depth and water level but had a TDS of 4,050mg/L at the last measurement (1999), and no evidence of elevated concentrations in analytes like those in ASP22. This suggests that the poor quality water characteristic of ASP22 is very limited in extent. No impacts to Area A spoil water are expected from the proposed AM4 mining. Mining has been completed in Area A for over 25 years and no migration of spoil water impacts outside of the spoils has been observed, thus future migration of spoil water down gradient is not expected to cause conditions which would render water unsuitable for domestic use or livestock and wildlife watering, are harmful, detrimental, or injurious to listed beneficial uses, or cause exceedances of numeric water quality standards and material damage is not anticipated.

Area B

Ten spoil wells record the recovery of water levels in Big Sky Area B (**Figure 9-67**). The saturated thickness in the wells ranges from zero (BSP9936) to almost 19 feet (BSP9966), with an average of 12 feet among the nine wells that contain a measurable amount of water (**Figure 9-77**). A few wells have reached or are close to comparable water levels observed during premine measurements in the Rosebud coal. Spoil well BSP1216 contains nine feet of water and has a water level that is within a foot of the premine water level in a Rosebud coal well at the same location. The premine water level in a Rosebud well in the same location as spoil well BSP816 was approximately four feet above the water level in the spoil well. The spoil well currently contains almost 11 feet of water. None of the other spoil wells are paired with premine Rosebud wells for comparison of recovery to premine water levels. Spoil wells located further north (e.g. BSP9976 and BSP9966) have a slightly greater saturated thickness (17-19 feet) than the spoil wells to the south, but they remain far below the heads measured in the currently active, upland Rosebud coal monitoring wells. The upland wells have pressure heads that are not expected to be replicated in the homogeneous spoil when fully saturated, and thus the water level measured in the spoil will not be the same as that of the Rosebud coal wells. Water in the Rosebud coal to the north remains a source of lateral recharge to spoil wells in the former pit areas.

Water quality in the spoil wells is relatively poor, with a range in TDS concentrations from recent samples of between 2,800 mg/L and 5,280 mg/L, and an average of 3,897 mg/L (median = 3,160 mg/L). Four of the wells (BSP816, BSP1216, BSP9926R, and BSP9956) show a rising trend in TDS coincident with a rise in water level. No impacts to Area B spoil water are expected from the proposed AM4 mining due to the distance between the proposed cuts and the Area B spoils. Future migration of Area B spoil water down gradient is not expected to cause conditions which would render water unsuitable for domestic use or livestock and wildlife watering, or, are harmful, detrimental, or injurious to listed beneficial uses, or cause exceedances of numeric water quality standards. Therefore material damage is not anticipated.

9.2.6 Water Quality Exceedances

Determination of water quality exceedances is based on:

- Changes in groundwater quality that cause a change in beneficial uses based on narrative standards (17.30.1006)
- Exceedance of HHS in DEQ-7

As explained in **Section 2.1.2**, this CHIA assesses possible violation of water quality standards for groundwater by applying the standard for the parameters of concern, salinity, which is governed by the narrative standard set forth in ARM 17.30.1006. Accordingly, the CHIA assesses whether a parameter may increase to a level that would render the waters unsuitable for domestic use or livestock and wildlife watering, or harmful, detrimental, or injurious to the beneficial uses listed for the classification of the groundwater.

Water quality samples that have an analyte that meets or exceeds the human health standards established in Circular DEQ-7 are listed in **Table 9-9** for the Rosebud Mine and **Table 9-10** for the Big Sky Mine. Analyses are conducted per the requirements of the monitoring and sampling plan for each mine. Groundwater sample results are reported as dissolved concentrations. **Section 9.2.6.2** through **Section**

2.6.2.10 discuss the exceedances listed in those tables. Mining related water quality exceedances have not migrated beyond the permit boundary.

9.2.6.1 Adversely Affected Land Use or Beneficial Use of Groundwater

Beneficial uses of groundwater in the Colstrip area include domestic supply and stock drinking water. Potential effects to beneficial uses of groundwater from mining include diminishment of supply so that it is no longer available for uses, and/or change in water quality so that it is no longer suitable for uses. Drawdown of water level (or diminishment of pressure head) in an aquifer is the most likely impact to private wells outside the permit area. Wells completed in Rosebud coal are the most susceptible. Wells in the underburden typically are deep enough to be protected from drawdown which would make the supply insufficient for the use. Potential drawdown impacts to private wells are discussed in more detail in **Section 9.2.7.1**.

Up gradient drawdown in affected aquifers generally does not cause changes to water quality, although a number of other factors may alter water quality. Spoil water generally is of poorer quality than Rosebud coal or McKay coal and may impact wells down gradient of mining. The Rosebud coal crop is close to down gradient pit margins in many permit areas and thus limits the lateral extent of potential down gradient exposure to spoil water in the Rosebud coal. Wells completed in McKay coal that are overlain by a sufficient thickness of interburden are generally protected from vertical infiltration of spoil water. The McKay coal crop line is also located near mining limits and thus limits laterally down gradient impacts to that unit. Water bearing zones in the underburden are usually deep enough to be protected from vertical infiltration of spoil water.

Shallow wells in the alluvium of EFAC and Lee Coulee are wells most likely to be affected by water quality changes attributable to mining. Alluvial wells in Rosebud Mine and Big Sky Mine have experienced mining-related increases in TDS concentrations from rising water levels due, in part, to MPDES discharges. Increases in TDS are also linked to infiltration from sediment ponds or infiltration from spoil where mining has taken place adjacent to stream margins. Discussions in **Section 9.2.5.1.1** and **Section 9.2.8** discuss current and expected impacts to EFAC alluvium. Water quality projections indicate that EFAC alluvial water quality will not render water unsuitable for a domestic use or livestock and wildlife watering; or harmful, detrimental, or injurious to listed beneficial uses. Thus, material damage will not occur. If material damage unexpectedly occurs such that water quality becomes unsuitable for uses based on the narrative and numeric standards for groundwater listed in 17.30.1006, the operator will mitigate the damage, including replacing the water supply (ARM 17.24.648).

9.2.6.2 Arsenic

The Rosebud Mine began sampling groundwater for arsenic in the late 1990's, thus there are no baseline samples for arsenic within the mined area. Up gradient wells or wells outside the limits of mining that have not been affected by mining are considered to represent background concentrations. Most of the arsenic exceedances are from one sample taken from a well. Review of the sample history for wells with a single arsenic exceedance confirms that the remainder, and typically more recent, arsenic analyses are either non-detect or are below standard limits. Five wells have two or more arsenic concentrations at or above the human health limit of 0.01 mg/L. The samples ranged between 0.01 mg/L and 0.019 mg/L.

The wells with two or more arsenic exceedances include:

- WA-214 had two samples at 0.014 mg/L and 0.01 mg/L. This is an alluvial well up gradient of mining, west of Area B. Due to the up gradient location of this well, the appearance of arsenic in this well is not associated with mining.
- WD-195 had three consecutive samples from 2009 to 2011 that ranged between 0.013 mg/L and 0.019 mg/L. This is a deep, up gradient well and the appearance of arsenic in this well is not attributable to mining.
- WI-153 had three samples above the arsenic standard that ranged from 0.012 mg/L to 0.018 mg/L. This is a relatively shallow (42 feet) interburden well in Area C at the north edge of mining. The water level and water quality have shown little variation throughout the life of the well. Unusual or anomalous concentrations of analytes in this well include boron above 1 mg/L and dissolved iron as high as 9.6 mg/L. The appearance of arsenic at or above 0.01 mg/L correlates with iron at 8.57 mg/L or higher. Rosebud and McKay wells at this location (WR-126 and WM-153) have detectable arsenic concentrations at or below 0.0005 mg/L. The McKay well also has higher than usual boron and iron, but it remains lower than in WI-153. Spoil well WS-122 at this location has not had enough water to sample and is not a likely source of the arsenic. Well WI-186, some 4,700 feet down gradient to the east, shows effects from surface uses such as road stabilization materials, but does not contain arsenic above 0.005 mg/l. The source of the arsenic in WI-153 is unknown. It is not associated with spoil water and may be associated with surface uses. There are no down gradient users near well WI-153.
- WM-189 is in the mined out area in Area D and had two samples with arsenic at 0.01 mg/L and 0.013 mg/L in 2002 and 2005. Two subsequent samples have reported arsenic concentrations at 0.001 mg/L and non-detect. Spoil well WS-128 at the same location has had non-detectable concentrations of arsenic and thus is not a likely source. It is worth noting that WM-188 and WS-187, located north northeast and northeast, respectively, of WM-189, also reported arsenic concentrations at and slightly above the standard during the same time frame. The absence of arsenic exceeding standards since then points to either a synchronous and temporary occurrence of arsenic in the area (August 2002 and September 2005) or a consistent sampling or analytical error. The lack of persistence of arsenic at these locations suggests there is not a problem.

At the Big Sky Mine, 19 samples taken between 1985 and 1987 from Area A wells were reported to have concentrations of arsenic between 0.01 mg/L and 0.054 mg/L, and all but two are less than 0.02 mg/L. The only well with repeated exceedances of arsenic is spoil well ASP22, which had exceedances of 0.018 mg/L to 0.054 mg/L in four consecutive year, 1985 through 1989. The last exceedance was 0.012 mg/L in 1989. This well is in a pre-law mine area that has been released from the Area A permit area.

At Big Sky Mine Area B, arsenic has been among the analytes in the water quality monitoring suite since the middle 1980's. In Area B, 83 samples reported the presence of arsenic, most of them in a single sampling even in 1985, which calls into question the accuracy of either the sampling or analysis. The highest concentration of arsenic reported in the Area B wells was 0.048 mg/L.

The wells with two or more arsenic exceedances include:

- BIN1217 is a historic well that had three exceedances of 0.025 mg/L, 0.012 mg/L, and 0.01 mg/L during 1985 and 1987. The well was removed during mining.
- BIN617 is an active well at the north permit boundary that had three exceedances between 0.01 mg/L and 0.022 mg/L during 1985-1988. Subsequent samples have been mostly non-detect; a few have reported detection below 0.005 mg/L. This well is up gradient of mining.

- BMC1214 is a historic well that reported three exceedances of 0.011 mg/L to 0.027 mg/L during 1985 and 1987, prior to removal by mining.
- BMC314 had four exceedances between 1985 and 1988 ranging from 0.012 mg/L to 0.028 mg/L. All subsequent samples were non-detect. The well was removed in 1994.
- BOV112 had two samples, one each in 1985 and 1990, at 0.021 mg/L and 0.014 mg/L but has reported non-detect or concentrations below 0.005 mg/L since those two samples. This well is up gradient of mining.
- BSM1215 had four samples in the middle 1980's that ranged from 0.01 mg/L to as high as 0.033 mg/L, but has reported only non-detect or concentrations below 0.005 mg/L since.
- BSM315 had four samples between 0.01 mg/L and 0.026 mg/L in the middle to late 1980's, but returned only non-detect concentrations until removal of the well in 1994.
- BSM615 had two samples in the middle to late 1980's of 0.014 mg/L and 0.024 mg/L but has been non-detect in all subsequent samples.
- BSM915 had three samples in 1985 that ranged from 0.012 mg/L to 0.033 mg/L but all subsequent samples returned non-detectable concentrations.

Arsenic occurs naturally at concentrations which can exceed human health standards in aquifers in the Fort Union Formation. Based on the above discussion of samples with arsenic exceedances at Rosebud Mine and Big Sky Mine there is no indication that mining has caused or created a situation that has contributed the occurrence of arsenic inside or outside the mine areas. None of the exceedances reported for arsenic may be attributed to mining operations. Therefore, there is no reason to expect material damage outside the permit boundary due to arsenic.

9.2.6.3 Cadmium

The inclusion of cadmium in water quality analyses has been part of the groundwater monitoring program since sampling began in 1976. In the Rosebud Mine database, cadmium exceeds the human health standard (0.005 mg/L) more often than any other regulated trace metal. However, 92% of the exceedances were from samples taken before 1990, with most occurring in the 1970's and 1980's. Commonly, a single sampling event resulted in widespread exceedances (e.g. July and August 1999). This suggests that a persistent and widespread source of cadmium above human health standards was present during the early days of sampling that is not now present, or there was a long-standing problem with sampling and analysis of this metal that produced spurious results. Water quality samples are currently collected from some of the same wells active in the 1980's in addition to new wells. Only 14 groundwater samples have reported cadmium concentrations above the human health standard since 1990 and only three of those were reported since 2002. None of the exceedances since 1990 are persistent in a given well:

- WR-168 reportedly had a cadmium concentration of 0.24 mg/L in 2010. The analysis reporting 0.24 mg/L is likely a data entry error, as the boron concentration from the sample is also 0.24 mg/L, a typical concentration for boron. Previous samples, when above non-detect, were an order or magnitude below the human health standard.
- WA-172 reportedly had a cadmium concentration of 0.017 mg/L in 2010 but had been at non-detect concentrations before this sample and has remained non-detect. This sample also reported exceedances for arsenic (0.019 mg/L) and lead (0.016 mg/L). Subsequent analyses for this well reported non-detect for all three of these trace metals.

At the Big Sky Mine, Area B, cadmium exceedances were limited to sample events in 1985, 1986, 1987, and one sample in 1990. One hundred and five samples from all monitored hydrostratigraphic units

reportedly had cadmium concentrations between 0.005 mg/L and 0.029 mg/L. Many of these wells are still active and have not had subsequent samples that contained cadmium above the human health limits. Generally, cadmium concentrations do not exceed the detection limit. As in the above discussion of arsenic exceedances, the appearance of cadmium above the standard during this limited timeframe is likely associated with sampling or lab error.

As described above, exceedances the human health standard for cadmium were common prior to 1990, and are attributable to imprecise analytical methods for this trace metal during this time. More recently cadmium exceedances have been rare and are considered anomalous. None of the exceedances for cadmium may be attributed to mining operations. Therefore, there is no reason to expect material damage outside the permit boundary due to cadmium.

9.2.6.4 Copper

There are no exceedances of the copper human health standard (1.3 mg/L) reported from any groundwater samples in the Rosebud Mine or Big Sky Mine. Therefore, there is no reason to expect material damage outside the permit boundary due to copper.

9.2.6.5 Fluoride

There are five reported exceedances of the human health standard for fluoride (4.0 mg/L) in groundwater at the Rosebud Mine. None is from the same well and some of the reported concentrations likely are reporting or data entry errors.

- WA-118 reported the highest concentration at 801 mg/L, which is assumed to be an error in reporting or analysis. This concentration, reported in 2004, is extremely high and exceeds by many orders of magnitude the typical concentration of < 0.05 mg/L at this well.
- WI-102 reported a fluoride concentration of 13 mg/L in 2008. This is most likely a reporting error and should be 0.13 mg/L. All other samples are <0.37 mg/L.
- WA-214 had a reported exceedance of 7.29 mg/L in 2007, although all other samples from this well are <0.34 mg/L. Concentrations of other analytes that appear anomalous, compared to the historic and more recent analyses from the well, call into question the accuracy of the analysis.
- WM-138 reported a concentration of 6.3 mg/L in 2009. All other fluoride concentrations reported from this well are at or below 0.05 mg/L.
- WD-182 is a 500 foot deep underburden well in Area E that has had a persistent high concentration of fluoride since 1985. It had a concentration of 5 mg/L in 1993 and maintains a concentration of 3 mg/L. This well has been monitored since 1984. It has a consistent water quality (TDS = 1,220 mg/L) with an alkaline pH. It shows no water quality evidence of being affected by spoil and depth of this well makes susceptibility to spoil unlikely. Two shallower wells (WI-182, WM-182) at the same location have fluoride concentrations <0.50 mg/L.

No exceedance of fluoride has been reported in samples taken at the Big Sky Mine.

Exceedances of fluoride are uncommon and usually appear to be the result of problems in laboratory analysis or reporting. The exceedance at well WD-182 is likely due to natural causes and not related to mining. None of the exceedance for fluoride may be attributed to mining operations. Therefore, there is no reason to expect material damage outside the permit boundary due to fluoride.

9.2.6.6 Lead

The human health limit for lead is 0.015 mg/L. At the Rosebud Mine, fifteen groundwater samples have exceeded this limit, twelve were from analyses in the 1970's-1980's. The wells that yielded the exceedances do not have recent concentrations that approach the human health limits, suggesting that there is not a persistent problem.

- WA-204 had a concentration of 0.67 mg/L in 2001 in a sample that also has an anomalous iron concentration of 0.67 mg/L, suggesting that there was an error in the analysis or reporting.
- WM-158 had an error similar to the one described above in WA-204, when in 2001, the lead concentration of 0.29 mg/L was reported for both lead and iron.
- WI-162 had a lead exceedance in 2006 with a concentration of 0.37 mg/L, when again, both lead and iron had the same concentration.

At the Big Sky Mine Area A, 113 exceedances for lead have been reported. Most of them were in the 1980's when lab results have been demonstrated to be frequently inaccurate for most metal analyses. A few wells have reported exceedances in the 1990's, but none more recently. Wells with repeated exceedances that include analyses more recent that the 1980's are discussed below:

- AAL14 is an alluvial well down gradient of mining that had four exceedances, most were in the middle 1980's but the most recent was in 1992 at 0.02 mg/L. The shallow depth of this well subjects it to influence from surface water. Surface water often carries sediment that contributes to traces of dissolved metals. This well has also had exceedances of zinc, nitrate, cadmium and arsenic. None of these analytes are persistent and are not interpreted to result from mining impacts.
- AAL51 is an alluvial well in pre-law mining that had four exceedances, including one in 1994. The lack more recent lead exceedances from this well suggest lead is not a problem in this well.
- AMC20 is a McKay coal well that is completed in pre-law mining that has had four exceedances. Three were in the middle 1980's, the latest in 1996.
- AOVM73 has had six exceedances, the most recent in 1996 and the remainder in the middle 1980's. This well is up gradient of mining and therefore represents background water quality.
- ARC30 is a Rosebud well southwest of pre-law mining that has had two exceedances, one in 1984 and one in 1993. Water quality does not show mining related impacts at this well.
- ASSM27 had three exceedances, the most recent in 1992. This is a sub-McKay well located south of the permit boundary that has shown slight increases in TDS but no recent exceedances of lead or other parameters of concern.
- ASMTW4 had two exceedances, the last one in 1992. This is one of the "truck wash" wells located near the pond that received water from the equipment washing facility. Water quality analyses indicate this well has been affected by mine related impacts, but has improved over time, and currently has no parameter concentrations that exceed or are likely to exceed water quality standards.
- ASP40 is a spoil well in pre-law mining that had three exceedances, the most recent in 1992. This well has shown an increase in TDS concentration but currently has no parameter concentrations that exceed or are likely to exceed water quality standards.
- ASPS15 is completed in spoil in pre-law mining and has had six lead exceedances, all but one (1993) in the 1980's. It has water chemistry that suggests it has been affected by mining but currently has no parameter concentrations that exceed or approach water quality standards.
- ASPW1 is a spoil well in pre-law mining that had three exceedances, the most recent in 1996. Other than the two exceedances and one analysis in 1984 of a concentration below the lead standard, lead analyses from this well are non-detect.

At the Big Sky Mine Area B, 66 samples have lead concentrations above the human health limit. The exceedances are from the middle 1980's and the early to middle 1990's. Most of the exceedances are 0.02 mg/L, but they range from 0.015 mg/L to and anomalously high concentration of 0.390 mg/L. Most exceedances are from one sample at a given well. There have been no recent exceedances. Even though lead has remained part of the analytical suite, no subsequent samples have contained lead above the human health limits and most sample concentrations are below detection. The limited timeframe for the exceedances again leads to the likelihood that a problem in sampling or analysis is the reason for the exceedances.

The anomalously high and persistent lead concentrations are discussed below:

- BAL2011, BAL2321, BAL 2521, BAL9011, BAL9031, and BAL9091 are alluvial wells in the north reaches of Lee Coulee that had repeated exceedances (generally in the 0.02 mg/L range) of lead in the early to middle 1990's. Mining was active east of the stream in 1991 and was not active in the uppermost reaches until after 2000. The MPDES discharge point associated with mining on the east side of the stream below the location of most of these wells. The wells were sampled frequently and were non-detect for lead except for the reported exceedances. It seems most likely that the exceedances were spurious.
- BMC714 was located on the south permit boundary and yielded a single sample that reported a lead exceedance of 0.173 mg/L in 1985, prior to mining in Area B. Examination of sample results for other parameters indicates there was a problem with the analysis similar to that observed in BRC413 below.
- BRC413, located southwest of the permit area, had two samples and both had lead exceedances of 0.39 mg/L and 0.24 mg/L in 1985. The initial sample had anomalous analytical results that suggested a problem with the analysis. Calcium and magnesium were exceedingly low (19 mg/l and 14 mg/l), and unusual concentrations of molybdenum (12 mg/L), selenium (0.026 mg/L), aluminum (3.2 mg/L), and exceedances of arsenic (0.02 mg/L) and cadmium (0.029 mg/L) were reported. The latter sample also had unusual results with low calcium and magnesium but most metals other than lead were within normal range. Given its location, this well was outside the influence of mining.

The reports of lead concentrations above the human health limit likely are spurious and likely represent problems with sampling, laboratory analysis, or reporting. None of the lead exceedances are may be attributed to mining operations. Therefore, there is no reason to expect material damage outside the permit boundary due to lead.

9.2.6.7 Nickel

Three groundwater samples reached the human health standard of 0.1 mg/L for nickel at the Rosebud Mine in 1976 and 1977 in wells S-04 and S-05. Subsequent analyses from these wells do not report an exceedance. Nickel does not represent a problem in the Rosebud Mine area.

At the Big Sky Mine two samples in Area A report nickel concentrations above 0.1 mg/L:

- ASP22 had one sample in 1987 that reached the standard. This well commonly reports nickel above the detection limit but has remained an order of magnitude below the standard in all other samples.
- ASPS15 had one sample at 0.1 mg/L in 1990 and commonly has nickel concentrations above the detection limit of 0.010 mg/L, although the last two samples have been non-detect.

In Big Sky Area B, one sample had a nickel concentration above the human health standard. The sample was taken from overburden well BOV1712 in early 1996 and had a concentration of 0.36 mg/L. The well has remained active and has reported subsequent low-level nickel concentrations at least an order of magnitude below the standard. The well is located in an undisturbed area east of the pit and it not likely affected by mining.

Nickel exceedances are rare and appear associated with problems in sampling or laboratory analysis. None of the exceedances reported above for nickel may be attributed to mining operations. Therefore, there is no reason to expect material damage outside the permit boundary due to nickel.

9.2.6.8 Selenium

Eleven groundwater samples from Rosebud Mine reported selenium concentrations above the limit set for human health (0.05 mg/L):

- Two of the samples are from the same well (WO-105); they were taken in 2012 and 2014. This well is located immediately adjacent to the east pit in Area A. Both samples indicate a large increase in TDS (up to 10,000 mg/L) and all major analytes. Field notes indicate this well was damaged and it appeared an animal had fallen into the well. Unusual water quality results confirm there was a problem. Additionally, unusual water quality in the well may be attributable to interception of pit water which had been concentrated by evaporation due to inactivity since 2000. Pit water has been removed from the pit and mining has recently resumed in this part of Area A.
- WA-171 located west of and up gradient of mining in Area B reported a single exceedance of selenium at 0.11 mg/L in 2012. Coincident with this exceedance for selenium, the well experienced a spike in chloride, TDS, calcium, magnesium, nitrite, sodium, and sulfate. This suggests surface influences have affected this alluvial well.
- WA-225 and WO-187 are located far west of Area C in areas undisturbed by mining and thus represent background levels (0.05 mg/L and 0.099 mg/L, respectively).
- WR-126, located at the north edge of Area C central and immediately beyond the margin of mining, had a single selenium exceedance in 2013 of 0.05 mg/L, the standard limit. This well is only 20 feet deep and has water quality that suggests it is affected by surface influences. It has higher than usual boron, chloride, and nitrate, and spikes in calcium and magnesium, likely from road runoff. Selenium is often detected in this well, but the concentrations are usually not close to the human health standard. The water quality changes are not attributed to spoil water as a nearby spoil well (WS-122) contains only four feet of water.

Big Sky Mine Area A had a number of samples that met or exceeded the standard in well

- ASMTW3 had three exceedances, two in the middle 1980's and one in 2000. Most were near the reporting limit (0.05 mg/L), although the first sample in 1984 had 0.17 mg/L.
- ASMTW4 had two exceedances in 1985 near the reporting limit. The ASMTW wells monitored groundwater at the truck wash site and the selenium was likely came from hydrocarbons such as oil and grease. These wells have been part of the monitoring plan for decades and have not had any more recent exceedances than the ones described above.
- Spoil well ASP-22 had one exceedance of selenium in 1984.

There were no samples in Big Sky Area B with exceedances of selenium.

Selenium exceedances are sporadic and often appear associated with a problem in sampling or laboratory analysis. The selenium exceedances in the Big Sky mine truck wash wells were likely caused by the mine, but were within the permit boundary. None of the exceedances reported above for selenium may be attributed to mining operations. Therefore, there is no reason to expect material damage outside the permit boundary due to selenium.

9.2.6.9 Zinc

Sixty-one exceedances for zinc in groundwater are reported in the Rosebud Mine database. Of these, all but three were from samples taken between 1981 and 1989. As most of the wells identified pre-1990 are still active and have no recent exceedances, the appearance of zinc above standards pre-1990 suggests either a temporary, widespread abundance of zinc in groundwater or persistent problems in analytical methods for zinc. As a widespread, temporary source for zinc in groundwater is unidentified and unlikely, the analytical results for zinc, as with other analytes during this period, are suspected to be problematic, indicating there reported exceedances were spurious. Of the samples taken in 1990 and later, there is no indication that there is a cause for concern in the mine areas:

- WA-186 in WFAC had a zinc concentration of 2.09 mg/L in 2000 but had non-detect or low concentrations in samples prior to and after the exceedance.
- WM-181 had an exceedance of 2.71 mg/L in 1990 and an exceedance of 4.67 mg/L in 1988. This McKay well in the west part of Area C was not subject to mining influences at the time of the exceedances, as mining in the west part of Area C did not begin until 2008.
- WS-126 had an exceedance of 3 mg/L in 1999 but analytical results are usually non-detect.

In Big Sky Area A, four wells reported single analyses of zinc above the human health standard of 2 mg/L:

- AAL 14 located south of the permit area reported a zinc concentration of 8.75 mg/L in 2009. This well commonly reports zinc concentrations above detection (0.01 mg/L) but the results of the sample in 2009 is anomalous. No persistent problem with zinc is present in this well.

Three exceedances were reported in spoil wells:

- ASP22 had a single exceedance in 1985 of 4.77 mg/L. Zinc in this well is commonly reported above detection but is generally low and is not perceived to be a problem.
- ASP25R had a single report of zinc at 2.04 mg/L during the same sample event in 2009 that reported zinc above the standard in well AAL14. This well has zinc concentrations above detection on a regular basis but they are orders of magnitude below the human health standard.
- ASP29 had a reported zinc concentration of 37 mg/L in 1997. This is an exceedingly high concentration and is assumed to represent a problem in sampling or analysis. Zinc concentration in this well is generally only slightly above detection or non-detect.

Twenty-six exceedances of zinc were reported from samples taken in Big Sky Area B. Approximately two-thirds of these were reported from two sampling events; one in February 1985 and a second in September 1997. The reported concentrations ranged from 2.38 mg/L to 130 mg/L. The highest concentrations were reported from 15 samples during the September 1997 event, ranging in concentration from 20 mg/L to 130 mg/L. These are extremely high concentrations and likely represent a problem in analysis or reporting. Three wells had two exceedances:

- BRC513 had two exceedances, one each year in 1984 and 1985 of 2.38 mg/L and 8.57 mg/L. The latter sample also was at the standard for lead (0.015 mg/L) and arsenic (0.01 mg/L). This well is north of the permit area and up gradient of mining.
- BSM1015 had exceedances of 3.72 mg/L in 1985 and 40 mg/L in 1997. The remaining analyses are barely above detection (0.01 mg/L).
- BSM1715 had exceedances of 13.1 mg/L and 130 mg/L in 1988 and 1997. More recent analyses are barely above the non-detect limit of 0.01 mg/L.

The exceedances from September 1997 are the last ones reported. A low level of dissolved zinc is generally common in groundwater and a lack of persistent exceedances suggests zinc does not represent a problem in groundwater at Big Sky.

Zinc exceedances are sporadic and appear associated with problems in sampling or laboratory analysis. None of the exceedances reported above for zinc may be attributed to mining operations. Therefore, there is no reason to expect material damage outside the permit boundary due to zinc.

9.2.6.10 Nitrite-Nitrate

Thirty-two samples from the Rosebud Mine have had nitrate concentrations above the human health limit of 10 mg/L. Many represent a single exceedance from a given well that appears to be anomalous when compared to analyses of other samples from the well. No further consideration was given to these wells. Wells that have had persistent exceedances or persistent nitrate near regulatory limits are discussed below.

Three spoil wells have had recent, persistent exceedances of the nitrite-nitrate human health limit:

- Well WS-127 is located in Area D, between the Colstrip power plant and pond 151 and has been monitored for water quality since 1999. This well has high TDS (average 7,882 mg/L), chloride and magnesium concentrations and had nitrate concentrations above the human health standard in five out of six samples collected between 1999 and 2014. The nitrite-nitrate concentration ranged between 7.6 mg/L (Sept. 2011) and 50 mg/L (Sept. 2005) and most recently (2014) was 29.8 mg/L. The well also has an unusually low pH that averages 6.4. The high chloride and magnesium concentrations in this well are most likely related to the application of road stabilization products (magnesium chloride) on the adjacent haul road. A possible source of the persistent nitrite-nitrate concentration in spoil is from blasting agents used during mining. The area is also subject to influences from the power plant and cattle grazing. Groundwater flow in the area is to the southeast. Well WS-126, located southeast of WS-127, serves as a down gradient well to intercept water from WS-127 before it approaches the permit boundary. Nitrate in WS-126 ranges between 0.01 mg/L and 0.06 mg/L, concentrations well below the human health standard. There is no evidence that the proposed expansion of mining in Area B will exacerbate nitrite concentrations in Area E.
- WS-100, located approximately 1,000 feet from the east boundary of permit Area A, has had three samples (2009-2014) that exceed the nitrite-nitrate human health standard of 10 mg/L. The most recent sample (2014) was 24.1 mg/L. Although it is uncertain if the nitrate is associated with mining, agricultural (the reclaimed area is used as grazing pasture) or another unidentified source, ammonium nitrate blasting agents remaining in spoil are a possible source. A stipulation in the approval of AM4 will required expanded monitoring with the expectation that a well will be installed down gradient of WS-100, closer to the permit boundary, to monitor for potential movement of nitrate toward the permit boundary.

- WS-111 is located in the former Pit 6 area. Nitrate concentrations began to rise in 2005 (16 mg/L) and were 12 mg/L in the last two samples (2008 and 2011). Because Pit 6 was a pre-law mine area, it was not subject to current bond release standards, including the requirement to prevent material damage outside the permit area. Pit 6 was released from bond in 2006.

The greatest nitrate exceedance recorded from a monitoring well is 351 mg/L, a highly anomalous value, from WA-113 in 1985. However, this well has a history of elevated concentrations that spans the life of the well. This well is located in a drainage in the town of Colstrip and downstream from a subdivision. Anthropogenic sources such as lawn fertilizer are the most likely source of nitrate in this 15 foot deep well.

A few alluvial wells in the east part of Area B had an exceedance when mining was adjacent to EFAC in the middle 1980's, including well WA-124, and WX-110. Other nearby alluvial wells (e.g. WA-104) showed elevated nitrate below the HHS. The exceedances and persistent elevated nitrate concentrations in alluvial wells from 1982 to 1989 may be attributable to blasting agents used in mining. Use of the stream by cattle is also a potential source of nitrate.

Alluvial well WA-154 was located downstream of Colstrip on EFAC, below the power plant, but showed evidence of elevated nitrate from 1983 until 1995 when monitoring was discontinued. Nitrate here has multiple potential anthropogenic sources other than mining, including the water treatment plant, runoff from the golf course and cattle grazing.

Two Rosebud wells reported nitrate concentrations above the HHS, one (WR-125) in 2000, and another (WR-126) in 2007. WR-125 is up gradient of mining, eliminating mining as the source of the elevated concentrations. WR-126 located along the country road in Area C has shown persistently elevated nitrate since 1987 with one HHS exceedance in 2007. The source is not spoil as water level in the spoil (WS-122) remains 11 feet below the water level in WR-126.

Five samples exceeded the nitrate-nitrate standard in Area A of the Big Sky Mine:

- ASTMW3 and ASTMW4 were the locations of all of the exceedances during the middle 1980's. These wells are known as "truck wash" wells and are located adjacent to the former equipment washing area. The nitrate-nitrogen concentration in four of the samples was over 100 mg/L and ranged as high as 234 mg/L. The source of the nitrate was most likely degreasing and cleaning agents used on equipment at the truck wash.

In Big Sky Mine Area B, fourteen samples had concentrations that ranged from 10.3 mg/L to 54.6 mg/L. The bulk of the samples were from the 1980's and 1990's. Repeated exceedances were from two wells:

- BSM115 (a sub-McKay well) had two exceedances of 11 mg/L and 11.7 mg/L; one in 1998 and one in 2008. This well is located 4,000 feet north and up gradient of mining. Exceedances are due to another land use other than mining.
- BSM2515 (sub-McKay well) is a historic well located below the Rosebud coal crop line in the center of Area B. Both samples with exceedances were 10.3 mg/L and 10.4 mg/L in 1987 and 1995. The reason for the elevated concentration is unclear.

As noted above, elevated nitrate-nitrite have been detected in several locations in both the Rosebud and Big Sky mines. None of these instances are considered material damage because they are either within the permit boundary, or are have a likely source other than coal mining. Because the exceedance at WS-100 is near the permit boundary and could potentially be a result of mining, a stipulation in the

approval of AM4 will require expanded monitoring with the expectation that a well will be installed down gradient of WS-100, closer to the permit boundary, to monitor for potential movement of nitrate toward the permit boundary.

9.2.7 Groundwater Flow Models

The AM4 application included two transient groundwater flow models for permit areas A, B, and C to evaluate potential water level changes caused by mining. The "Rosebud Mine Groundwater Model" evaluates the response of the hydrologic system in and adjacent to the mine area at the end of currently approved mining (Western Energy Co., 2014). The "AM4 Model" evaluates the additional impacts that would result from the mining proposed in application AM4. A flow model was constructed for the Area D permit area in July, 1999 (Western Energy Co., 1999). Mining in Area D concluded in 2012.

Areas A, B, and C
The models simulate flow in all of the shallow aquifers (alluvium, overburden, Rosebud coal, interburden, McKay coal and underburden or sub-McKay) but focus on the Rosebud coal and McKay coal as these are the primary shallow aquifers and the ones most likely to show the greatest effects of mining. Groundwater models are a simplification of the geologic and hydrologic system yet provide reasonable predictions of the local hydrologic function and response to the stresses of mining. After the development of a conceptual groundwater model, a model structure is defined and calibrated. The model is calibrated by comparing model results to measured water levels from monitoring wells and adjusting model parameters to achieve the best simulation of groundwater conditions.

The Rosebud Mine Model simulates drawdown in the Rosebud coal and McKay coal in 2011 (**Figure 9-78** and **Figure 9-79**), and at the end of 2020 (**Figure 9-80** and **Figure 9-81**), the year currently approved mining in Area B is expected to conclude. Drawdown in 2011 was predicted to be greatest in the east part of Area B, with 90 feet of drawdown (including decline in pressure head) in the Rosebud coal and 30 feet in the McKay coal. Because it is confined throughout most of the area, drawdown in the McKay generally extends slightly more than in the Rosebud coal, with the 5-foot drawdown contour reaching slightly less than two miles south of the permit boundary. In 2020, the greatest drawdown in Rosebud coal attributable to currently approved mining is predicted to be 80 feet in the southwest as well as the east half of Area B. In the McKay coal, drawdown in Area B is predicted to be approximately the same as in 2011. In both the Rosebud coal and McKay coal, five feet of drawdown is expected to extend up to two miles outside of the south permit boundary.

Rosebud coal in Area A remains largely unchanged in the amount of drawdown between 2011 and 2020, showing approximately 20 feet of drawdown. Likewise, for the McKay coal, there is approximately 20 feet of drawdown in 2011 and 2020. Area C drawdown is 60 feet in the east part of Area C in 2011, 40 feet in the central part, and 30 feet in the western part. By 2020, drawdown associated with approved mining is 70 feet in the east part, 60 feet in the central part and 30 feet in the west part of Area C. The McKay increases in drawdown by about five feet in 2020 to 30 feet.

The AM4 Model predicts drawdown in areas A, B, and C through 2026 (**Figure 9-82** and **Figure 9-83**), when the additional mining proposed in AM4 is expected to conclude. The largest simulated drawdown at the end of the proposed mining is about 110 feet in the Rosebud coal in the east part of Area B, at the south permit boundary. Five feet of drawdown is projected to extend almost two miles south of the Area B permit boundary. The maximum projected drawdown in the McKay coal is 35 feet in the east half

of Area B. Five feet of drawdown is expected to extend slightly more than two miles south of the Area B permit boundary. In 2026, the increase in drawdown from AM4 mining compared to mining in 2020, at the end of currently approved mining in Area B, is 30 to 40 feet in Area B Rosebud coal and five feet in McKay coal (**Figure 9-84**).

To evaluate the recovery of the system, the AM4 model predicted drawdown remaining in 2076 (**Figure 9-85** and **Figure 9-86**), 50 years after the predicted conclusion of mining in Area B. Fifty years was chosen as the timeframe for insight to the response of the system. For the Rosebud coal, the maximum residual drawdown in 2076 is projected to be about 50 feet in Area B and Area C, and the extent of the five-foot drawdown contour is predicted to be between two and three miles south of the permit boundary. Residual drawdown in the McKay coal is projected to be about 25 feet in the east part of Area B, near the south permit boundary. The five-foot drawdown contour is projected to extend up to two and a half miles south of Area B. The increase in simulated drawdown in 2076 between that expected from currently approved mining and mining proposed in AM4 is as much as 15 feet in Rosebud coal and five feet in McKay coal (**Figure 9-8**7).

Unlike drawdown modeling, there is not a reliable way to calibrate recovery water levels. Modeling the recovery for any period gives a prediction of how the system will respond, but it should be regarded as an estimate. There are limitations to any model based on the input variables used to quantify a hydrologic system. The limitations are even greater in a large area with naturally variable and complex hydrogeology, as found in the Colstrip area. Recovery of the system is not expected to be linear over time. A model for recovery over a determined period, such as 50 years, may be used to extrapolate to a longer time frame, but the results become less reliable with time.

Area D

Application 161 for mining the east part of Area D was approved by DEQ in 2001. The application included a flow model (Western Energy Co., 1999) that predicted water level drawdown and recovery associated with all mining in Area D. The model predicted impacts to the Rosebud coal, interburden and McKay coal. Two scenarios were modeled. Scenario 1 assumed leakance between interburden and McKay coal would increase due to fracturing from blasting, particularly in the south part of the permit area where interburden is thinnest. Scenario 2 assumed no interburden fracturing and thus no increase in leakance. The outcome for both scenarios is similar, with more drawdown to interburden water levels resulting in Scenario 1 along with an increase in water level over beginning levels in the McKay coal. Maximum drawdown for Rosebud coal, interburden and McKay coal at the end of mining was predicted to be about 30 feet, with most of the drawdown to occur in the west-central part of Area D, coincident with a structural depression in the Rosebud coal.

The model assumed Area D mining would be completed in 2011 (**Figure 9-88** and **Figure 9-89**). The modeled Rosebud coal potentiometric surface (Layer 1) closely resembles the Rosebud coal and spoil potentiometric surface developed from current water levels at the end of mining in 2013. However, the McKay coal potentiometric surface measured at the end of mining is 10 feet to 20 feet lower than either one of the model scenarios. The model predicts no drawdown in the McKay coal at the end of mining near the west edge of the permit area. Hydrographs of McKay well WM-110 and the well that replaced it after mining, WM-189, indicate that the current water level closely approximates the water level in 1979 (**Figure 9-50**).

Fifty years after completion of mining, the model predicts between 20 and 25 feet of drawdown in the Rosebud/spoils aquifer in Scenario 1 (**Figure 9-90**). Under this scenario, between 10 and 15 feet of

drawdown will remain in the interburden and up to 10 feet of drawdown will remain in the McKay. A head increase of approximately five feet above the premine potentiometric surface is predicted in the central and southeast permit area. Scenario 2 (**Figure 9-91**) gives similar results after 50 years. Rosebud coal and spoil water levels are predicted to remain 15 feet to 20 feet below starting water levels in the south central part of the permit area. Interburden is predicted to be 10 feet to 20 feet below starting levels, and drawdown in the McKay is predicted to be five feet to 10 feet below starting levels. Drawdown in the sub-McKay units is not expected and was not modeled.

9.2.7.1 Drawdown Impacts to Private Wells

Anticipated drawdown (head decline) in the Rosebud coal and McKay coal in response to current mining and mining proposed in AM4 is discussed in **Section 9.2.7**, Groundwater Models. Numerous private wells outside the permit boundary lie within the area of predicted drawdown in the Rosebud coal , both at the end of currently proposed mining (**Figure 9-94**) and the end of proposed AM4 mining (**Figure 9-95**). The anticipated impact to private wells is included in **Table 6-1** and is based upon the approximate location of the wells as indicated in the GWIC database. Analysis of the potential impact to a given well is based on completion information, where available, static water level provided in the GWIC database and location of the well within the zone of predicted drawdown. Based on reported static water level, wells completed in the Rosebud coal that lie within the area of drawdown generally have adequate head to retain sufficient supply. Wells are not likely to be significantly impacted unless water levels drop below the level required for pumping. Wells with low static water levels that are completed in the Rosebud coal are the wells most likely to be affected. Wells that are impacted by mining are required under ARM 17.24.648 to be replaced by the operator.

The following private wells within the zone of mine related drawdown were initially identified as potentially vulnerable based on their completion depths. Private wells numbered 77 (NE1/4 Section 4, T1N, R39E) and 75 (SE1/4 Section 32, T2N, R39E), are used for stock water and are located west of Area C. Western Energy Company has acquired surface ownership and anticipates abandonment of the wells.

Private wells 82 and 83 are in Section 17 and 18 (T1N, R40E), respectively, and are over a mile from active mining in Rosebud Mine Area B and Area C. Well 82 is completed at 145 feet and has a static water level of 70 feet reported in the GWIC database. Rosebud monitoring well WR-125 (**Figure 7-2**) with a completion depth of 228 feet is less than 600 feet away from well 82. The difference in depth between the two wells suggests that well 82 is completed in the overburden and is not likely to experience drawdown. Drawdown in the overburden is limited due to the typically discontinuous and extremely slow transmissivity of the stratigraphic units that composed the overburden.

Well 83 is completed at 124 feet and reports a static water level of 64 feet. It is located on the 10-foot drawdown contour predicted by the AM4 groundwater model for the year 2026. There is no nearby monitoring well for comparison of water levels or effects of mining to date. It is unlikely to be affected by the predicted 10 feet of drawdown in the Rosebud coal at this location.

Private wells 86, 87 and 89 also lie within or close to the margins of drawdown. Based on predicted drawdown to these wells (five to 10 feet), depth of completion of the wells and the response of monitoring wells that lie even closer to mining, wells 86, 87, and 89 are not anticipated to be significantly affected by drawdown from current or proposed mining operations.

Well 91 located south of the west part of Rosebud Mine Area B (Section 23, T1N, R40E) and northwest of Big Sky Area B, is completed in overburden or Rosebud coal and had a static water level of only 30

feet. It lies near the Rosebud coal 10-foot drawdown contour interval. Rosebud monitoring well BRC1313, located between Rosebud Area B and Big Sky Mine Area B, northeast of well 91, had nine feet of drawdown and now has a stable water level and a head of 110 feet. It is unlikely that well 91 will be vulnerable to drawdown from proposed mining.

None of the potential drawdown impacts described above are considered likely to constitute material damage. Wells located within the expected area of drawdown either have a sufficient water column that predicted drawdown will not affect their use, or are owned by Western Energy Company.

9.2.8 Cumulative Impact of Historic, Current and Proposed Mining

Currently and formerly permitted areas at the Rosebud and Big Sky mines total approximately 53 square miles. Pre-law mining disturbance and approved LOM disturbance is equivalent to approximately 43 square miles (27,305 acres). Rosebud coal has been removed at the Rosebud Mine and Big Sky Mine from easily accessible coal at or near the crop line to interior areas where the depth of overburden cover allows economic extraction of the underlying coal. Mining at Area D and Area E of the Rosebud Mine and Area A and Area B of the Big Sky Mine has been completed and the areas reclaimed. Mining remains active at Rosebud Mine Area A, Area B, and Area C.

Surface disturbance in permit areas established after the enactment of MSUMRA has been reclaimed to the approved postmine topography with equivalent groundwater recharge capacity. Much of the pre-law mining disturbance has been reclaimed to some extent and the remaining unreclaimed topography is not expected to create a barrier to recharge.

Drawdown in water level or declines in pressure head are the most obvious and widespread impact associated with past and present mining in the Colstrip area, with the Rosebud coal aquifer the most widely and severely impacted. Head declines of up to 90 feet in the Rosebud coal from mining at the Rosebud Mine were estimated in a model based on 2011 water levels (**Figure 9-78**) (Western Energy Co., 2014). Based on the model, maximum head decline in Area A has been approximately 20 feet; east central Area B had 90 feet and Area C experienced up to 60 feet. Based on a model of Area D during a proposed expansion in 1999, drawdown (decline in head) was estimated to be between 20 and 30 feet (**Figure 9-88** and **Figure 9-89**)(Western Energy Co., 1999). Part of Area E was mined pre-law and early impacts were not monitored. Based on monitoring in Area E since 1981, Rosebud coal west of the pit has recovered 20 feet since mining concluded in 1986 (Western Energy Co., 2015).

Amount of decline in Rosebud coal in Big Sky Mine Area A is uncertain as initial mining was prior to enactment of statutes regulating coal mining. Monitoring wells initially installed by MBMG in the middle to late 1970's recorded up to 50 feet of head decline in Rosebud coal. Head decline in Rosebud coal at Big Sky Mine Area B has measured as much as 30 feet.

Five feet of head decline in the Rosebud coal currently extends over a mile from the south permit boundary of Rosebud Mine Area B and represents the location of the greatest extent of decline outside the mine permit boundaries. Based on monitoring near the permit boundary and extrapolating from the response of the Rosebud coal aquifer in the Rosebud Mine, the extent of the five-foot head decline west of Big Sky Area B permit boundary is approximately a mile. Head decline in the Rosebud Mine and Big Sky Mine overlaps and coalesces in the area between the two mines. Total extent of drawdown in the Rosebud coal is approximately 8 miles in a north-south direction and 15 miles in an east-west direction.

Mining has also created head decline in aquifers below and adjacent to the Rosebud coal. As overburden removal is preliminary to coal removal, the overburden may experience a drawdown response in areas where it is saturated. However, the discontinuous nature of the fine-grained overburden strata, and thus extent of saturation, causes less of a widespread impact. Head reduction has also been observed locally in the McKay coal. The McKay coal is separated from the overlying Rosebud coal by a few feet to tens of feet of interburden and is not physically disturbed by mining. Some of the reduction in head may be due to unloading of the overlying rock units (overburden and Rosebud coal) or removal of recharge from the Rosebud coal. Steepest head decline in the McKay coal is modeled to be approximately 30 feet in the east part of Rosebud Mine Area B (**Figure 9-79**). Based on monitoring response, head loss in McKay coal in Big Sky Mine Area A is estimated to be between 12 feet and 16 feet and as much as 20 feet to 30 feet in Area B.

Removal of the Rosebud coal has also caused localized declines in the underburden, as observed in Rosebud Mine Area B, Area D and Area E. Recovery of head in unmined Rosebud coal, McKay coal and underburden has occurred relatively quickly in areas where reclamation has been completed, including Area D and Area E of the Rosebud Mine and both areas of the Big Sky Mine. Even where decline has been observed in these units, substantial confined head remains in most of the McKay coal, underburden and unmined Rosebud coal, particularly in areas away from the coal crop line.

Alluvial groundwater in ephemeral drainages is generally unaffected by mining. However, mining has affected alluvium levels as well as water quality in the east part of EFAC and Lee Coulee. Proximity of the Rosebud coal to alluvium in intermittent reaches of EFAC between Rosebud Mine Area A and Area B resulted in drawdown early during Area B mining. Connection of alluvium with Rosebud coal and McKay coal at the east end of the permit areas resulted in recharge to spoil and bedrock units, particularly in Area B. The recharge has been aided by MPDES discharges to EFAC. The increase in water level from MPDES discharges as well as above normal precipitation in recent years has resulted in increases in TDS concentrations in alluvium. MPDES discharge to Lee Coulee (Big Sky Mine Area B) increased alluvial water levels and caused declines in water quality.

Infiltration into backfilled pits is slowly creating a spoil aquifer. The length of time necessary for spoil to recover to premine Rosebud water levels will vary based on hydrologic setting and time of completion of mining and reclamation. Source of recharge to the spoil is mainly from adjacent, unmined Rosebud coal but local surface water contributions from streams, ponds and mine pits may provide additional, recharge. Areas without significant lateral recharge, such as Rosebud Mine Area A, Area D, and the north part of Area C, will take longer to recover than other areas. Spoil currently ranges from dry to thinly saturated in most former pit areas. Recovery is predicted to take many decades after the completion of mining. Fifty years after mining is completed in Area B, including mining the proposed AM4 cuts, depressed heads of up to 50 feet were modeled to remain in Area B and Area C (Western Energy Company, 2015). A stipulation on permit issuance for AM4 will require that the operator eliminate approved and proposed cuts in Section 9 and Section 10 (T1N, R41E) in Area B. This will decrease some of the additional drawdown predicted by AM4 mining.

Spoil water quality is most similar in TDS concentration to overburden water. TDS concentrations from recent spoil water quality samples ranged from 1,830 mg/L to 7,690 mg/L (average = 3,963 mg/L; median = 3,690 mg/L) at the Rosebud Mine and 2,800 mg/L to 5,280 mg/L (average = 3,897 mg/L; median = 3,160 mg/L) at the Big Sky Mine. Water quality in the Rosebud coal up gradient of mining is not affected by spoil water. Except where interburden is thin, the underlying McKay coal is generally not subject to water quality changes from spoil. Due to the low conductivity of underburden rocks, the

underburden remains unaffected by spoil water. Laterally down gradient Rosebud coal has the greatest potential for water quality changes from spoil water, but as pit areas remain largely unsaturated, down gradient coal has remained largely unaffected. At the Rosebud Mine down gradient exposure of Rosebud coal to spoil water is limited by the crop line in Area A, Area D, Area E and part of Area C. Premine Rosebud coal typically became more thinly saturated approaching the crop line and was dry by the time it reached the crop line. This is attributable to the slow movement of groundwater which allows time for evapotranspiration as it approaches the crop line. Given that the transmissivity of spoil is expected to be similar to that of coal, spoil water is expected to behave similarly as it moves toward crop lines. However, where the crop line is intercepted by drainages, the possibility exists for the development of springs, especially where springs existed at the crop line prior to mining.

Spoil water is expected to affect water quality in EFAC (Western Energy Co., 2015). The south margin of the crop line in Area A borders EFAC. Based on comparison of water levels in spoil and alluvium, Area A spoil water is moving toward EFAC alluvium. The contribution of Area A spoil water to the observed increase in TDS in EFAC alluvium currently is approximately three percent. Impacts to EFAC discussed in **Section 9.2.7.1.1** and **Section 9.2.8** indicate that the contribution from Area A spoil to EFAC alluvial water quality is estimated to reach as much as 13 percent. Water quality of the alluvium is expected to meet narrative standards for current and postmine water uses and will not exceed numeric HHS.

A possible connection of the Rosebud coal with alluvium in the southwest part of Area C (as suggested by the response of monitoring well WR-136) suggests EFAC may be subject to spoil water from Area C if there is substantial hydrologic connection with the alluvium. Based on the analysis of contributions from Area A to EFAC alluvium, input from Area C spoil into the stream is expected to be small but may contribute to diminished water quality in EFAC.

Upon saturation, the movement of water from some Area B spoil is anticipated to be to the southeast rather than toward EFAC. This spoil water will be directed to the area between the Rosebud Mine and the Big Sky Mine, and eventually to the Big Sky Mine crop limits. The distance between the Rosebud Mine and Big Sky Mine ranges between approximately a half-mile and two miles. Rosebud coal water quality in the unmined area between the two mines is variable (monitoring wells average between 690 mg/L and 4300 mg/L). Groundwater quality in this area is currently unaffected by spoil. Area B spoil water quality generally exceeds the quality of Rosebud coal between the two mines (see **Section 9.2.5.1.7**). Mixing of spoil with the background Rosebud coal water will take place as spoil moves to the south. An increase in TDS will be due to analytes with narrative standards, mainly sulfate, calcium and magnesium. No analyte with a DEQ-7 numeric limit (e.g. trace metals, nitrate + nitrite) is expected to increase as concentrations of these analytes are generally non-detect in spoil and rarely is there an exceedance. There are no wells identified in the private well inventory that are completed in the Rosebud coal in the area between the Rosebud Mine and Big Sky Mine. No uses of the Rosebud coal water between the two mine areas are expected to be impacted. Due to the variability of water quality in Area B spoils, the unmined coal between Area B and the Big Sky Mine, and Big Sky Area A spoils, and the clinker-enhanced recharge in this area it does not appear that migration of spoil water from Area B will cause a parameter to increase to a level that renders the waters unsuitable for domestic use or livestock and wildlife watering, or harmful, detrimental, or injurious to the beneficial uses listed for Class II and Class III groundwater. If any such harm, detriment, or injury occurs, it will be local and capable of mitigation by providing replacement water.

Observed impacts are used to anticipate the response of the hydrologic system to approved and proposed mining. However, the response of a natural system cannot be predicted with exactness. A

basic understanding of the hydrogeologic system, determined largely by field measurements and observations of the response of the system to date, is used to anticipate future impacts and estimate recovery of the system. Natural systems are dynamic, characterized by special and temporal variability and do not lend themselves to precision, especially when considering large areas and long time frames. Recovery from the extensive mining in the Colstrip area, past and present, is expected to take numerous decades, if not longer. Recovery of water levels and water quality will depend on the response of local hydrogeology, climate, and chemical reactions, all of which individually and in concert are unpredictable and play a part in the outcome. There is no known, generally accepted groundwater model or modeling methodology capable of predicting, with a reasonable probability of certainty, the concentration of inorganic constituents at any time in a hydrologic unit subject to migration of groundwater for an area mined by strip mine methods. Awareness of this inexactness of the prediction of impacts from strip mining is reflected by the statute and rules that require that the "probable hydrologic consequences", rather than the exact hydrologic consequences, of mining be determined.

9.3 NON-MINING IMPACTS

There are numerous sources of impacts to the hydrologic balance in the Colstrip area from sources other than strip mining. Water use and effluent associated with the Colstrip power plant and utilities for the town of Colstrip contribute to impacts to groundwater and surface water.

9.3.1 Colstrip Power Plant

The Colstrip Power Plant is a coal fired plant located east of the Rosebud Mine Area A and west of Area D and Area E (**Figure 1-1**). The Colstrip plant is owned by Talen Energy, Puget Sound Energy, Portland General Electric Company, Northwestern Energy, Avista Corporation, and Pacific Corp.

Operated by Talen Energy, the four-unit coal fired generating power plant can produce 2,200 megawatts. Units 1 and 2 produce 307 megawatts each. These units began producing electricity in 1975 and 1976 and have an average yearly coal consumption of 2.8 million tons. Units 3 and 4 began operation in 1984 and 1986, respectively. Units 3 and 4 average yearly coal consumption is 6.4 million tons and production is 740 megawatts each (PPL, 2011). Sub-bituminous coal is delivered to the power plant from the Rosebud Mine via a four-mile long overland conveyor system. In recent years, coal consumption has declined somewhat due to the combined use of coal and natural gas at the power plant.

The bottom ash from Units 1 and 2 and Units 3 and 4 are hauled to on-site ponds just south and southeast of the plant, respectively. After settling of particulates, the clear water is returned to the plant. Fly ash from Units 1 and 2 is pumped to the Units 1 & 2 ponds, located in a drainage northeast of Rosebud Mine Area A, for final settlement and storage. Fly ash from Units 3 and 4 is pumped via a pipeline to the evaporation holding ponds located approximately 3.5 miles southeast of the plant on a tributary to Cow Creek, outside the Rosebud Mine permit boundary. The evaporation holding pond and clear well have a combined design surface of approximately 324 acres and a usable surface of area of approximately 180 acres (Hydrometrics, 1990).

Failures of the pipeline used to pump slurry to the evaporation holding pond in Cow Creek resulted in five accidental releases of fly ash slurry between 1987 and 1989, with a cumulative volume of more than 280,000 gallons released (DNRC, 1990). Subsequently, more recent leaks have also occurred. Pump-back wells have been installed, and have been partially successful in capturing pond leaks and maintaining or reducing groundwater levels. Water quality and water level data from Rosebud Mine monitoring wells

adjacent to Area D and Area E, suggest that down gradient ground water quality has been impacted by leakage from the pond or releases of slurry.

Leakage of facility ponds at the power plant has been a source of recharge to the groundwater system in the past. The net effect of plant site pond and Castle Rock Lake seepage and Colstrip municipal wastewater effluent discharges, estimated at 390 acre-feet per year in the 1990's, to EFAC was much greater than the estimated 10 acre-feet per year loss in alluvial groundwater due to mining (Montana Department of Environmental Quality, 1998) and represented a more than 50 percent increase to the estimated 730 acre-feet of annual alluvial flow below Colstrip prior to 1970. Rosebud Mine monitoring wells WM-135, WS-116, and WI-116 in Area E, adjacent to ponds at the power plant, indicate that seepage from the ponds caused water levels to rise.

The water quality of influx to EFAC from the above mentioned sources ranges from 200 mg/L to 600 mg/L TDS for Yellowstone River water stored in Castle Rock Lake, to 5,000 to 50,000 mg/L TDS for discharges and seepage from municipal and industrial sources (Montana Department of Environmental Quality, 1998). Most of this influx reaches EFAC downstream of the mine permit area.

Montana DEQ and Talen Energy have entered into an Administrative Order on Consent to address seepage from the on-site ponds. A portion of the seepage from ponds at the plant site, estimated at 130 acre-feet per year in 2014, is currently captured by a system of groundwater interception wells which have lowered water levels under portions of the plant site (Hydrometrics, 2015).The operation of this groundwater interception system has resulted in some improvements in water quality near the plant site, however residual water quality impacts from historic pond seepage are expected to persist for the foreseeable future.

More than 8,000 acre-feet of water per year is pumped from the Yellowstone River via a 29-mile long pipeline to a 2,250 acre-feet storage pond known as Castle Rock Reservoir located on the west side of town, adjacent to Rosebud Mine Area A. Ninety to 95 percent of annual reservoir storage is used by the power plant, with the overwhelming majority of that water lost to evaporation through cooling processes, from pond surfaces and in water used for dust suppression. The remainder is used to supply the town of Colstrip. An estimated 180 acre-feet per year of water leaks from the pond into sub-McKay underburden and EFAC alluvium, increasing the flow in the stream north of the power plant.

9.3.2 Colstrip Municipal Uses

The Colstrip Water Treatment Plant provides potable water from Castle Rock Reservoir. Backwash from the potable water treatment plant is discharged back to the reservoir under MPDES permit MT0030422. Municipal sewage flows via a collection system to the Colstrip Wastewater Treatment Plant which operates at around 200,000 gallons per day, about one third of stated capacity (City of Colstrip, 2014). The City of Colstrip is authorized to discharge from its sewage treatment plant to EFAC pursuant to MPDES discharge permit MT0022373.

The nine-hole public golf course is located adjacent to EFAC approximately a mile downstream of Colstrip. Water used to maintain the greens infiltrates into EFAC, likely causing undefined changes in water level and water quality.

10.0 CONCLUSION

The above sections of this CHIA represent an in depth analysis of impacts to the hydrologic balance from mining that includes an assessment of existing or probable changes to the hydrologic balance inside and outside the permit area and an evaluation of material damage outside the permit area associated with current and proposed mining. The conclusion of the analysis is that no material damage is identified from current or approved mining and that the additional mining proposed under AM4 will not create material damage.

Current water uses include livestock and wildlife drinking water, aquatic life, and domestic uses. Designated uses for the C-3 intermittent and perennial reaches of drainages identified in the cumulative impact area are: bathing, swimming, and recreation, and growth and propagation of non-salmonid fishes and associated aquatic life, waterfowl, and furbearers, and maintenance as marginal for drinking, culinary, and food processing purposes, agriculture, and industrial water supply. *See* ARM 17.24.629(1). Listed beneficial uses for class II groundwater are: 1) public and private water supplies; 2) culinary and food processing purposes; 3) irrigation of some agricultural crops; 4) drinking water for livestock and wildlife; and, 5) most commercial and industrial purposes. *See* ARM 17.30.1006(2)(a). Listed beneficial uses for Class III groundwater are: 1) irrigation of some salt tolerant crops; 2) some commercial and industrial purposes; 3) drinking water for some livestock and wildlife; and, 4) drinking, culinary, and food processing purposes where the specific conductance is less than 7,000 microSiemens/cm at 25ºC. *See* ARM 17.30.1006(3)(a). No changes to water quality attributable to proposed expansion of mining in Area B will render surface or groundwater unsuitable for existing uses. No changes to water quality attributable to mining in Area B will render surface water unsuitable for a listed use or groundwater unsuitable for a current or anticipated use, or harmful, detrimental, or injurious to a listed beneficial use. This conclusion is generally based on the location of proposed expanded mining away from potential impact areas and the range of natural variability of water quality in comparison to potential increases in parameters attributable to proposed expanded mining in Area B. No reductions in water quantity related to mining are expected to impact groundwater uses outside the permit boundary. If unexpected water quantity or quality impacts to groundwater uses were to occur, Western Energy Company has committed to providing replacement water to the affected users by drilling deeper wells.

No numeric DEQ-7 water quality exceedances associated with mining were identified outside the permit boundary. Numeric water quality exceedances inside the permit boundary are uncommon. Persistent nitrate-nitrite nitrogen over the HHS has been identified within the permit boundary at two spoil monitoring wells in the Rosebud Mine. As a stipulation to the permit, additional monitoring wells will be required to monitor potential down gradient movement of the affected water to ensure that it does not leave the permit boundary. Additional monitoring wells are also required inside the south permit boundary of Area B to monitor the quality of spoil water once the backfill becomes saturated and follows the natural flow direction to the southeast. Currently, most of Area B spoil remains unsaturated. Mitigation will be implemented if groundwater concentrations above the HHS appear to be moving close to the permit boundary. A potential rise in parameter concentrations (TDS, calcium, magnesium and sulfate) are not expected to reach concentrations that will render groundwater unsuitable for domestic use or livestock and wildlife watering, or harmful, detrimental or injurious to a listed use for a given groundwater class (ARM 17.30.1006).

Storm-driven runoff and sediment load in the channels downstream of the mine area will be diminished during mining as sediment control ponds capture all runoff within the mine. Consequently, in stream

dams for stock water on ephemeral drainages may see a reduction in water quantity until the sediment control ponds are reclaimed. Once reclamation is complete and the sediment control ponds are removed, a similar quantity of runoff water is anticipated to be delivered from the mine area, and the runoff water is expected to carry less entrained sediment. In reclamation, some sediment ponds will be converted into permanent ponds or small depressions to function as replacement surface water resources.

Intermittent reaches of streams by the mines experienced a reduction in flow during mining as baseflow was reduced through mining the bedrock aquifers. These reaches are expected to reestablish once the spoil and alluvial aquifers recover. For intermittent stream reaches the most sensitive use is aquatic life. Water quality in the stream may change with spoil saturation, but the beneficial uses of the streams, including suitability for aquatic life, are expected to be maintained. Similarly, any springs that have experienced changes in flow due to mining will recover as their source aquifers recharge. Springs that have been destroyed by mining may be replaced by new springs within reclamation. Water quality at springs sourced by spoils is expected to vary over time as spoil water quality changes.

	Nickel[3]	0.1	1.5	0.17		mg/L
	Selenium	0.05	0.02	0.005		mg/L
	Vanadium					mg/L
	Zinc[3]	2	0.39	0.39	5	mg/L

Table 2-1: Continued.

Parameter		DEQ-7 Human Health Standard	DEQ-7 Surface Water Aquatic Life Standard		NSDWR	units
			Acute	Chronic		
Nutrients	Total Nitrogen					mg/L
	Total Phosphorus					mg/L
	Nitrate-Nitrite	10				mg/L
	Total Ammonia[4]		24.1	3.65		mg/L

[1] *NSDWRs are non-enforceable guidelines for contaminants that may cause cosmetic effects (such as skin or tooth discoloration) or aesthetic effects (such as taste, odor, or color) in drinking water.*

[2] *Analyte collected for stream and pond samples only.*

[3] *Aquatic life limits are dependent on hardness. Median hardness of surface water samples from Bull Mountains Mine and nearby drainages is > 400 mg/L so the aquatic standard is shown calculated at a hardness of 400 mg/L.*

[4] *Aquatic standards shown calculated at 22°C, 7.0 pH with early fish life stages present.*

Table 2-2: Guidelines for livestock water quality.			
Analyte	**Threshold limit (mg/L=ppm)**	**Upper limit (mg/L=ppm)**	**Comments**
Alkalinity (total as CaCO3)	Unknown	1000*	
Aluminum	5**	10**	
Arsenic	0.2**	0.2[+]	
Bicarbonate (total as CaCO3)	Unknown**	<1000	
Boron	5**	30**	
Cadmium	0.01**	0.05[+]	
Calcium	100**	150**	
Chloride	100**	300**	
Copper	0.2**	0.5[+]	
Fluoride	2**	2[+]	
Iron	---	----*	Not established, >0.3 may affect taste
Lead	0.05**	0.1[+]	
Magnesium	50**	100**	
Manganese	0.05**	0.5**	
Nickel	0.25**	1[+]	
Nitrate (NO_3 as N)	10**	20**	
Sodium	50**	300**	
Selenium	0.05**	0.10**	
Sulfate	1500*	2500*	Upper limit is upper concentration for “no harmful effects” category
Total Dissolved Solids (TDS)	3000*	4999*	“Should be satisfactory for livestock”
Vanadium	0.05*	0.1[+]	
Zinc	25**	50**/25*	

** Suitability of Water for Livestock Fact Sheet (Sigler and Bauder, 2012)*

*** Beef Briefs (Hutcheson, 2001).*

[+] *Both references have the same limit and use common references*

Table 2-3: Iowa sulfate criteria for surface water to protect macroinvertabrates uses.
Sulfate criteria is based on the concentration of chloride (Cl) and hardness (H) as $CaCO_3$ (Iowa DNR, 2009).

	Cl < 5 mg/L	5 mg/L <= Cl < 25 mg/L	25 <= Cl
H < 100 mg/L	500	500	500
100 mg/L <= H <= 500 mg/L	500	[-57.478 + 5.79*(H) + 54.163*(Cl)]*0.65	[1276.7+5.508*(H)-1.457*(Cl)]*0.65
H > 500 mg/L	500	2000	2000

Table 2-4: Beneficial uses of MT groundwater [ARM 17.30.1006].				
Montana GW Class [ARM 17.30.1006]	**Class I**	**Class II**	**Class III**	**Class IV**
EC @ 25°C (µS/cm)	<= 1000	> 1000; <= 2500	> 2500; <= 15000	> 15000
Suitability Criteria	Suitable	Marginally suitable	Marginally suitable	
Public water	x	x		
Private water	x	x		
Irrigation	x	x	salt tolerant	
Livestock water	x	x	x	
Commercial/ industrial	x	x	x	x
Food Processing	x	x	< 7000µ/cm	
Violation Prohibitions -- DEQ-7 human health standards	x	x	When EC > 7000 µS/cm & K >= 0.1, nitrate nitrogen and nitrate plus nitrite nitrogen must not exceed 50 mg/L	Only carcinogen standards apply. When K >= 0.1, nitrate nitrogen and nitrate plus nitrite nitrogen must not exceed 50 mg/L
Violation Prohibitions -- standards not in DEQ-7	No increase that renders the waters harmful, detrimental, or injurious to beneficial uses			No increase that adversely affects existing beneficial uses

Table 6-1: Private wells and groundwater rights within the groundwater CIA.

AL – Alluvium
MK – McKay coal
OB - Overburden
PWS – Public water supply
RC – Rosebud coal
SM – sub-McKay

Table 6-2: Active surface water rights listed with the Montana Department of Natural Resources and Conservation near the Rosebud Mine.
The max flow and max volume in the table refer to the maximum amount of water that can be used by the owner at any one time and in total for the year respectively.

Map ID	Water Right Number	Mine or PPL ID	Purpose	Priority Date	Means of Diversion	Name	Max Flow	Max Vol. (ac-ft)	Site Name / Description	Anticipated Impact from Mining
1	42A 108272 00		Stock	1908	Direct from source	Great Northern Properties Ltd Prtnrshp			Spring, Tributary Of Cow Creek	Quantity may be reduced due to aquifer drawdown from mining. Quality may be impacted if aquifer replaced by spoils.
2	42A 108275 00		Stock	1948	Dam	WPP LLC			Tributary Of Lee Coulee	None. Site is upstream of mine disturbance
3	42A 108297 00		Stock	1968	Dam	Avista Corporation; Northwestern Energy; Pacificorp; Portland General Electric Co; PPL Montana LLC; Puget Sound Energy Inc			Tributary Of Cow Creek	Watershed disrupted by prelaw mining reclamation, roads, and a railroad embankment upstream of dam.
4	42A 108300 00	PO-808	Stock	1939	Dam	Great Northern Properties Ltd Prtnrshp			Tributary Of Spring Creek	Site downstream from Area D mining. May have reduced water quantity until sediment ponds are removed.
5	42A 108302 00	BLDGL	Stock	1948	Dam	WPP LLC			Lee Coulee	Water quantity greatly reduced during mining. May permanently have some reduction in quantity due to flatter topography in watershed.
6	42A 108303 00		Stock	1968	Dam	Great Northern Properties Ltd Prtnrshp			Miller Coulee	Water quantity reduced during mining due to upstream sediment ponds.
7	42A 108308 00	PO-912	Stock	1943	Dam	Avista Corporation; Northwestern Energy; Pacificorp; Portland General Electric Co; PPL Montana Llc; Puget Sound Energy Inc			Cow Creek, South Fork	Watershed disrupted by prelaw mining reclamation and a railroad embankment upstream of dam.
8	42A 141170 00		Irrigation	1959	Pump	Rocker Six Cattle Co	30 gpm		Rosebud Creek	None. Fed by large watershed.
9	42A 145437 00	BUFGL	Stock	1941	Dam	Ashenhurst Gene T; Ashenhurst Ranch Inc			Tributary Of Lee Coulee	None. Site is upstream of mine disturbance
10	42A 145440 00	PO-986	Stock	1942	Dam	Ashenhurst Gene T; Ashenhurst Ranch Inc			Lee Coulee	Small amount of mine disturbance along drainage divide. Impact should be small.
11	42A 171897 00		Stock	1942	Dam	Genie Land Co			Tributary Of Pony Creek	None. No disturbance in watershed
12	42A 171898 00		Irrigation	1885	Headgate	Genie Land Co	10.8 cfs		Rosebud Creek	None. Fed by large watershed.
13	42A 171903 00		Stock	1940	Dam	Garfield Family Lp			Tributary Of West Snider Creek	None. No disturbance in watershed

188	42KJ 69974 00	SW-01	Irrigation	1988	Headgate	Colstrip Parks And Recreation District			EFAC	Water quantity may be reduced during mining due to upstream sediment ponds.

Table 6-3: Macroinvertebrate taxa richness.
Unique taxa are defined using the Operational Taxa Units listed in WQPBWQM-009 (2012).
The total taxa per year is a sum of sometimes multiple sampling events and methodologies. Sampling methodologies also may have differed year to year at the same site.

Drainage	Approx. Sampling Location	1976	1977	1978	2015
Cow Crk	PO-905	11	12	14

(1) Analyzed for ponds, stream, and spring water only.

(2) Groundwater samples for metals analysis are filtered and metals are reported on a dissolved basis.

Surface water samples for metals are not filtered and metals are reported on a total basis.

Notes

(1) Scheduled rotation for water quality sampling are as follows:

I = 2012, 2015, 2018…

II = 2013, 2016, 2019…

III = 2014, 2017, 2020…

(2) New wells put in in Water Year 2012, scheduled to be sampled in 2012, 2013, 2014 and then every three years

Table 8-1: A comparison of flood-frequency estimates (in cfs).
Peak flows are calculated from a Log Pearson Type 3 fitted curve. Shaded rows indicate stations which have a significantly mine-impacted basin upstream of the station during data collection.
* Sites monitored by Rosebud or Big Sky mines with flows reported as average daily flows. The flood-frequency calculations consequently are maximum average daily flow.
** For the ungauged drainage basins, the 90% prediction interval of peak flows is calculated using the USGS method of estimation given in Parrett and Johnson (2004). Note that these estimates are based only on basin and climate characteristics.

				Return Period (years)

*To convert ft^2/day to gpd/ft multiply ft^2/day by 7.481 gallons.

Table 9-1: Alluvial Valley Floor (AVF) determinations at the Rosebud Mine and Big Sky Mine.

AVF Investigation	Decision Date	Mine	Location	Decision Y/N
Coal Bank Coulee [MDSL, 1982 (1)]	October 1982	Big Sky Mine Area A	Big Sky Mine Area A	**N:** Failure to meet geomorphic criteria for a stream channel.
Lee Coulee (MDSL, 1986)	March 1986	Big Sky Mine Area B	Headwaters to confluence with Rosebud Creek.	**N:** Determined to be an upland area based on geologic and hydrologic criteria.
East Fork Armells Creek (MDSL, 1981)	December 1981	Rosebud Mine Area C	Highway 39 crossing (Sec. 3, T1N, R41E) to west end of Area C (Sec. 17, T1N, R40E)	**N:** Insufficient water to support agriculture
East Fork Armells Creek [MDSL, 1984 (2)]	1984	Rosebud Mine Area C	**1)** Highway 39 crossing (Sec. 3, T1N, R41E) north to confluence of Stocker Ck. (Sec. 16, T2N, R41E) **2)** Stocker Ck. (Sec. 16, T2N, R41E) north to confluence of Corral Ck (Sec. 28, T3N, R41E)	**1) N:** Insufficient water to support agriculture **2) Y:** Yes
Portion of Stocker Creek [MDSL, 1982 (2)]	June 1982	Rosebud Mine Area C	Headwaters to corner section of Sec. 23, 24, 26, 26, T2N, R40E	**N:** Insufficient water to support agriculture
Portions of Stocker Creek and East Fork Armells Creek [MDSL, 1984 (1)]	February 1984	Rosebud Mine Area C	Corner section of Sec. 23, 24, 26, 26, T2N, R40E to confluence with East Fork Armells Creek	**N:** Stocker Ck: Insufficient water to support agriculture
Portions of Pony, Spring and Cow Creeks [MDSL, 1984 (3)]	August 1984	Rosebud Mine Area D	Within and adjacent to proposed Area D permit area	Pony Creek: **N:** Insufficient water to support agriculture. Spring Creek: **N:** Insufficient water to support agriculture. Cow Creek: **N:** Headwaters to Section 31. Insufficient water to support agriculture. **Y:** Section 31 to corner of Sections 4, 5, 32, 33, T2N, R42E. Sufficient water to support agriculture.

Table 9-2: Life of mine (LOM) disturbance area and permit area for current and proposed mining activities.
The permit area and disturbance area do not include pre-law mining. Areas are calculated against premine drainage basins, and the calculated acreages for each category may differ from the acreages presented in the permit application due to differences in the delineation of drainage basins. The premine drainage basins used to calculate area are shown in **Figure 9-9**.

Drainage Basin	Pre-mine Drainage Area		Approved LOM Disturbance		App. 184 LOM Disturbance		Total LOM Area		Approved Permit Area		App. 184 Permit Area		Total Permit Area	
	sq. mi.		sq. mi.	% of basin	sq. mi.	% of basin	sq. mi.	% of basin	sq. mi.	% of basin	sq. mi.	% of basin	sq. mi.	% of basin

Table 9-4: Estimated maximum discharge and runoff volumes derived from HEC-HMS modeling of NRCS Type II Storms.
The models show only the hydrograph response to changes to stream length, drainage basin size, channel slope, and infiltration rates. Postmine scenarios assume at least 10 years of vegetation (all of the mine meets Phase III bond release requirements and have fully established vegetative communities). See Appendix B for more details on the model.

Table 9-7: Fraction of surface water quality samples from perennial or intermittent stream reaches that exceed Human Health Standards of Circular DEQ-7, Aquatic Life Standards of Circular DEQ-7, or guideline livestock thresholds.
Analysis includes spring, pond, and stream data from in-stream sources. Exceedences shown as a ratio: # of exceedences / # of samples analyzed
For DEQ-7 standards, the smallest limit is used for comparison: chronic aquatic, acute aquatic, or human health.
Sites are listed as 'baseline' (sample taken before mining started upstream) or 'mining' (sample taken after mining started upstream).

	Analytes with DEQ-7 Human Health or Aquatic Life Limit for Surface Water											Analytes with Guideline Livestock Thresholds (no DEQ-7 limit)

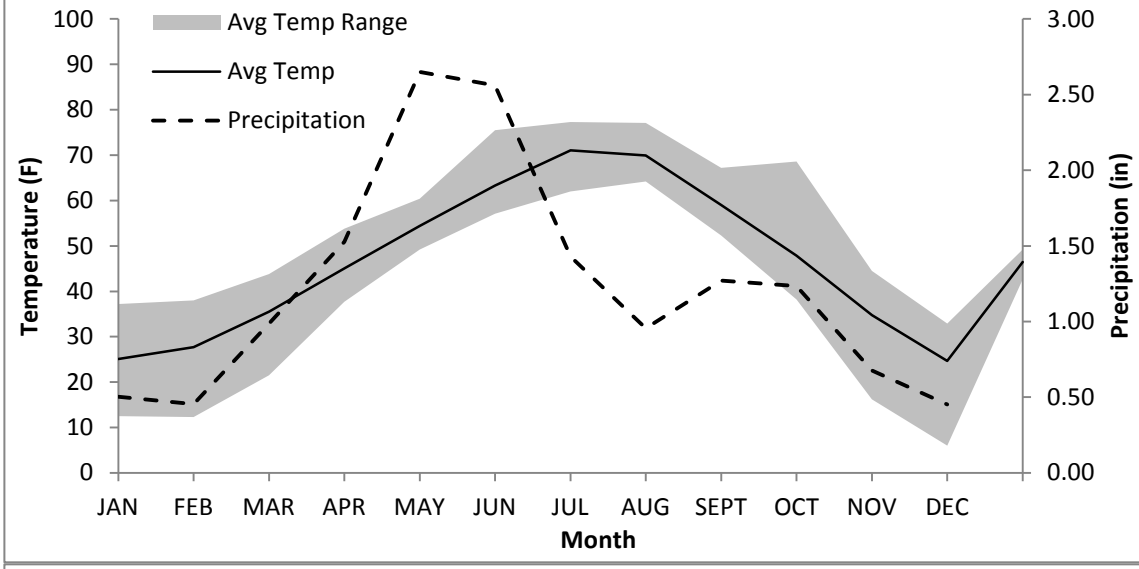
Exhibit 2

Figure 4-1: Location of Powder River Basin, Wyoming and Montana.
(Casper Star Tribune, 2014).



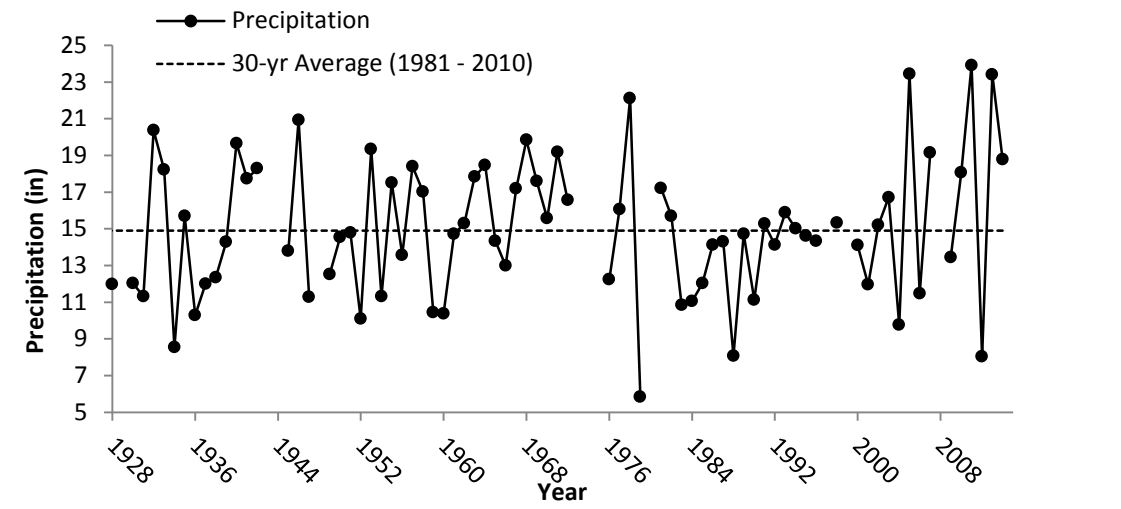


Figure 4-2: Monthly 30-year climate summary for Colstrip, MT from 1981 – 2010 and yearly precipitation totals (WRCC b, 2012).

	Wasatch Formation – Fine to coarse-grained lenticular beds of sandstone and interbedded shale and coal. Locally eroded off in Colstrip area. **Fort Union Formation –** three members **Tongue River Member** – Fine to medium grained thick-bedded to massive and lenticular sandstone and siltstone. Commonly contains shaly siltstone and shale, and numerous coal beds. **Lebo Shale Member**– Predominately dark shale with interbeds of carbonaceous shale, siltstone and local thin coal beds. **Tullock Member –** Interbedded shale, siltstone and sandstone; thin but persistent coal beds grade upward to carbonaceous shale. At the top is a resistant ledge-forming sandstone. Base is marked by predominately massive channel sandstone and dark shale of underlying unit. **Hell Creek Formation –** Shale, siltstone, silty sandstone; locally massive silty sandstone with thin coal beds. **Fox Hills Sandstone** – Near shore sand facies represents uppermost marine deposit. Massive to thin bedded sandstone with sandy shale and siltstone. **Bearpaw Shale –** Marine shaly claystone and shale. Some thin-bedded siltstone, silty sandstone; local thin beds of bentonite.

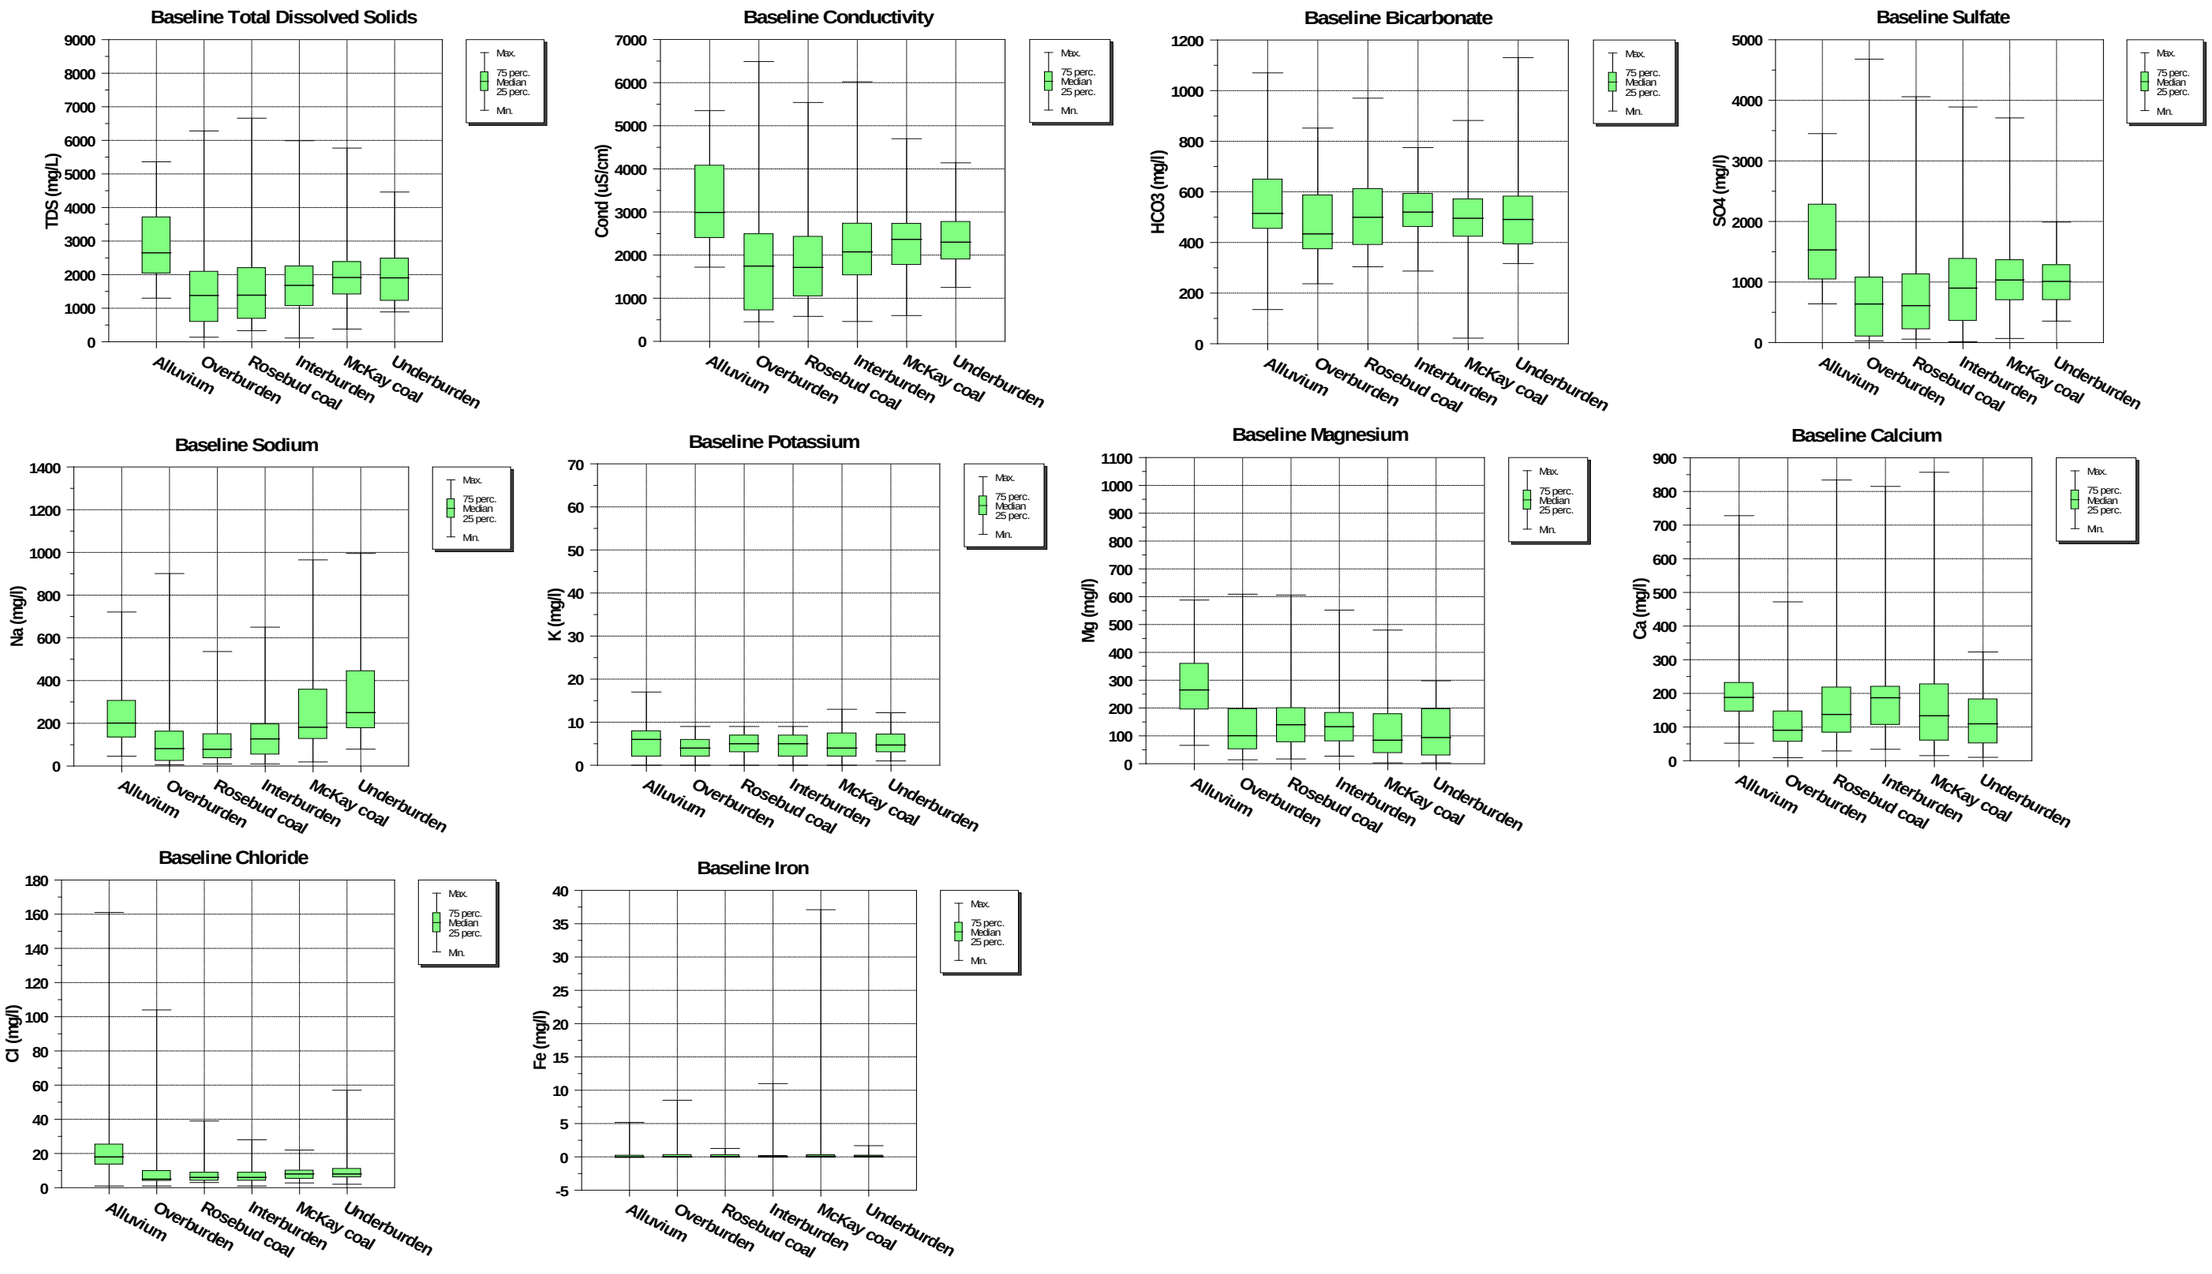

Figure 8-9: Box and whisker plots of baseline analyses from Rosebud Mine monitoring wells.
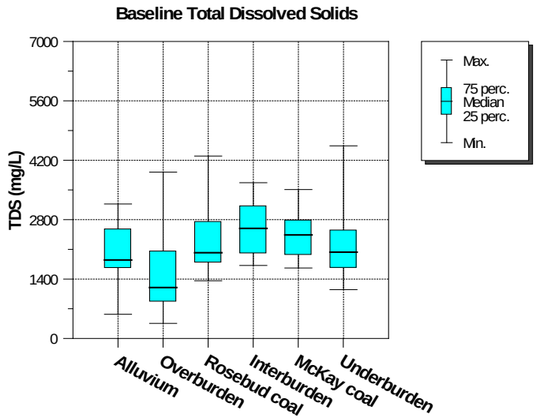
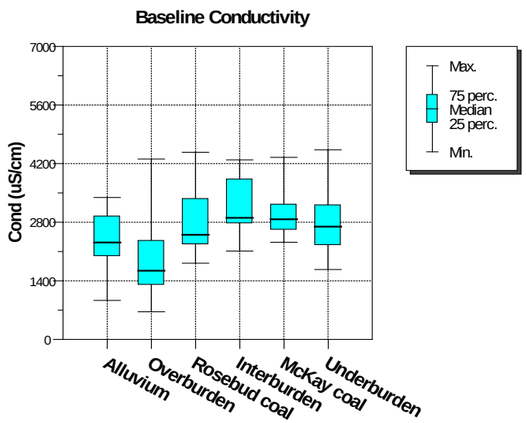
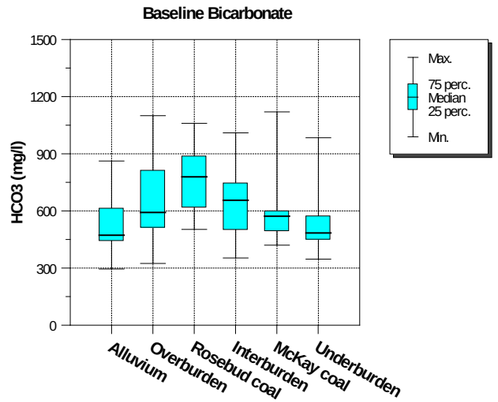
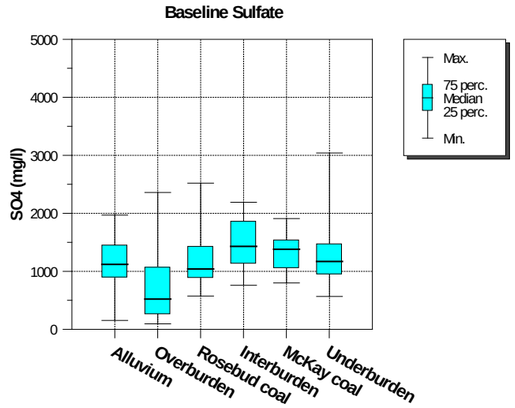
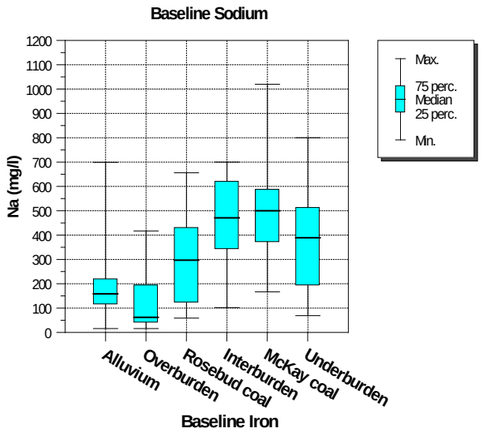
Total samples= 245; Alluvium=59; Overburden=31; Rosebud=50; Interburden=33; McKay=48; Underburden=24.

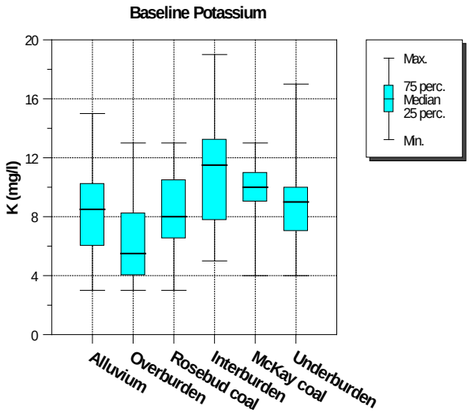


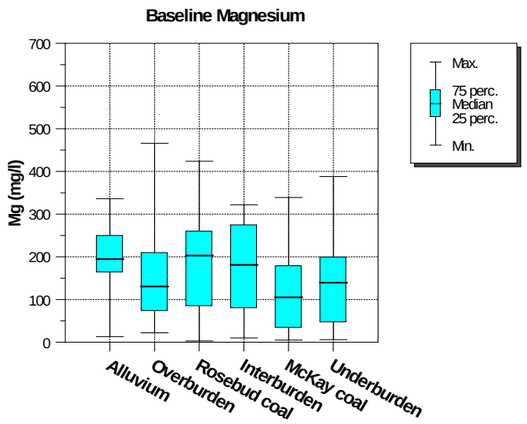


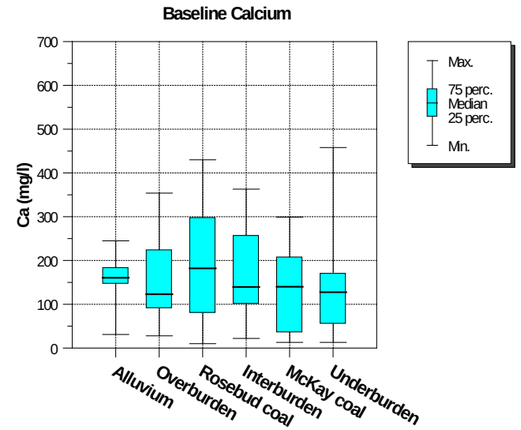


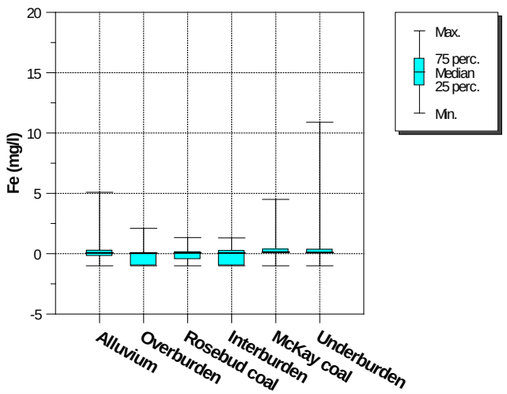












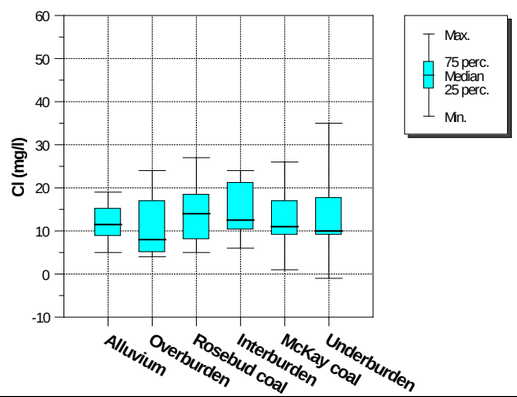


Figure 8-10: Box and whisker plots of baseline analyses from Big Sky Mine Area B monitoring wells.
Total samples=114.

Exhibit 2

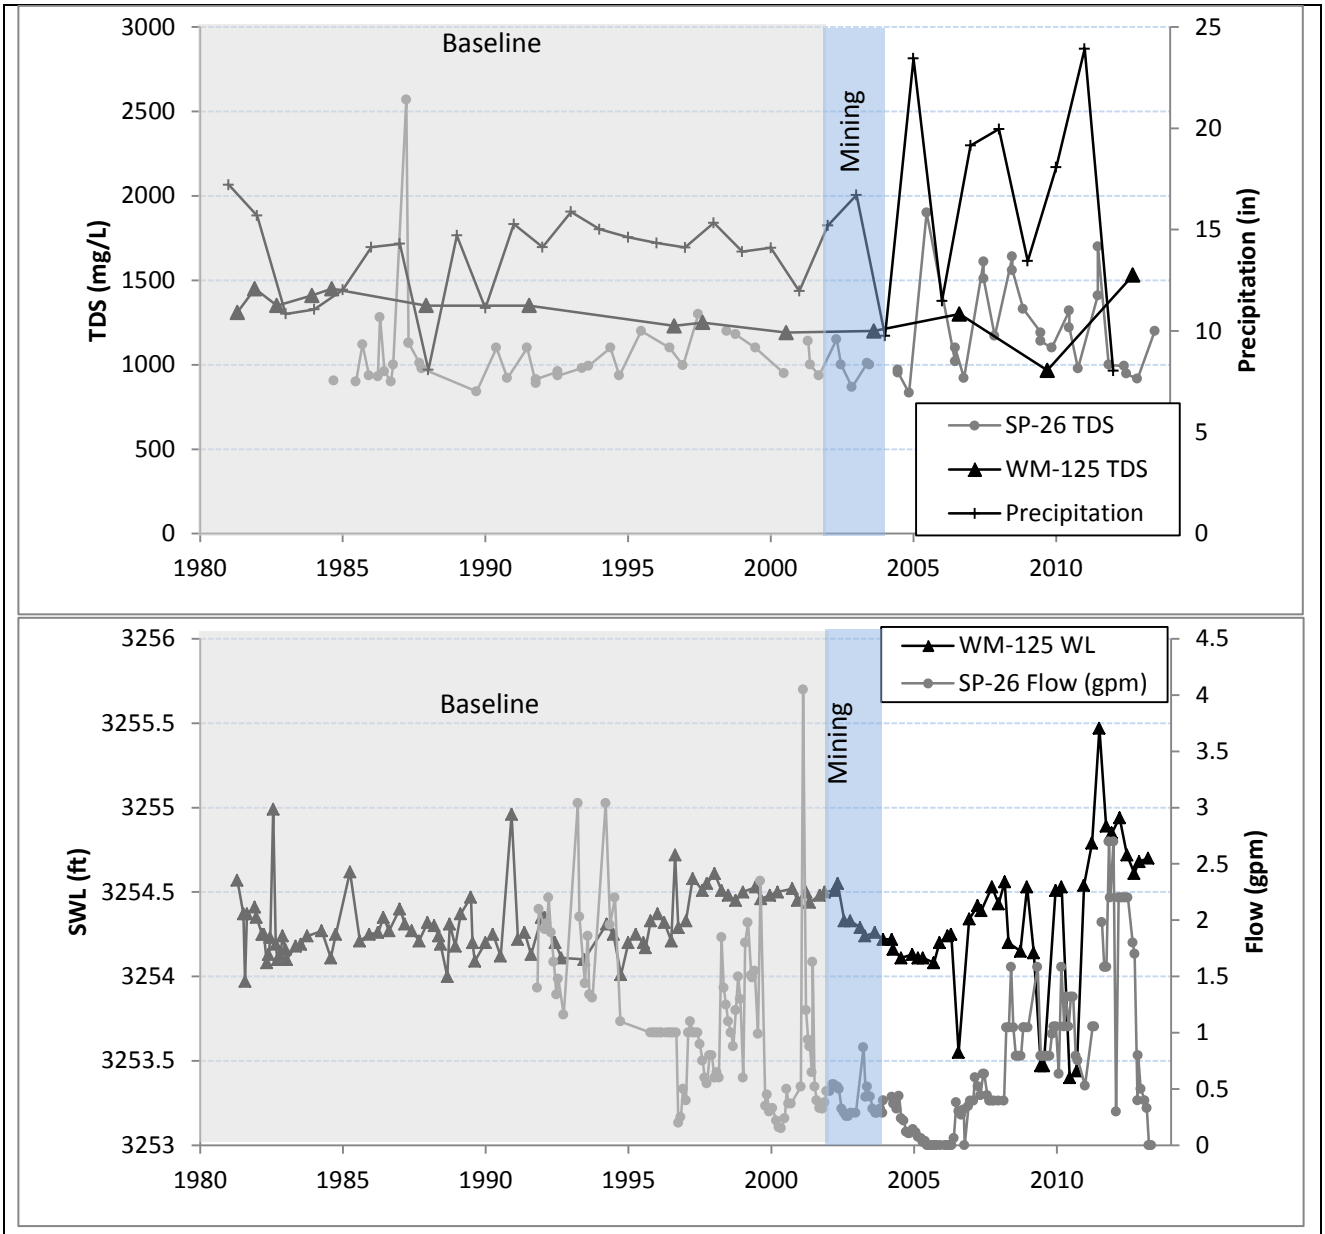

Figure 9-1: Water quality and quantity at Spring SP-26 and nearby McKay well WM-125.

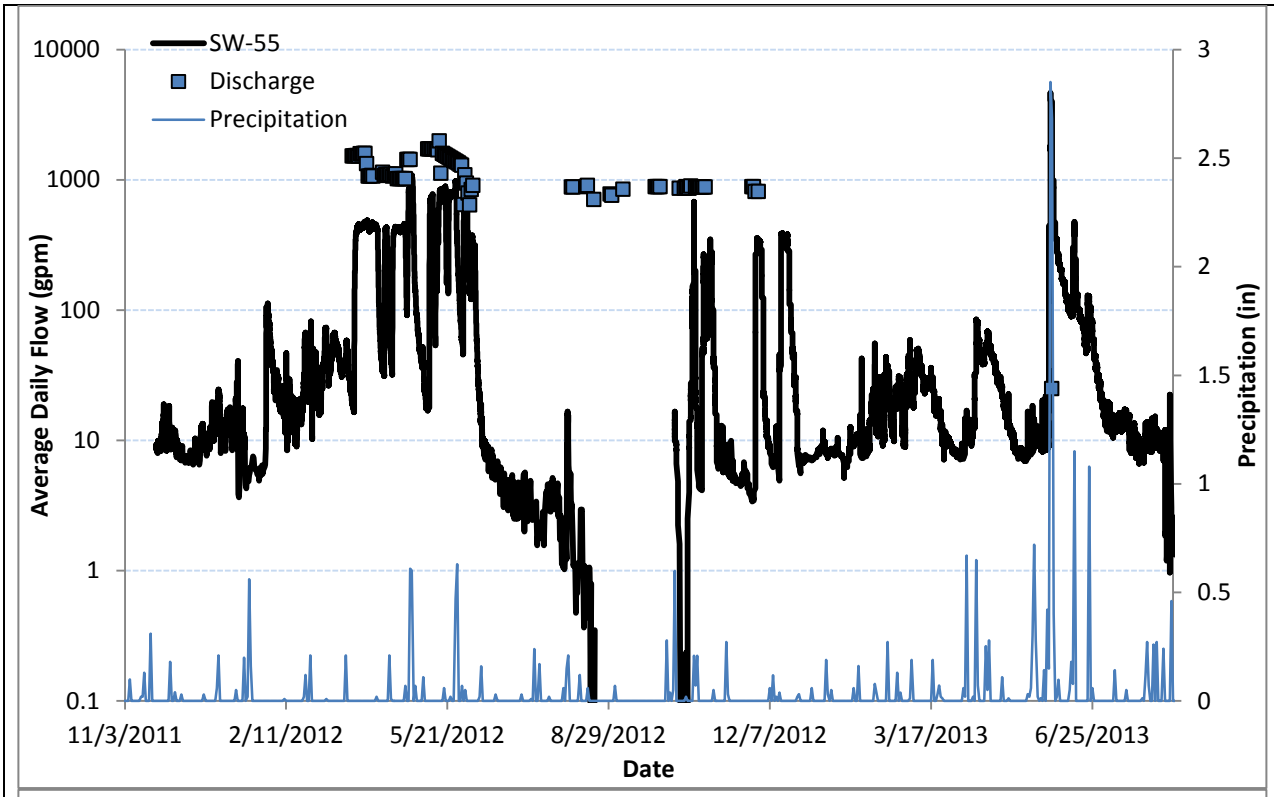
Note that flow measurements at SP-26 include periods when the developed spring was almost frozen. Annual total precipitation (Jan-Dec) is plotted against SP-26 TDS for comparison.



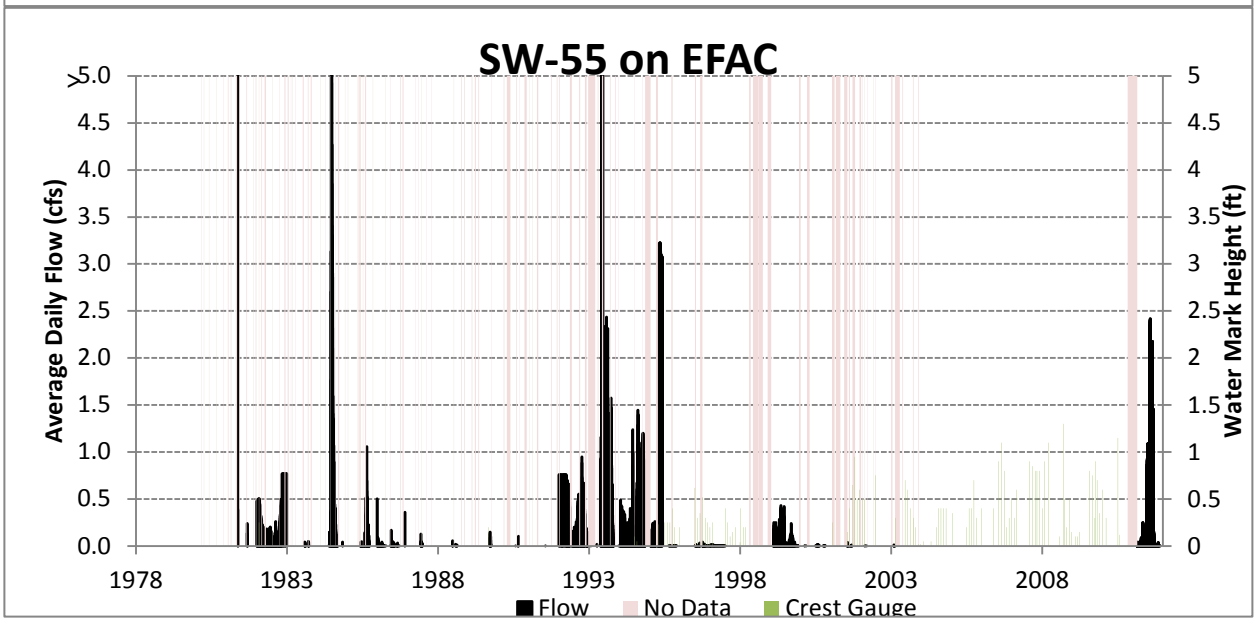


Figure 9-2: Flows measured at SW-55 in East Fork Armells Creek.
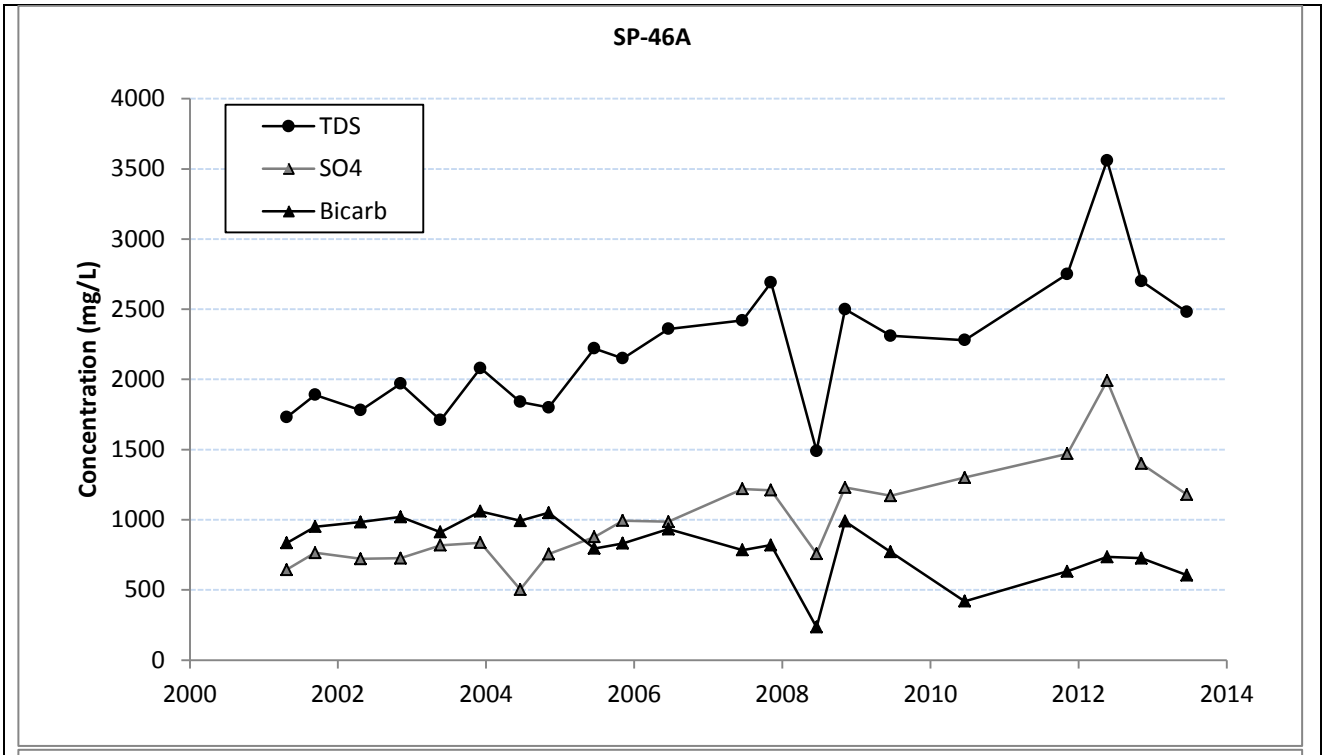
In the top graph, flow (in gpm) is compared with MPDES discharge rates of pit water into the creek and precipitation. In the bottom graph, the entire record of flow and crest gauge measurements at SW-55 is shown. The conversion between crest gauge height and instantaneous flow is not known for the site.



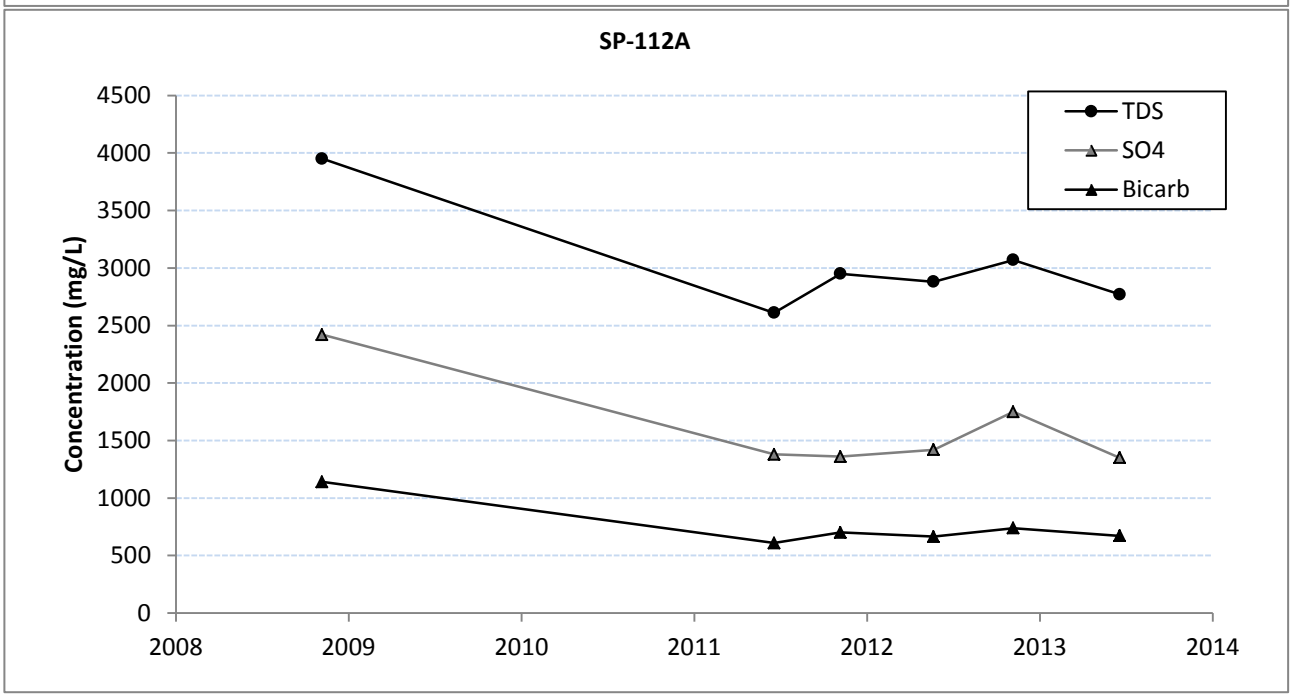


Figure 9-3: Water quality in springs SP-46A and SP-112A.
Both springs are sourced from the spoils aquifer.

Exhibit 2

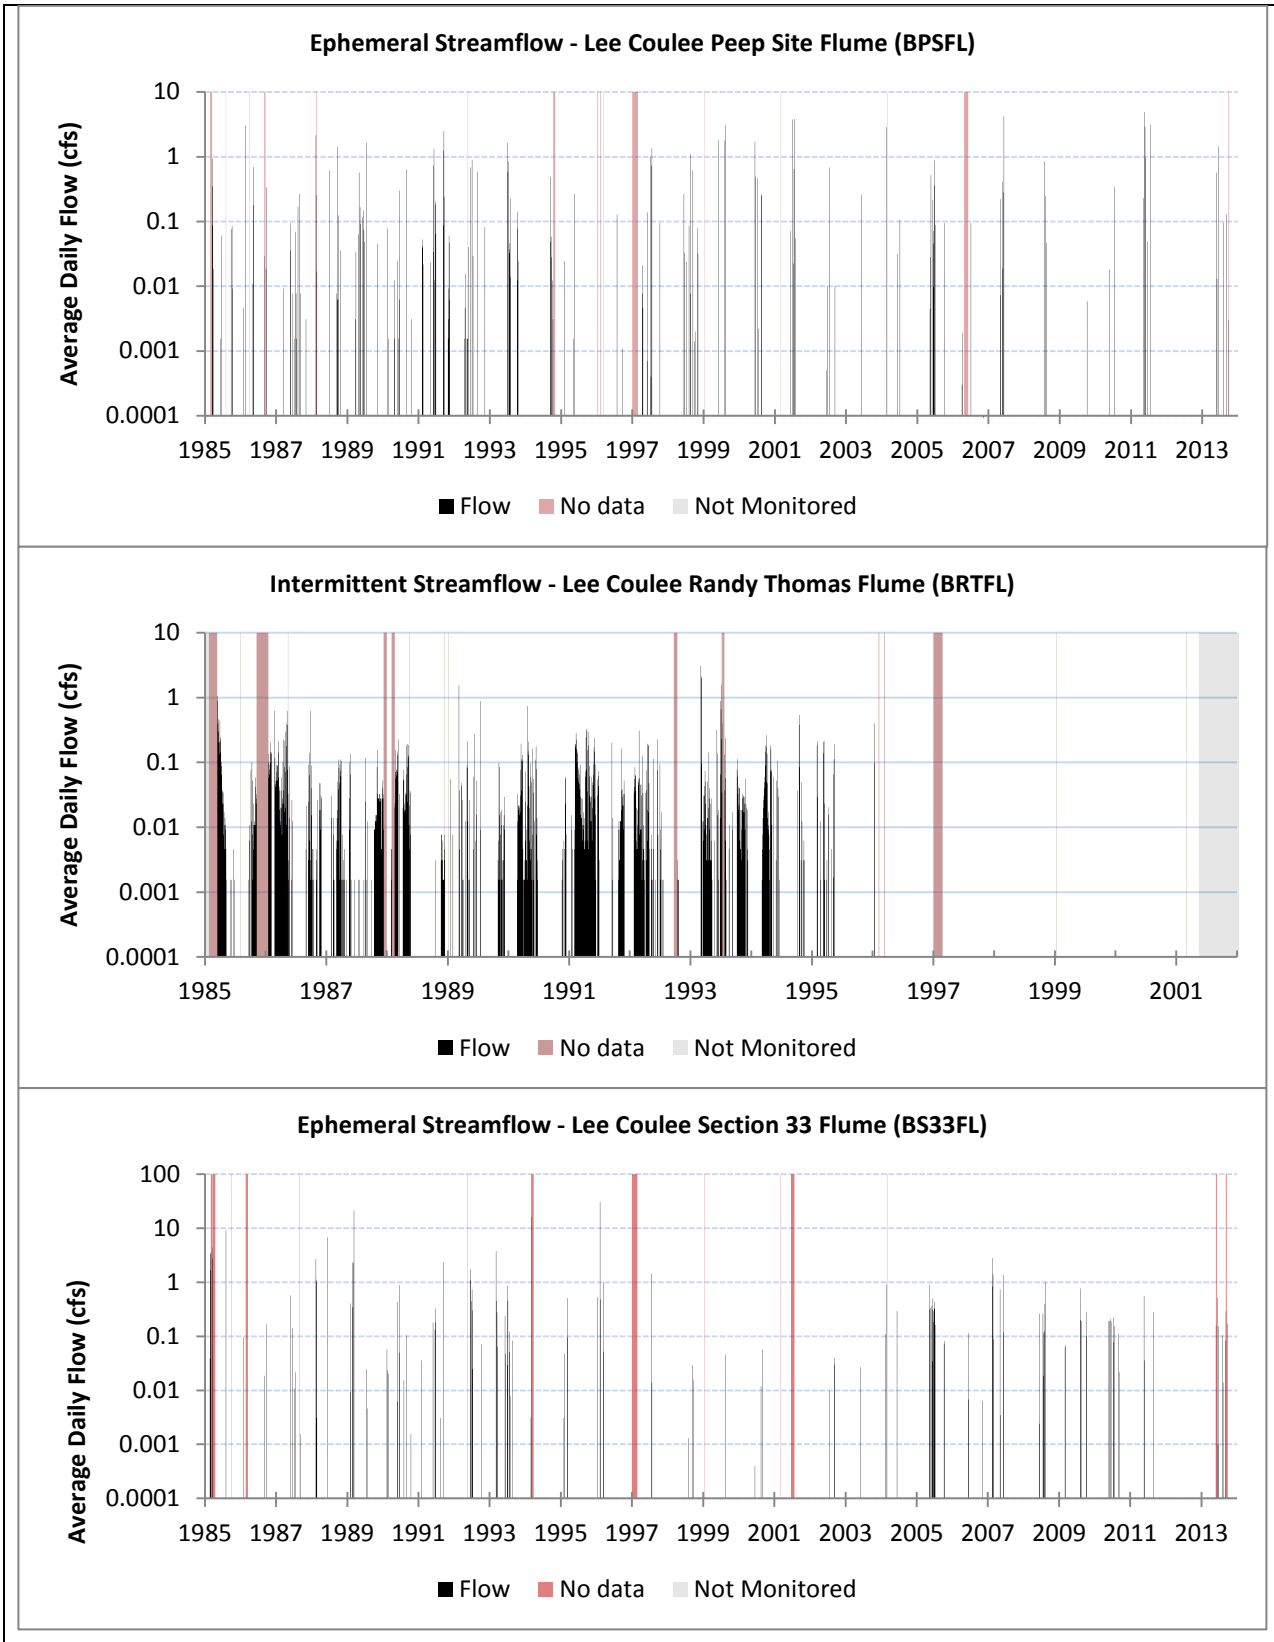

Figure 9-4: Flows measured by flumes on Lee Coulee.

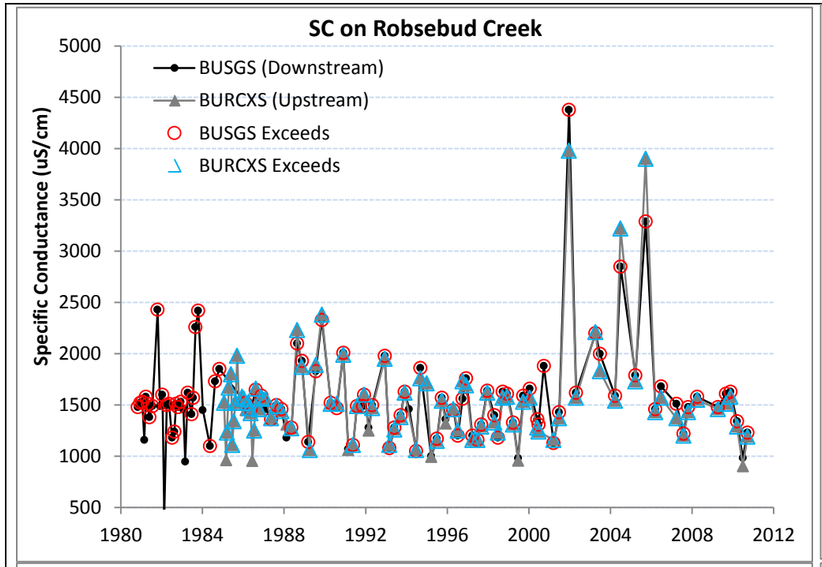

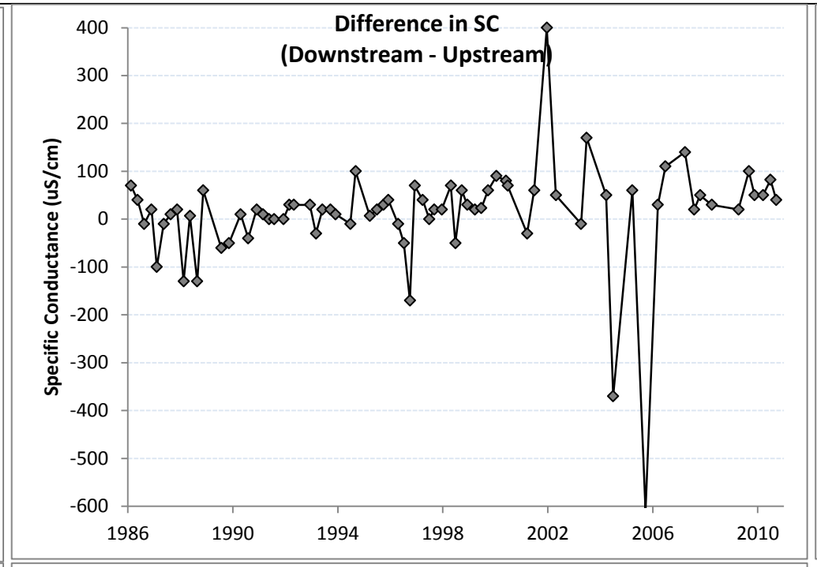

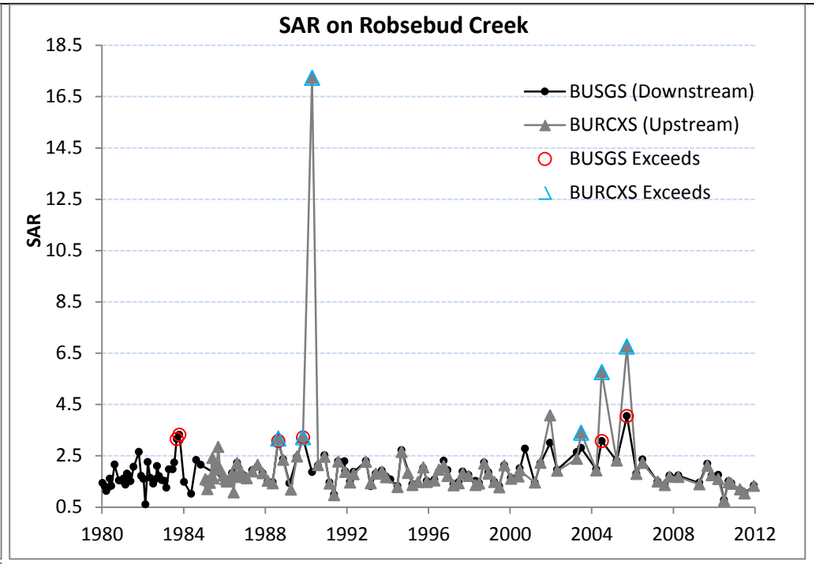

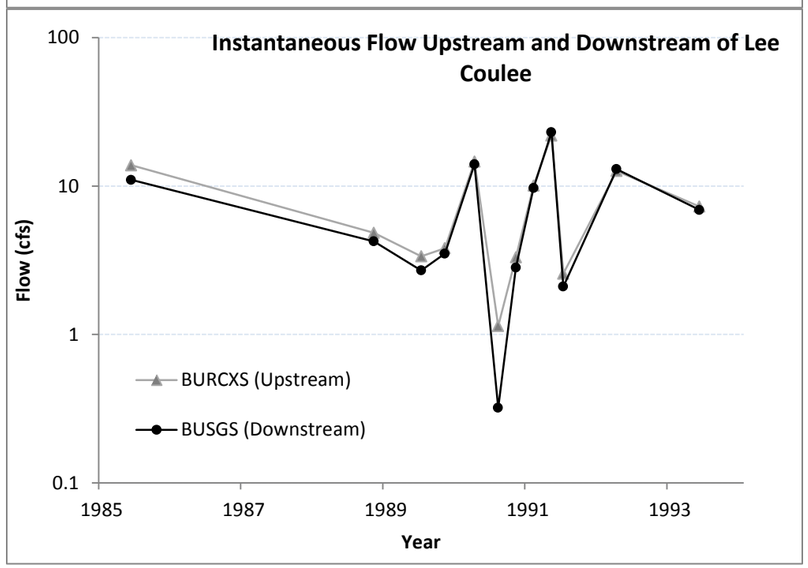

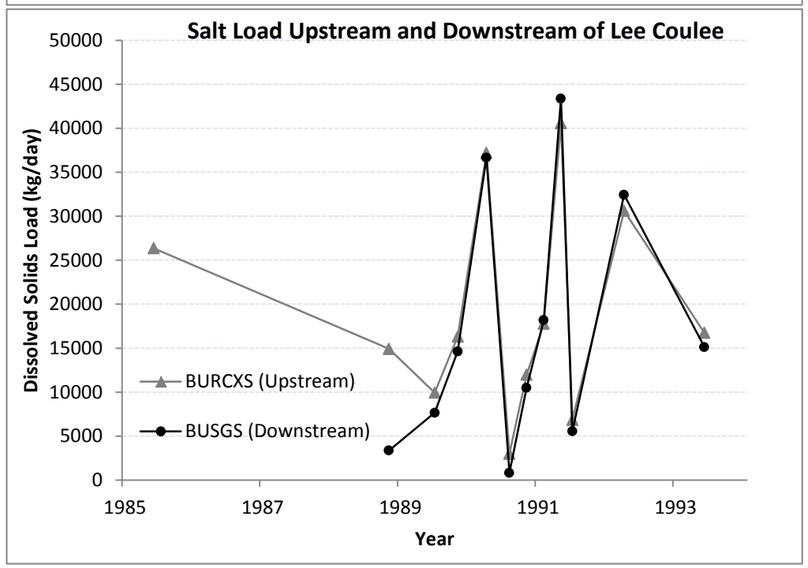

Figure 9-5: SC, TDS, and flow upstream (BURCXS) and downstream (BUSGS) of Lee Coulee on Rosebud Creek and the difference between the two concentrations.
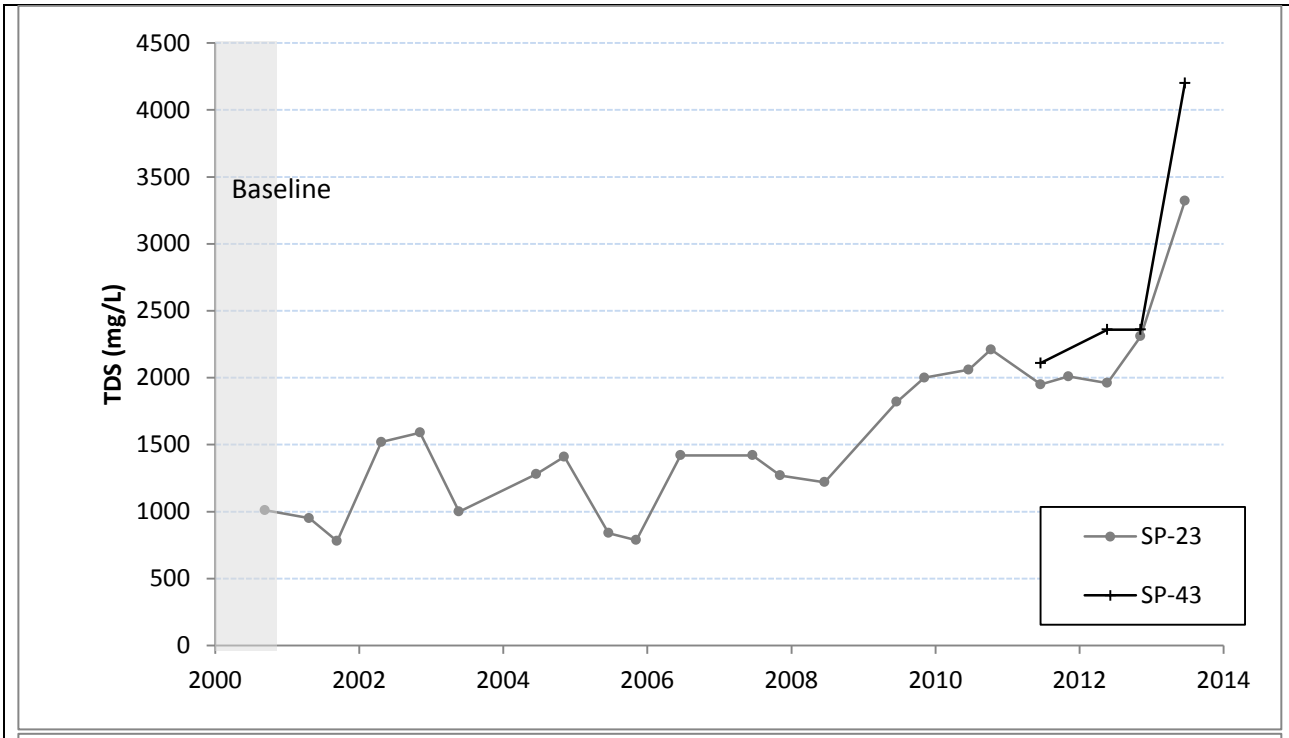
The difference is shown as downstream minus upstream, and consequently positive values indicate that the downstream sample is has a higher Specific Conductance than the upstream sample taken on the same date. Mining started in Lee Coulee in approximately 1989. Exceedances of the monthly average SC (1,500 uS/cm from Nov. through Feb. and 1,000 uS/cm from Mar. through Oct.) and SAR (5 from Nov. through Feb. and 3from Mar. through Oct.) standards are shown in blue and red. Flow measurements taken on the same day indicate that there is a losing reach on Rosebud Creek where Lee Coulee enters.



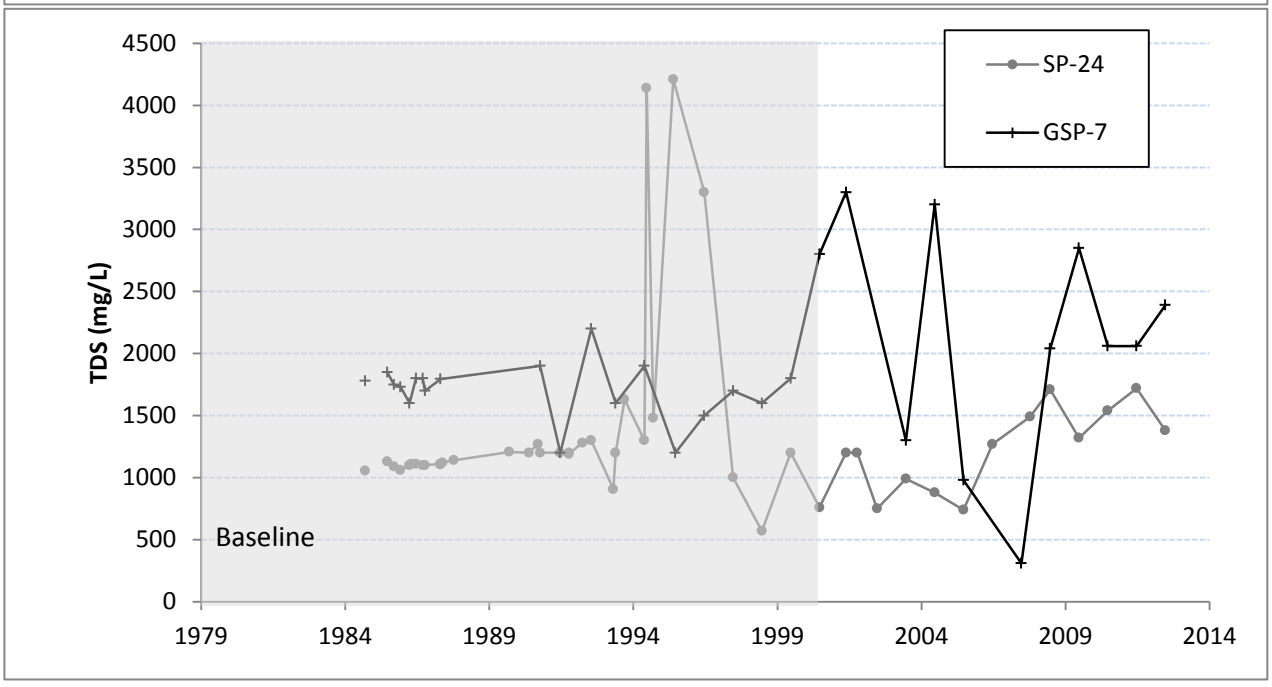


Figure 9-6: TDS changes over time for springs located in Spring Creek (SP-23 and SP-43) and Pony Creek (SP-24 and GSP-7).

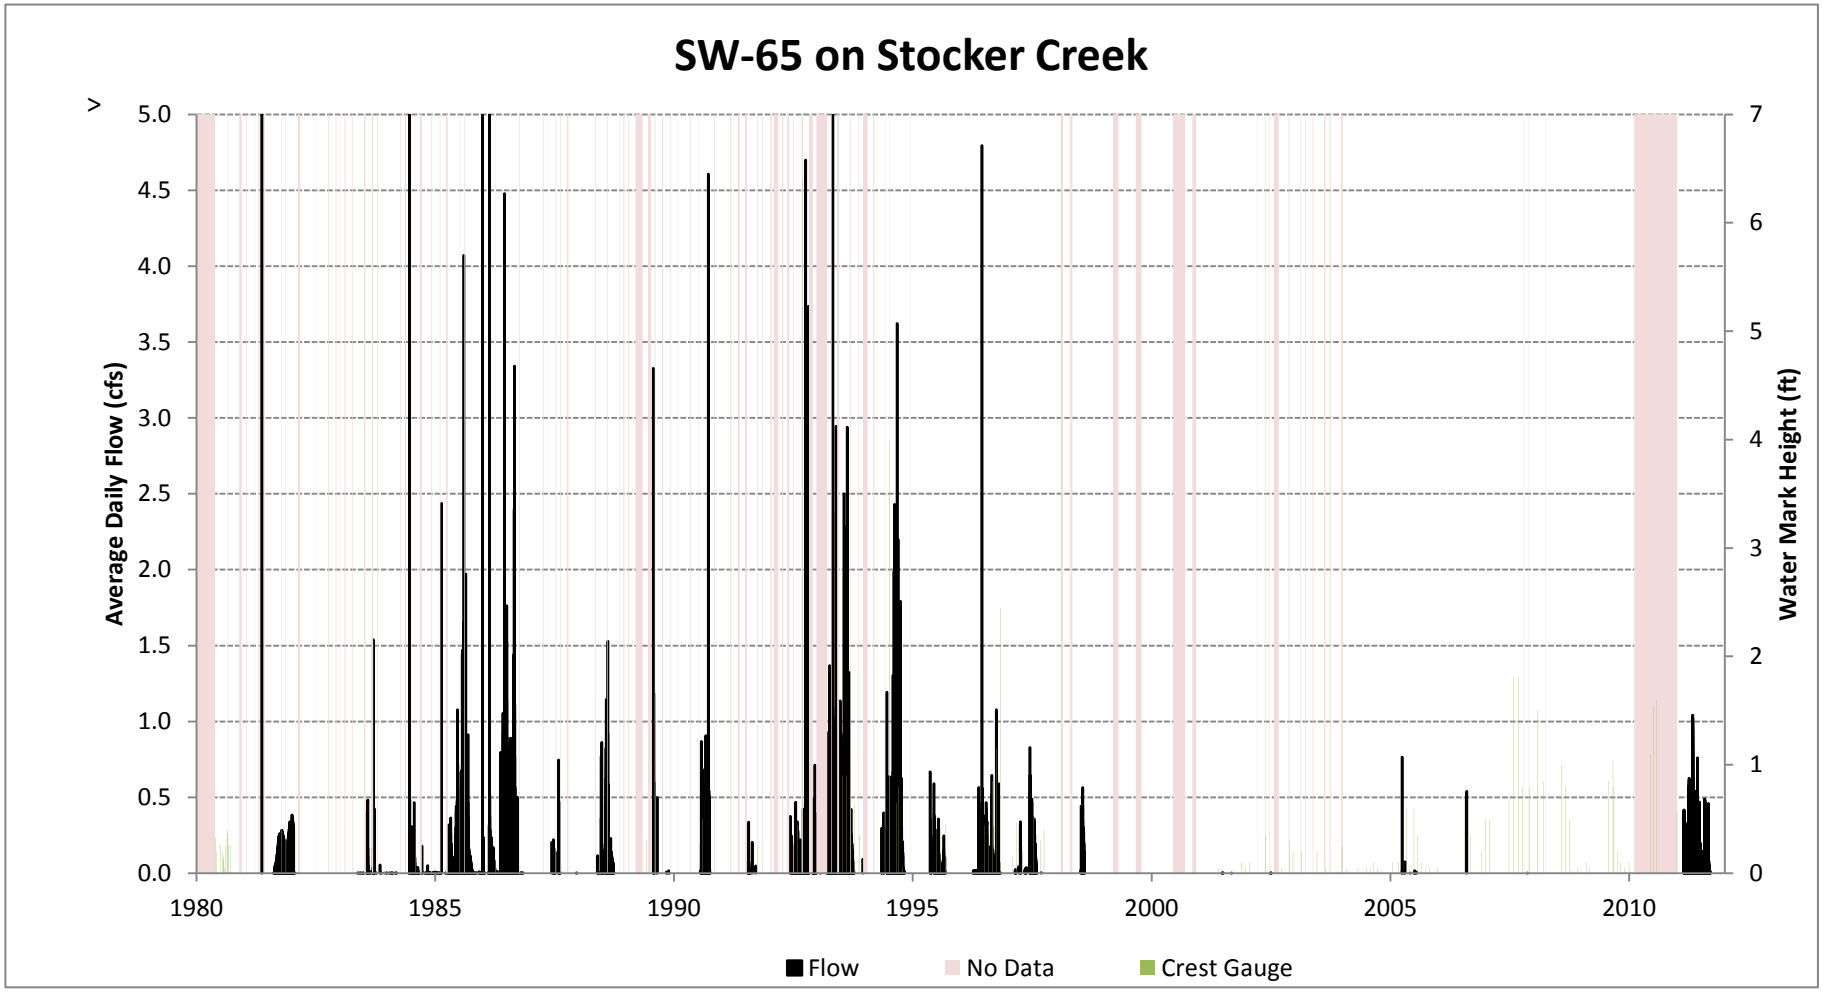

Figure 9-7: Flows recorded at Stocker Creek station SW-65.
Flows greater than 5 cfs are truncated. The conversion between crest gauge height and instantaneous flow is not known for the site.

ATTACHMENTS

ATTACHMENT 1: 2015 CUMMUALTIVE HYDROLOGIC IMPACT ASSESSMENT
ATTACHMENT 2: PRIVATE PROPERTY TAKINGS ASSESSMENT
ATTACHMENT 3: WESTERN ENERGY COMPANY RESPONSE TO OBJECTIONS TO DEQ'S ACCEPTABILITY DETERMINATION FOR ROSEBUD AREA B EXPANSION

INTRODUCTION

1. Western Energy Company's (Western's) Rosebud Mine Area B was originally permitted on January 18, 1978. A total of three amendments to the original permit area have been previously approved. Additionally, the permit area has been adjusted with a couple of incidental boundary changes (surface disturbance only – no additional mining). The amendment area does not include any new federal surface or coal that was not in the existing federal mine plan (Permit Number MT-0002, 12/80).

2. Western applied to the Montana Department of Environmental Quality (DEQ) for the fourth amendment to Area B of the Rosebud Mine (AM4) surface mining permit (the permit) on June 15, 2009. The application was ruled complete on August 7, 2009. After eight rounds of acceptability deficiencies the application was ruled acceptable on July 8, 2015.

3. AM4 proposes the following changes to the permit: a 49 acre increase in the area permitted; a 146 acre increase in the proposed amount of surface disturbance limit (5,531 to 5,677); 8.6% increase in the minable coal reserve (approximately 12.1 million tons); 306 more acres of coal removal or 8.3% increase in the amount of coal aquifer disturbed (3,686 to 3,992); re-calculation of the performance bond to account for current practices and future conditions (increase from $48,403,696 to $73,650,000); and, changes to the postmine topography (PMT). The additional proposed disturbance and mining will be a continuation of existing operations to the south and east.

4. Mining and reclamation operation under AM4 will not deviate substantially from what was previously approved. As coal is removed, the operator will proceed with reclamation according to the requirements of the Reclamation Plan, as described in Section 17.24.313 of the currently approved permit. Topsoil will be removed prior to mining and either direct-hauled to areas graded to the approved PMT or stockpiled. Soil stockpiles will be marked with an identification sign and stockpiles will be protected from erosion. Currently approved permit maps depicting vegetation plans will need to be reviewed and updated as a general course of permit renewal, mid-permit review or an additional minor revision to the permit. Regardless of future permit revisions, the vegetation plan will be monitored over time and adjusted as necessary to achieve successful establishment of plant communities which will support the approved postmine land use.

5. These written findings and permit decision are based on information provided by Western (Amendment application AM4 and existing permit C1984003B), the Checklist Environmental Assessment completed by DEQ dated July 2015 and updated December 2015, and the Cumulative Hydrologic Impact Assessment (CHIA) completed by DEQ dated December 2015.

Exhibit 1

6. Table I - Introductory Table

Applicant	Western Energy Company
Name of Mine	Rosebud Coal Mine Area B
MSHA Number	24-01747
Type of Mine	Strip
Type of Application	Amendment
Area within existing permit boundary (acres)	6,182
Proposed Increase in Permit Area (Acres)	49
Total proposed permit area (acres)	6,231
Anticipated Annual Production	4 million tons

FINDINGS

7. Permit and Review Chronology

December 8, 1980	Surface Mine Permit C1984003B is issued.
June 11, 2009	Various permitting actions December 1980 to June 2009.
June 15, 2009	Application 00184 (AM4), Area B Permit Amendment is submitted to DEQ by Western Energy.
June 25, 2009	Western submits the revised Application Form for the Area B Permit Amendment.
August 7, 2009	DEQ determines that Application #00184 (AM4) is complete and that an environmental impact statement is not necessary.
August 21, 2009	DEQ sends out the notice of application.
September 22, 2009	DEC received the affidavit of publication from Western. The public notice was published on August 27, September 3rd, 10th and 17th, 2009.
December 22, 2009	DEQ sends first round technical comments to Western.
March 18, 2010	DEQ receives Western's response to the first round technical comments for Application 00184 (AM4).
June 1, 2010	DEQ sends the second round deficiency letter to Western.
July 16, 2010	DEQ receives the Area B-East; Hydrological Control Plan and

Exhibit 1

	Associated Ponds.
November 15, 2010	DEQ receives Western's second round deficiency response.
December 8, 2010	DEQ completes a search of the Applicant/Violator System.
January 6, 2011	DEQ requests the CAD versions of the revised exhibits from Western.
January 25, 2011	DEQ receives the CAD for the revised exhibits.
March 14, 2011	DEQ sent Western a third round deficiency letter for Application 00184 (AM4)
January 19, 2012	DEQ receives Western's third round technical deficiency response.
February 29, 2012	DEQ sends Western comments for the Area B PHC via e-mail.
April 4, 2012	DEQ sent Western a request to update the PHC for Rosebud Coal Mine Area B as it had been several years since it was completed.
April 27, 2012	DEQ received information from Western in response to a data request for the amendment.
May 16, 2012	DEQ sent Western a fourth round deficiency letter for Application 00184 (AM4)
March 25, 2013	DEQ received Western's fourth round deficiency response.
April 30, 2013	DEQ sent Western a digital data request to assist in completing the CHIA for amendment.
May 3, 2013	DEQ sent Western a letter detailing a phone conversation describing the requirements of a comprehensive PHC including Areas A, B, and C.
June 13, 2013	DEQ receives the data requested in April 30, 2013 request from Western.
June 16, 2013	DEQ receives the updated PHC from Western.
July 23, 2013	DEQ sent Western a fifth round acceptability deficiency.
November 1, 2013	DEQ receives Western's response to the fifth round

	acceptability deficiency.
January 15, 2014	DEQ sent Western a sixth round acceptability deficiency.
February 3, 2014	DEQ receives Western's response to the sixth round acceptability deficiency.
February 24, 2014	DEQ receives Table 15A for the Area ABC PHC from Western.
June 3, 2014	DEQ sent Western a seventh round acceptability deficiency.
February 2, 2015	DEQ received a response to the seventh round acceptability deficiency.
March 5, 2015	DEQ sent Western an eighth round acceptability deficiency.
March 10, 2015	DEQ received Western's response to the eighth round acceptability deficiency.
May 11, 2015	DEQ received a copy of the Modification of Area B Resource Recovery and Protection Plan (R2P2) for Logical Mining Unit MTM 83589 containing Federal Coal Leases MTM35734, MTM54711 and MTM073109.
June 10, 2015	DEQ received an updated acreage table from Western associated with the Area B permit.
July 8, 2015	DEQ sent Western an acceptability determination letter with a request to verify the acreage for the amendment.
July 8, 2015	DEQ received the acreage table as request in the acceptability determination letter.
July 8, 2015	DEQ sent a Notice of Acceptability to the interested parties as well as having it published in the Billings Gazette which was published on July 17, 2015.
July 8, 2015	DEQ completes and makes available to the public a DRAFT Checklist Environmental Assessment for AM4.
July 22, 2015	DEQ receives a public records request from Western Environmental Law Center
August 3, 2015	DEQ receives public comment from Western Environmental Law Center.

August 24, 2015	DEQ's decision due date is missed due to review of legal counsel requesting changes to the format of the Cumulative Hydrologic Impact Assessment (CHIA).

8. DEQ found that the Rosebud Area B Amendment original application, submitted on June 12, 2009, and revised through March 10, 2015, is complete and accurate, and the applicant has complied with Montana's permanent regulatory program. *See* Administrative Rule of Montana (ARM) 17.24.406(a).

9. The applicant has demonstrated that reclamation, as required by the Montana Strip and Underground Mine Reclamation Act and regulations, can be accomplished under the proposed reclamation plan (*see* ARM) 17.24.406(a).

10. The AM4 amendment area is not located:

a) within an area under study or administrative proceedings under a petition to be designated as unsuitable for strip or underground coal mining operations. *See* (82-4-227(9), MCA;
b) within an area designated unsuitable for strip or underground coal mining operations pursuant to 82-4-227(9), MCA;
c) on any lands within the boundaries of units of the national park system, the national wildlife refuge system, the national wilderness preservation system, the national system of trails, the wild and scenic rivers system, including study rivers designated under section 5(a) of the Wild and Scenic Rivers Act or study rivers or study river corridors established in any guidelines issued under that act, or national recreation areas designated by an act of congress, or on any federal lands within national forests, subject to the exceptions and limitations of 30 CFR 761.11(b) and the procedures of 30 CFR 761.13 (*see*, 82-4-227(13));
d) on any lands upon which mining would adversely impact any publicly owned park or place included in the National Register of Historic Places (*see* ARM 17.24.1131);
e) where the operation will constitute a hazard to a dwelling, public building, school, church, cemetery, commercial or institutional building, public road, stream, lake, or other public property (*see* 82-4-227(7), MCA) except as conditioned below;
f) within 300 feet of any occupied dwelling (*see* 82-4-227(7)(a), MCA);.
g) within 300 feet of any public building, church, school, community or institutional building, or public park ((*see* 82-4-227(7)(b), MCA);
h) within 100 feet of a cemetery (*see* 82-4-227(7)(c), MCA); or
i) within 100 feet of the outside right-of-way line of a public road (*see* 82-4-227(7)(d), MCA).

11. Western has obtained all surface and mineral rights to conduct mining and reclamation operations authorized under AM4.

12. DEQ has made an assessment of the cumulative hydrologic impacts of all anticipated coal mining on the hydrologic balance within the cumulative impact area. See Attachment 1 which is incorporated into these findings by reference. In that

assessment, DEQ has determined that this amendment will not result in material damage to the hydrologic balance outside the permit area.

13. Western has paid all reclamation fees from previous and existing operations as required by 30 CFR Chapter VII, Subchapter R, as verified through the Applicant Violator System (AVS check of 11/25/15).

14. The proposed amendment is not likely to jeopardize the continued existence of threatened or endangered species or result in the destruction or adverse modification of their critical habitats, as determined under the Endangered Species Act of 1973 (16 U.S.C. 1531 et seq.) (*see* ARM 17.24.751)(*see* letter of 11/13/01 from USFWS).

15. Western has obtained all required air quality and water quality permits (*see* 82-4-231(2), MCA).

16. There are no pending MSUMRA violations for Western at the Rosebud Coal Mine Area B. No other strip- or underground-coal-mining operation that is owned or controlled by the applicant or by any person who owns or controls the applicant is currently in violation of Public Law 95-87, as amended, any state law required by Public Law 95-87, as amended, or any law, rule, or regulation of the United States or of any department or agency in the United States pertaining to air or water environmental protection, the department may not issue a strip- or underground-coal-mining permit or amendment, other than an incidental boundary revision, until the applicant submits proof that the violation has been corrected or is in the process of being corrected to the satisfaction of the administering agency (82-4-227(11), MCA) (AVS check of 11/25/15).

17. Records of DEQ and OSMRE show that the applicant does not own or control any strip- or underground-coal-mining operation that has demonstrated a pattern of willful violations of Public Law 95-87, as amended, or any state law required by Public Law 95-87, as amended, when the nature and duration of the violations and resulting irreparable damage to the environment indicate an intent not to comply with the provisions of the Montana Strip and Underground Mine Reclamation Act (82-4-227(12), MCA) (AVS check of 11/25/15).

18. Western is in compliance with all applicable federal and state cultural resource requirements, including ARM 17.24.318, 1131 and 1137, and as explained in the conditions listed below.

19. The current bond for the Rosebud Area B permit is $48,403,696. The bond was recalculated as part of the permit renewal application submitted on April 8, 2015. DEQ determined that a bond in the amount of $73,650,000 would be required for both the renewal and AM4 to account for current practices and future conditions. DEQ received adequate bond on December 3, 2015.

PRIVATE PROPERTY TAKINGS

23. The 1995 Montana state legislature passed House Bill (HB) 311, which requires a state agency to prepare an assessment of whether a proposed agency action will result in a taking of private property. DEQ prepared the assessment which concludes that the action approval of AM4 does not result in the taking of private property. The Private Property Takings Assessment is attached to these Written Findings as Attachment 4.

DECISION

20. Based on the information found in Western's Amendment Application 4 and these findings, DEQ hereby approves Amendment Application 04 as revised through March 10, 2015, and DEQ grants the amendment subject to the following conditions:

21. 17.24. 318, 1131[1]: Treatment of cultural resources within SMP C1984003B and the amendment area is covered by a MOA developed under the provisions of Section 106 of the National Historic Preservation Act and pursuant regulations (36 CFR 800). Treatment of all cultural resources, including incidental discoveries during the course of mining, must be handled according to the provisions of this MOA.

22. 17.24.304(1)(e); 17.24.417(1): The stream bottom of all named drainages must be surveyed in a manner acceptable to DEQ. The data must be submitted by the operator via a minor revision for incorporation into the permit by June 30, 2016.

23. 17.24.645(3); 17.24.646(1): Groundwater monitoring must be expanded in order to adequately determine the potential effects of mining to the hydrologic balance outside the permit area. Additional monitoring wells will be required to monitor potential down gradient movement of the affected water to ensure that it does not leave the permit boundary. Additional monitoring wells are also required inside the south permit boundary of Area B to monitor the quality of spoil water once the backfill becomes saturated and follows the natural flow direction to the southeast. This must be accomplished via a minor revision to the MQAP that is approvable by DEQ. The minor revision must be submitted to DEQ for review within 90 days of permit issuance.

24. 17.24.646(1) and (3): Surface water monitoring must be expanded at all streams downstream of mining in order to adequately determine the effects on mining on the hydrologic balance inside and outside the permit area. This must be accomplished via a minor revision to the MQAP that is approvable by DEQ. The minor revision must be submitted to DEQ for review within 90 days of permit issuance.

[1] The number preceding each permit condition is a reference to the provisions of the permit that is the subject of the condition.

257. 17.24.723(1) and (2): Macroinvertebrate monitoring on all intermittent reaches of all streams affected by mining must be performed on a schedule approved by the DEQ (every five years to be submitted with renewal). The proposed monitoring plan must be submitted to DEQ via a minor revision for incorporation into the wildlife monitoring plan.

RESPONSES TO PUBLIC COMMENTS

1. Western Energy is ineligible for a permit because of current violations of environmental laws at the Absaloka Mine.

DEQ Response: See AVS discussion at Written Finding nos. 16 and 17.

2. Western Energy is ineligible for a permit because of current violation of environmental laws at the Rosebud Mine.

DEQ Response: See AVS discussion at Written Finding nos. 16 and 17.

3. According to DEQ's 2014 Final Water Quality Integrated Report, the principal stream impacted by the strip-mining operation, East Fork Armells Creek, is currently not meeting water quality standards…DEQ has determined that the upper portion of the creek is not meeting water quality standards due to "alteration in stream-side or littoral vegetative covers," caused by "surface mining."

DEQ Response: DEQ's Waterbody Assessment Record for East Fork Armells Creek (MT42K002_170.pdf) was conducted in 2006, and no substantive updates have been conducted since this initial assessment. The Assessment Record identifies 'aquatic life' as an unsupported use, with the cause being 'alteration in stream-side or littoral vegetative covers' resultant from surface mining.

Regarding habitat impairments identified in the Assessment Record, the record states that:

a) Grazing is occurring throughout the reach with little impact. The riparian vegetation is mostly grasses and shrubs. Trees are generally missing, but are not required for sustainability.

b) Mining activity has, at a minimum, moderately impaired the habitat in this segment.

c) Because the habitat is impaired, aquatic life is partially supporting, despite the fact the stream is ephemeral.

The Assessment Record makes the claim that 'because the habitat is impaired, aquatic life is partially supporting'. In 2014, Western Energy Company, under the direction of the DEQ, conducted an aquatic survey with the objective of evaluating aquatic life support in upper

EFAC (waterbody segment MT42K002_170). The results of this survey show that the aquatic environments in upper EFAC support a diverse assemblage of aquatic insects, and consist of taxa commonly found in eastern Montana prairie streams. The recent aquatic survey provides empirical evidence that Aquatic Life support is not adversely impacted by mining activity.

4. DEQ has also determined that the lower portion of East Fork Armells Creek is not meeting water quality standards for Nitrate/Nitrite, nitrogen, specific conductance (SC), and total dissolved solids (TDS) and that the cause of these violations of water quality standards includes "coal mining."

DEQ Response: The lower portion of EFAC receives nitrogen-rich effluent from numerous sources including: runoff from the town of Colstrip, the water treatment plant, infiltration and runoff from the golf course (with fertilized and irrigated greens), agriculture, and grazing. The relative contribution from "surface mining" can be evaluated by examining water quality analyses from surface water and alluvial groundwater. Exceedances for nitrate-nitrite nitrogen are discussed in the CHIA (Attachment 1) in Section 9.2.4.4.4 and Section 9.2.6.10. Examination of the Table 9-7 and Table 9-8 in the CHIA (Attachment 1) indicates that the exceedance of nitrate-nitrite nitrogen is uncommon.

The sources listed above as contributors of nitrate-nitrite nitrogen along with leaking power plant ponds, also contribute to SC and TDS in the downstream section of EFAC. Water quality samples taken from EFAC surface and alluvial groundwater below the Highway 39 bridge and the town of Colstrip typically report much higher SC and TDS concentration (as well as nitrate-nitrite) than samples taken upstream of the bridge. Please refer to water quality data in the comprehensive Rosebud Mine database that was previously requested by and submitted to MEIC. The Colstrip power plant also has sampled EFAC south of the Highway 39 bridge and has regularly submitted stream water quality data to the DEQ that is available to the public for review and compare with data from the mine.

5. Indeed, WECo acknowledges that an upper section of the creek in Section 15 was intermittent in 1986 and that recent surveys indicate that it is now dry.[4] "Given the decreased water levels in alluvial wells between Areas B and C, it is possible that the change in flow is a result of mine related dewatering."[5]

DEQ Response: It is unknown whether there was baseflow in the stream section in question, and the premine quantity of water is also unknown. Statements as to the nature of this section premine are anecdotal. Since the nature of this section was not well documented in the 1970's, material damage to this section cannot be determined. While macroinvertebrates were documented using the water in Section 15 in the 1970s, it is unknown if water was present every year or only after wet years when runoff accumulated behind the instream dam, or only after years where the alluvium was saturated to the point of baseflow. Without knowing the true nature of the stream flow and the interaction between groundwater and surface water, a determination of material damage cannot be

made. Refer to page 9-22, 23 of the CHIA (Attachment 1) for a full discussion of the section 15 reach of EFAC.

6. WECo is clearly responsible for all violations of water quality standards in the upper reach of East Fork Armells Creek.

DEQ Response: Please refer to the response to Comment 1, above.

7. WECo also identifies ammonium-nitrate explosives from blasting as a contributor to elevated nitrate plus nitrite nitrogen levels in the East Fork Armells Creek alluvium.

DEQ Response: See the above discussion regarding nitrate-nitrite nitrogen; please refer to the CHIA (Attachment 1) in Section 9.2.6.4 and Section 9.2.8.9. Examination of the Table 9-7 and Table 9-8 in the CHIA (Attachment 1) indicates that the exceedance of nitrate-nitrite nitrogen is uncommon.

8. With respect to groundwater, the PHC recognizes that TDS levels in the spoils will be "two to three times that of the baseline coal groundwater."[10] WECo acknowledges that this will likely result in deterioration of groundwater quality within some areas of the mine backfill to a degree that will require at least temporary reclassification of the groundwater to a lower usage class."

DEQ Response: The comment is mistaken to the extent that it applies the material damage requirement to hydrologic consequences of mining within the permit area. Within the permit area, the Act requires the operator to minimize disturbance to the hydrologic balance. A reduction of water quality in the mining area is expected and is not grounds for denial of a mine permit application as long as reasonable conservation practices are being applied.

9. Further, neither the PHC nor DEQ's draft checklist EA addresses the best science about sulfate impacts to livestock. The PHC states that the sulfate standard for livestock is between 2500 and 3000 mg/L. However, the most recent science shows that sulfate concentrations as low as 1,000 mg/L are harmful to cattle:…

DEQ Response: There is a lack of consensus in the scientific and agricultural communities on the appropriate or acceptable concentrations for livestock drinking water quality. Desirable concentrations or limits on concentrations for livestock generally reflect the regional water quality in combination with feed and exposure, or lack of exposure, to trace elements during foraging. This is especially true for water quality constituents with narrative standards, such as sulfate. The document referenced by WELC as representing the "most recent science" [M.F. Raisbeck, et al. (2008)] has no greater scientific value than the other published water quality criteria for livestock. Indeed, some of the references listed in the document show that livestock growth appeared not to be significantly affected

at higher sulfate concentrations than ones proposed as harmful by the document and WELC.

10. The PHC demonstrates that the strip mine will cause and contribute to ongoing material damage to surface water…The PHC confirms that due to continued operation of the mine, TDS and nitrate/nitrite concentrations will increase in the alluvium of East Fork Armells Creek. PHC Addendum ("Once those water levels fully recover, it is estimated that the increase in TDS in the alluvium will be about 13 percent when compared to baseline conditions."); ("Nitrate plus nitrite nitrogen exceedances were found mostly in alluvium along the EFA and spoils wells…)"

DEQ Response: DEQ does not agree that there is ongoing material damage to surface water in EFAC or that the anticipated increase in TDS concentration in EFAC will create material damage. The standard for determination of material damage is deterioration of the quality or quantity of water outside the permit area to an extent that land uses or beneficial uses are adversely affected or water quality standards are violated. The predicted increase in TDS from mining does not anticipate violation of numeric standards or decline in water quality so that listed beneficial uses as defined by narrative standards are adversely affected. For the most sensitive use of EFAC water, aquatic life, there is no scientific evidence that the 13% increase in TDS will adversely affect macroinvertebrates in EFAC. DEQ will require the operator to monitor aquatic life to determine whether mining activity is materially detrimental to aquatic life in EFAC.

Also, an increase in TDS does not equate with an increase in nitrate-nitrite nitrogen. In their letter, WELC exaggerates the prevalence or extent of nitrate-nitrite nitrogen associated with mining. As discussed in Section 9.2.4.4.4 and Section 9.2.6.10 of the CHIA (Attachment 1), the occurrence of nitrate-nitrite nitrogen that can be clearly associated with mining is relatively rare.

11. Further, WECo's attempts to shirk its responsibility for increased TDS concentrations in alluvial waters are not believable. First, WECo inflates baseline TDS levels in East Fork Armells Creek to 2,299 mg/L.[20] However, the only samples that unquestionably predate mining at Colstrip, which were taken by the U.S. Geological Survey in 1923, had TDS concentrations of 845 and 688. Further, the last time that DEQ appears to have considered the cause of increased TDS concentrations on water quality in East Fork Armells Creek, the agency stated that the baseline average was 2,200 mg/L.

DEQ Response: With the exception of the easternmost part of Area A and Area B where mining was active in the early to mid-1970's, there are numerous monitoring sites with multiple sample analyses that represent premine, baseline conditions in EFAC alluvium. Two water quality samples from a system as dynamic as EFAC alluvium are not an adequate representation of premine baseline. The two samples that WELC refers to "that unquestionably predate mining" were not taken from alluvial water. WELC gleaned the data from MBMG Open-File Report 640 (hereinafter OFR 640), clearly titled Spring and

Stream Water Quality, Powder River Basin, Montana, which did not include alluvial samples. Further, if one examines the 1929 USGS source document (Water Supply Paper 600, hereinafter WSP 600) in which the samples listed in OFR 640 were originally reported, it becomes apparent that the sample location, source, and concentration reported for these samples in OFR 640 are not accurate. The PLSS in the OFR 640 for GWIC ID 201 places the sample more than a mile north of EFAC. WSP 600 indicates that this sample (USGS analysis 122) was collected from a 40 foot deep coal shaft and had a TDS of 1,102 mg/L (p. 138), not 845 mg/L. The sample identified as GWIC ID 309 (USGS analysis 123) was reported in WSP 600 as collected from a "water hole 6 feet deep" in EFAC and had a TDS of 962 mg/L (p. 138), not 688 mg/L.

Please be advised that a difference of 99 mg/L from two baseline averages determined by two different investigators using multiple water quality analyses from numerous wells is not significant and should not warrant concern regarding inconsistency or accuracy.

12. In addition to inflating baseline concentrations, WECo's suggestion that the measured increase in TDS upstream of Colstrip is due to "natural" factors is not credible.[23] First, the increase in alluvial TDS levels is not a recent development but has been documented since the 1990s.[24] DEQ attributed this increase in TDS to mining activity… The only citation that WECo offers for its theory that the increased TDS levels in the alluvium are "natural" is to an "email communication," with no additional explanation.[26]

DEQ Response: WELC refers to a DEQ document (letter to OSM, 1998) as evidence that the increase in TDS is due to mining. The author of the letter (D. Erbes) assumes the increase in TDS is the result of impoundment of surface flow in "upslope ponds". At of the date of these Written Findings, 17 years after the letter was written, subsequent data and more extensive and detailed investigation regarding increasing TDS leads to a different understanding of the source. This is described in detail in the PHC Addendum (Western Energy Company, 2015), a copy of which was obtained by MEIC in a recent information request.

13. The PHC, like DEQ's draft checklist EA, suffers from such generalized vagueness as to be devoid of any informational value to any save industry and agency insiders. For example, the PHC states that TDS concentrations will increase in spoils groundwater "during initial saturation and then decrease to an equilibrium level after one or more pore volumes of water pass through the backfill." There is no indication, however, about the length of time required for multiple "pore volumes" of water to pass through the backfill. … Regarding groundwater quantity, the PHC merely states that "full recovery" "will exceed 50 years in most portions that are mined" and that "[a]lthough it could take considerable time, there is no reason to expect that the regional groundwater flow gradient will not eventually recover because recharge and discharge areas for the principal aquifer will not be affected by mining."

DEQ Response: The comment addresses a lack of specificity in the time horizons for recovery of water quality and water levels that have undergone change due to coal mining. The simple answer is that the response of natural systems cannot be predicted with the exactness desired by WELC. A basic understanding of the hydrogeologic system, determined largely by field measurements, is used to anticipate the response to and recovery from disturbance to the system. Natural systems are dynamic, characterized by spaciotemporal variability and do not lend themselves to precision, especially when considering large areas and long time frames. Recovery of water levels and water quality will depend on the response of local hydrology, climate, chemical reactions, geology, all of which individually and in concert are unpredictable and play a part in the outcome. Awareness of this situation is reflected by statute and rules that require that the probable hydrologic consequences, rather than the exact hydrologic consequences, of mining be determined. Recovery of the hydrologic system will not be linear. Modeling the recovery of a system for the first 50 years gives a prediction of how the system will respond and may be used to extrapolate to a longer time frame, but given the limitations of the variables used in a model, especially for a large and complex area, estimates for time periods beyond fifty years become less reliable and less meaningful.

The DEQ endeavors to anticipate to the extent possible the impacts and outcomes of coal mining, and where more sensitive environmental settings are observed, increased examination is undertaken.

14. In addition to the unlawful vagueness and inconsistency with respect to the time horizons for impacts, the PHC is insufficient because it fails to address the impacts that climate change will have on the hydrologic balance.

DEQ Response: Specific weather changes in a localized area such as Colstrip that may occur over an undetermined period of time as a result of climate change are unknown, and cannot be realistically considered in the probable hydrologic consequences of mining.

15. DEQ's MEPA analysis is insufficient.

DEQ Response: For its response to this comment, DEQ incorporates by reference Environmental Assessment of Application AM4, December 3, 2015.

16. Approval of the proposed mine expansion violates the right to a clean and healthful environment.

DEQ Response: DEQ acknowledges that the Montana Constitution provides a right to clean and healthful environment. Among the inalienable rights declared in the Article II, Section 3 of Montana Constitution is the right to "a clean and healthful environment." The Legislature declared its intent that by enacting the Montana Strip and Underground Mine Reclamation Act ("MSUMRA") it was:

> [M]indful of its constitutional obligations under Article II, section 3, and Article IX of the Montana constitution, has enacted The Montana Strip and Underground Mine Reclamation Act. It is the legislature's intent that the requirements of this part provide adequate remedies for the protection of the environmental life support system from degradation and provide adequate remedies to prevent unreasonable depletion and degradation of natural resources.

Section 82-4-202 (1), MCA. Nevertheless, MSUMRA in pertinent part sets forth the standards and criteria for evaluating whether a proposed coal mine operation protects those constitutional rights. MSUMRA authorizes strip and underground coal mining operations within the state in accordance with its provisions and requirements. The Legislature has authorized DEQ to permit and regulate surface and underground coal mining operations in accordance with MSUMRA and other environmental laws applicable to coal mining operations. By issuing a permit that complies with the requirements of MSUMRA, the Department acts consistently with the declared intent of the Legislature to protect the right of Montanans to a clean and healthy environment.

No provision of MSUMRA authorizes the Department to deny an application to amend a coal mine operating permit based on potential impacts to climate change. To the extent that the comment questions whether MSUMRA in whole or in part is consistent the Montana Constitution or international law, DEQ as a state agency "must faithfully execute the laws of Montana" and questions touching on the constitutionality of MSUMRA lie within the exclusive jurisdiction of the Montana courts. *See Merlin Meyers Revocable Trust v. Yellowstone County*, 2002 MT 201, ¶ 21, 311 Mont. 194, 200, 53 P.3d 1268, 1272.

BEFORE THE BOARD OF ENVIRONMENTAL REVIEW
OF THE STATE OF MONTANA

IN THE MATTER OF: **APPEAL AMENDMENT AM4,** **WESTERN ENERGY COMPANY,** **ROSEBUD STRIP MINE AREA B** **PERMIT NO. C198400B**	**CASE NO. BER 2016-03 SM** **AFFIDAVIT OF STEVE GILBERT IN SUPPORT OF PLAINTIFF'S MOTION FOR SUMMARY JUDGMENT**

I, Steve Gilbert, hereby state as follows:

1. My name is Steve Gilbert. I reside in Helena, Montana. I am a citizen of the United States and am over 18 years of age. I am a member of the Montana Environmental Information Center (MEIC).
2. I have been a Montana resident since 1967. For forty-one of these years I have worked as a biological consultant. For twenty-five years I was part-owner and president of an environmental consulting company that specialized in wildlife, aquatics/fisheries, soils, vegetation, forestry, range and hydrology. Separate from my business, I worked in Yellowstone Park on grizzly bears and studied cliff-nesting falcons in Glacier Park. I am an associate with the Montana Peregrine Institute, and have conducted neo-tropical bird and raptor surveys in Montana and other parts of the west nearly every year since 1971.
3. I am a strong environmental advocate and have served for a number of years on the boards of various conservation groups in Montana, including MEIC. I am currently a board member of MEIC. I was chosen to be MEIC Community Activist of the Year in 2003. In 2013, I was awarded the Len and Sandy Sargent award for meritorious award by MEIC. I have testified in the Montana Legislature and the U.S. Senate on water and air quality, soils, aquatics, and wildlife habitat issues relating to irresponsible energy development, coal and hard-rock mines.
4. I was a professional licensed Montana fly fishing guide for 20 years. During those years, I guided on nearly every trout stream of note in Montana. I was

an Orvis endorsed guide for many years and National Guide of the Year in 1990.

5. I have worked and/or played in all 56 Montana counties and every mountain range, wilderness area and national park in the state. I have skied and walked through the Bob Marshall and Scapegoat Wilderness, the Mission Mountain Wilderness, Bitterroot-Selway Wilderness, Absaroka-Beartooth Wilderness, and into every corner of Yellowstone and Glacier Parks. I have paddled thousands of miles of Montana's spectacular canoe waters.
6. I presently do some biological consulting on a pro bono basis. I retired in early 2012 as the state nonmotorized trails specialist for Montana Fish, Wildlife and Parks. As such, I helped administer the federally-funded $1.5 million Recreational Trails Program and inspected trails projects funded by the program, walking many miles a year in the back country. I also worked part-time with the Land and Water Conservation Fund and inspected projects funded by the fund in every county of the state.
7. I am also the father of two adult children. I spend lots of time each fall filling freezers with elk, deer, waterfowl and upland game birds.
8. I have conducted biological research in the Tongue River Valley from 1977 to 1986, and during this time, I spent numerous days in the Colstrip area hunting upland birds, particularly along East Fork Armells Creek, Cow Creek, Green Leaf Creek and Rosebud Creek. In this same period I also wrote the wildlife biology report for the EIS on Area D of the Rosebud Mine and spent time in the field near Colstrip in preparation for writing. While there, I

observed East Fork Armells Creek, Cow Creek, and Rosebud Creek. At first glance, these appear to be pretty southeastern Montana creeks, but they have taken an unnecessary beating from industrial development. It is unfortunate that these creeks have been sacrificed to the degree that they have.

9. During the past ten years, I spent numerous days in and around Colstrip performing Land and Water Conservation Fund inspections on between 15 and 20 projects. Over the past 36 years, I have driven through and around Colstrip at least annually for work, recreation, or as a board member of conservation organizations. I expect to continue to visit the Colstrip area at least on an annual basis in the coming years. As I drive through the area, I will observe the countryside and creeks and streams, including East Fork Armells, Cow Creek, and Rosebud Creek. Most recently, in December of 2016 I hunted sharp tails and pheasants on a private ranch near Colstrip and the Rosebud mine.

10. All of my many experiences with the creeks, streams, and rivers near Colstrip occurred after coal mining had begun. Thus I had low aesthetic expectations, which were all too easily met. I have observed the pits of the Rosebud Mine that swallow the upper reaches of East Fork Armells Creek. I am also familiar with the documentation of the contamination and impairment of East Fork Armells Creek by the Rosebud Mine. In particular, I know that the Montana Department of Environmental Quality has determined that the upper and lower reaches of East Fork Armells Creek are impaired, that the creek does not support healthy assemblages of aquatic life, and that one cause of the

impairment is the strip-mining operation at the Rosebud Mine. I am also aware that the Western Energy Company, which operates the strip-mine, has on multiple occasions violated its pollution discharge limits for boron, iron, sulfates, total suspended solids, and total dissolved solids.

11. Because of my awareness of the pollution from the Rosebud Mine and the Colstrip Power Plant—including specifically water pollution from the mine and the fact that the mine has impaired the downstream receiving waters—it is extremely difficult for me to have positive recreational or aesthetic experiences in the outdoors near Colstrip. While there is some exceptionally beautiful country near Colstrip, my aesthetic experience is always compromised by the industrial development of the Rosebud Mine and Colstrip Power Plant. I love to hunt, fish, and hike in southeast Montana, activities I have done annually since 1977, and I would love to be able to do so in and near Colstrip, and along East Fork Armells Creek, Cow Creek, Rosebud Creek and their tributaries downstream from the Rosebud Mine; however, I am discouraged from doing so because of my concerns about the pollution from the mine and power plant, including specifically water pollution from the Rosebud Mine. The concern about water pollution in these creeks from the Rosebud Mine diminishes my aesthetic enjoyment of the creek and the surrounding area.

12. There is also an ever-present concern that when I drink water in a Colstrip restaurant or in the home of nearby ranchers, I may be drinking water that has been contaminated by mining at the Rosebud Mine or power generation

at the power plant. This concern with groundwater pollution lessens my aesthetic appreciation for the area and discourages me from recreating in the area.

13. While there is some exceptionally beautiful country near Colstrip, my aesthetic experience of East Fork Armells Creek, Cow Creek, Rosebud Creek and the area surrounding Colstrip is always compromised by the industrial development there, including the Rosebud Mine. I have hunted, fished, and hiked in southeast Montana annually since 1977. I have hunted upland birds along East Fork Armells Creek, Rosebud Creek, and Cow Creek five to ten miles downstream from the Rosebud strip-mine in 2014 through 2015. I plan to continue to hunt, fish, and hike in southeast Montana. I also plan to visit people in and around East Fork Armells Creek, Cow Creek, Rosebud Creek, Colstrip, and the Rosebud Mine. I would like to recreate around East Fork Armells Creek, Cow Creek, Rosebud Creek, and the Colstrip area; however, the continued air and water pollution from the mine and power plant will likely continue to impact my recreational interest in and aesthetic appreciation of the area. Because of this, I am less likely to recreate in the area. It is not a positive thing to say that one's low aesthetic expectations are not likely to be met there, but they are. This would be different if it were not for the significant pollution, including water pollution from the mine, in the area.

14. I am also concerned that the Montana Department of Environmental Quality does not always work for the best interests of the people of Montana.

Somehow, it seems DEQ has lost track of its mission to protect and enhance a clean and healthful environment for present and future generations of Montanans. Instead, DEQ seems to think its mission is to make things easier for industry to poison and destroy the air, water, soil, fish and wildlife habitat. Unless there are watchdog organizations, DEQ and the Rosebud Mine will continue to destroy everything they touch.

15. Montana's Constitution recognizes all citizens fundamental civil right to a clean and healthful environment. It is the responsibility of both DEQ and private industry, such as the Western Energy Company, to assure that their actions do not violate or lessen this right. WECo's continued discharge of pollution into the already impaired waters of East Fork Armells Creek and the tributaries of Rosebud Creek, and DEQ's failure to adequately protect the water from this pollution violates my constitutional right to a clean and healthful environment.
16. If DEQ complies with the law prior to issuing a permit to expand to the Rosebud Mine and ensures that no illegal pollution is discharged into East Fork Armells Creek, its tributaries, and the groundwater outside of the permit boundary, my aesthetic and recreational concerns will, to some degree, be reduced. If DEQ complies with the law and imposes lawful restrictions on the mine expansion, the violation of my fundamental civil right to a clean and healthful environment will also be remedied, at least partially.

I declare under penalty of perjury under the laws of the United States that, to the best of my knowledge, the foregoing is true and correct.

PREFACE

This volume is one of three that address the requirements of Public Law 95-87 (the Act) and its promulgated regulations related to the protection of the hydrologic balance on and adjacent to surface coal mines. This volume contains Guidelines for Preparation of a Cumulative Hydrologic Impact Assessment (CHIA). Another volume contains Guidelines for the Preparation of a Probable Hydrologic Consequences Determination (PHC). These guidance documents suggest processes and illustrations that applicants and regulatory authorities may use to prepare the required PHC and CHIA. A third volume contains appendices with supporting information for the PHC and CHIA volumes. In addition to the appendix volume, the PHC and CHIA volumes each include appendices specific to the respective document.

INTRODUCTION

PURPOSE AND SCOPE

The Surface Mining Control and Reclamation Act of 1977, 30 U.S.C. 1201 et seq. (1982) (SMCRA) requires the regulatory authority, before issuing a permit to conduct surface coal mining and reclamation operations, to make an assessment of the probable cumulative impacts of all anticipated mining in the area to assure that the proposed operation has been designed to prevent material damage to the hydrologic balance outside the permit area. The Office of Surface Mining (OSM) has termed this assessment a "cumulative hydrologic impact assessment" (CHIA). Although SMCRA is very specific that such an assessment is a necessary part of the permitting process, it provides little in the way of guidance as to how these assessments are to be made. The development of this manual provides this guidance to regulatory authorities in the form of a procedure for making technically sound and legally defensible CHIA's.

This guidance document suggests a thought process which will lead the regulatory authority to recognize and address the critical issues of each assessment. More specifically, this document (1) outlines the statutory basis for developing CHIA's and describes the regulatory requirements for CHIA's, (2) provides a process for the development of an acceptable CHIA, and (3) suggests data sources and proven analytical procedures that may be used in the assessment. These suggestions and procedures should be considered guidelines and not standards. The regulatory authority is not required to use this material. This is an advisory document and should not be construed as being regulatory in any way. There are no limits or conditions specified except those contained in the Act itself and in the promulgated Federal regulations and approved State programs.

The CHIA is an assessment which distinct and separate from the determination of probable hydrologic consequences (PHC), although elements of the PHC can be used to support and develop the CHIA. The CHIA is the responsibility of the regulatory authority, whereas the applicant must provide the PHC determination with the permit application. The PHC determination addresses hydrologic conditions on the permit and adjacent areas; the CHIA considers impacts over the entire cumulative impact area (CIA). This guidance document primarily addresses the CHIA process but may refer to information presented in the PHC determinations of the individual operations. It is assumed that prior to starting the CHIA process, the regulatory authority will have reviewed the hydrologic content of the permit application and will have made a determination that the hydrologic information, the analyses, and the PHC statement in the application provide a complete and adequate evaluation of the hydrologic systems that will be affected by the proposed operation and clearly indicate the magnitude of those effects. If such a determination shows these items to be inadequate or if such a determination has not been made, the CHIA process should not be initiated until these items are provided.

This document is directed primarily to the regulatory authorities, who have the responsibility of completing a CHIA for each permit application. However, coal mine operators and interested members of the public may also find it useful for preparing and understanding permit applications. If each party involved in the permitting process understands what is required of the others, conflicts should

Exhibit 36

occur less frequently and be more easily resolved. It is intended that this document provide a common understanding of the CHIA process for all interested parties.

Because this document is intended for nationwide use, the process presented is intentionally nonspecific. It gives the regulatory authorities flexibility to administer the process within regulatory requirements and standards of the individual States. It emphasizes the general elements that should be considered in conducting a CHIA but allows the regulatory authority to choose the specific approaches and methods that will be most appropriate to a given State, region, or cumulative impact area. Therefore, the prudent regulatory authority will develop State-specific CHIA guidelines, using the process presented here as a framework. Such action would allow the regulatory authority to standardize parts of the process, establish appropriate exceptions to the process, and, in general, streamline the whole CHIA process, thus minimizing the total effort required for a given CHIA analysis.

DEFINITIONS

The following definitions will facilitate the understanding of this document. They are provided solely to aid the reader in understanding this guidance document and are not to be construed in any way as official OSM definitions. Other definitions may be found in OSM's Permanent Regulatory Program, 30 CFR 701.5 (appendix A.1).

Baseline hydrologic information.--Information which describes the physical and chemical characteristics of a hydrologic system and the hydrologic balance of an area prior to the imposition of a specific stress, such as a mining operation.

Hydrologically isolated operation.--A surface mining operation where hydrologic impacts are negligible or are dissipated before reaching points in the system where they are additive to hydrologic impacts of other surface mining operations.

Hydrologic concern.--An issue or potential issue relating to some element or aspect of the hydrologic system which may be adversely affected by surface mining activities. Each concern can be described using specific hydrologic parameters and changes in those parameters. Cumulative impact assessments can be focused initially upon hydrologic concerns identified through analysis of baseline information, historical data, etc.

Hydrologic impact.--Any measurable change in hydrologic parameters or conditions associated with a particular hydrologic system caused by surface and underground coal mining activities.

Hydrologic model.--An equation, set of algorithms, or written qualitative description of a phase of the hydrologic cycle. Most often, an equation that results from the use of correlation-regression analysis that relates a hydrologic parameter to physiographic and climatic factors. Also, a computer program that predicts hydrologic parameters as time-series,

Exhibit 36

such as streamflow or soil moisture, given meteorologic time-series input. For cumulative impacts of surface mining, the applicable phase of the hydrologic cycle is from precipitation on the land surface or snowmelt to the discharge point at a downstream location or flow in an aquifer.

Hydrologic parameter.--A particular physical or chemical quantity, property, factor, or characteristic used to describe hydrologic conditions.

Material damage to the hydrologic balance means, with respect to CHIA, the changes to the hydrologic balance caused by surface mining and reclamation operations to the extent that these changes would significantly affect present and potential uses as designated by the regulatory authority.

Water availability means that, along with there being a sufficient volume, the water is in an accessible location and it is of acceptable quality for the uses designated by the regulatory authority.

Exhibit 36

CHAPTER I

STATUTORY AND REGULATORY REQUIREMENTS FOR CUMULATIVE IMPACT ASSESSMENTS

The statutory requirements for CHIA's are found in Sections 507(b) and 510(b) of SMCRA. These sections which delineate the requirements that the regulatory authority and the permit applicants must meet, state, in pertinent part:

> Section 507(b) "The permit application shall be submitted in a manner satisfactory to the regulatory authority and shall contain, among other things-- * * * (11) a determination of the probable hydrologic consequences of the mining and reclamation operations, both on and off the mine site, with respect to the hydrologic regime, quantity and quality of water in surface and ground water systems including the dissolved and suspended solids under seasonal flow conditions and the collection of sufficient data for the mine site and surrounding areas so that an assessment can be made by the regulatory authority of the probable cumulative impacts of all anticipated mining in the area upon the hydrology of the area and particularly upon water availability: Provided, however, That this determination shall not be required until such time as hydrologic information on the general area prior to mining is made available from an appropriate Federal or State agency: Provided further, That the permit shall not be approved until such information is available and is incorporated into the application" (emphasis in original).
>
> Sections 510(b) "No permit or revision application shall be approved unless the application affirmatively demonstrates and the regulatory authority finds in writing on the basis of the information set forth in the application or from information otherwise available which will be documented in the approval, and made available to the applicant, that * * * (3) the assessment of the probable cumulative impact of all anticipated mining in the area on the hydrologic balance specified in Section 507(b) has been made by the regulatory authority and the proposed operation thereof has been designed to prevent material damage to the hydrologic balance outside the permit area;"

The requirements of Sections 507(b)(11) and 510(b)(3) of the Act have been implemented by the Permanent Regulatory Program at 30 CFR 701.5, 780.21, and 784.14. Section 701.5 defines "cumulative impact area," the name given the area referred to in Section 507(b)(11) as that area which must be included in the assessment of probable cumulative impacts. This definition of the CIA addresses the physical extent of the area and the meaning of the term "all anticipated mining" as used in Section 510(b)(3). According to the preamble, anticipated mining is meant to include "all operations which have a reasonable expectation of receiving regulatory approval to mine and for which there is sufficient mine development information available to allow adequate analyses" (48 Federal Register 43957, September 26, 1983).

Sections 780.21(g) and 784.14(f) of the regulations speak specifically to the scope of the CHIA. Section 780.21 addresses surface mining and 784.14 concerns underground mining. These sections both read as follows:

Cumulative hydrologic impact assessment.

(1) The regulatory authority shall provide an assessment of the probable cumulative hydrologic impacts (CHIA) of the proposed operation and all anticipated mining upon surface- and ground-water systems in the cumulative impact area. The CHIA shall be sufficient to determine, for purposes of permit approval, whether the proposed operation has been designed to prevent material damage to the hydrologic balance outside the permit area. The regulatory authority may allow the applicant to submit data and analyses relevant to the CHIA with the permit application.

(2) An application for a permit revision shall be reviewed by the regulatory authority to determine whether a new or an updated CHIA shall be required.

Sections 780.21(c) and 784.14(c) discuss the responsibilities of the regulatory authority and the applicant for the collection of hydrologic data needed for the CHIA. These sections provide:

Baseline cumulative impact area information.

(1) Hydrologic and geologic information for the cumulative impact area necessary to assess the probable cumulative hydrologic impacts of the proposed operation and all anticipated mining on surface- and ground-water systems, as required by Paragraph 780.21(g) or 784.14(f), shall be provided to the regulatory authority if available from appropriate Federal or State agencies.

(2) If the information is not available from such agencies, then the applicant may gather and submit this information to the regulatory authority as part of the permit application.

(3) The permit shall not be approved until the necessary hydrologic and geologic information is available to the regulatory authority.

Exhibit 36

CHAPTER II

OVERVIEW OF THE CHIA PROCESS

This chapter presents an overview of the CHIA development process, along with the philosophy on which it is based, so that the user can immediately understand its full scope. In addition, brief statements of the functions of each of the process elements are presented. Detailed discussion of the various process elements is presented in later chapters.

PHILOSOPHY OF CHIA

With proper enforcement of surface mining regulations, the hydrologic impacts of individual mining operations will be minimized, though not eliminated entirely. These remaining or residual impacts, however small and individually insignificant, may, with the development of additional mines, accumulate to magnitudes that are significant and potentially damaging to the hydrologic balance. The cumulative hydrologic impact assessment, thus, is necessary to assure that such aggregate impacts will not be overlooked in the routine processing of individual permit applications. In effect, the CHIA is a safety net provision in the Act, and its overall objective is to require routine consideration of the aggregate impacts caused by the disruption of large areas (more than one individual permit area) due to surface mining operations.

The CHIA is a means of keeping the big picture of hydrologic impacts before the regulatory authority at all times, so that if the accumulated impacts reach potentially damaging magnitudes, they can be dealt with in a timely manner. Depending on the hydrologic setting, the potential for damage to the hydrologic system, and the evaluation of the significance of that damage through the application of material damage criteria established by the regulatory authority, the probable cumulative hydrologic impact assessment could result in the denial or delay of a mining permit. The regulatory authority may use the CHIA as a land use planning tool to balance current coal development in a region against probable future development. However, such use is not required (48 Federal Register 43973, September 26, 1983).

Because, through the CHIA process, the regulatory authority is continually reminded of the reality of cumulative impacts, it should not be necessary to completely analyze every facet of the hydrologic system. The process presented in this guidance document is based on the premise that the scope of the analysis can be reduced to those facets of the hydrologic system which are likely to affect the designated uses of water available from that system. At the start of an assessment, its scope should cover all possibilities. Thus, the scope of a CHIA should initially include a complete analysis of the ground- and surface-water systems in the CIA, from the standpoint of water quantity and quality. This initial scope can then be systematically and logically reduced to those concerns considered significant to maintaining the hydrologic balance of the area. The scope reduction procedures, which must be developed by the regulatory authority, are envisioned to often be qualitative in nature.

Exhibit 36

The procedures presented here are based on the understanding that hydrologic impact assessment is not a precise process. Because of the many uncertainties associated with hydrologic estimation, the predictions made under the process proposed herein, or under any similar process, must be considered as probable in nature rather than exact. Therefore, the regulatory authority must have the option of using professional judgment to make the final material damage determination. This should not detract from the significance of the process if the determination is based on the facts produced by a comprehensive analysis. Likewise, use of qualitative methods and techniques for the analysis is an acceptable option if the regulatory authority can show them to be adequate for the specific site situation.

OVERVIEW

A CHIA is a permit-specific assessment required by SMCRA and must be an integral part of the permit decision package. The CHIA should be included in the Technical Environmental Analysis (TEA) section of the decision package.

CHIA development is a process which consists of a logically and professionally documented evaluation of a defined set of elements. It basically involves the analysis of critical aspects of the hydrologic system within the cumulative impact area. Emphasis of the analysis is on predicting the type and magnitude of impacts to the hydrologic system attributable to the proposed operation in conjunction with existing operations and anticipated mining. Thus, during the CHIA process, the regulatory authority should (1) define the area to be studied, (2) describe the hydrologic system and determine baseline hydrologic resource values, (3) identify hydrologic resources likely to be affected, (4) develop standards for evaluating the impacts, (5) estimate the impacts of mining on the hydrologic resources, and (6) make a material damage determination and prepare a statement of findings. The regulatory authority should address these elements in a logical sequence based on good hydrologic practice.

Within the constraints of good hydrologic practice and those imposed by statutory and regulatory requirements, the regulatory authority has wide latitude to determine the exact manner in which individual elements will be evaluated. Thus, an assessment based on "professional judgment," or a rigorous analytical assessment may be used, as the situation requires. Also, some of the procedures and hydrologic concerns presented and discussed in this guidance document may not apply to every CHIA. They are offered as examples, and their use is in no way mandatory. The specific concerns, procedures, methods, and data needs may vary with each impact area, and the regulatory authority has complete latitude to use those that best apply to the particular conditions of each site. However, justification for the specific assumptions and decisions made by the professionals conducting the assessment must be included in the findings statement for use in the various review processes (including public review and the program oversight review). The justification of actions and methods should be considered an extremely important aspect of the CHIA process.

Each CHIA should be considered unique to a specific minesite or permit area. However, a totally new analysis is not necessary for each CHIA. It is acceptable to use portions of a previously prepared CHIA for the same area, provided that these portions do, in fact, describe the situation of the newly proposed operation. For

Exhibit 36

example, if the proposed permit area was included as a leasehold in a previous CHIA, then that previous CIA delineation may be an appropriate CIA for the CHIA of the newly proposed permit area. In addition, documentation of the procedures used to delineate this CIA should be transferable to the CHIA of the proposed mine with only minor modifications. Likewise, once material damage standards have been established for a specific area, they would be applicable, with little modification, to all future CHIA's in that area. Thus, even though a CHIA should be considered unique to each specific permit application, the actual assessment can draw heavily on the previously prepared CHIA's.

Figure II-1 illustrates the basic CHIA process that may be used by the regulatory authority. The letters in the element boxes are for reference only and do not imply a required process order. The process could be depicted in other, equally acceptable, sequences. The important factor is that the process considers the recommended elements in a logical and workable sequence.

The process illustrated in figure II-1 shows the interrelation of the elements to each other and to the process as a whole. The parallel arrangement of Elements A, B, and C is meant to suggest that these elements are highly interrelated and that their evaluation should take place concurrently and interactively. As a group, these three elements are evaluated first in the process because they provide an information base which forms the basis for selecting techniques and methodologies needed for impact prediction and material damage assessment. The sequential arrangement of Elements D through F indicates that completion of these elements is dependent on the prior evaluation of certain other elements. This should not be construed to mean that one element must be totally completed before the next is started. The feedback arrow suggests that the CIA delineation may need modification after the areal extent of the impacts has been evaluated.

Process Elements

Element A.--Element A addresses the delineation by the regulatory authority of the area for which the CHIA is being prepared. OSM refers to this area as the cumulative impact area (CIA) and defines it in the regulations (30 CFR 701.5) in terms of both a physical area and the type of operations located within the area that must be considered.

The proposed delineation process begins at a point downstream from the most downstream operation in the same river basin where the proposed operation is located. By procedures developed by the regulatory authority, operations spatially and hydrologically distant from the proposed operation are systematically tested to determine the significance of their impacts with respect to the proposed operation. In this way, the CIA is limited to operations whose hydrologic impacts are relevant to the CHIA being developed. The process may be iterative, with some evaluation of the impacts needed before the limits of the CIA can be finally delineated; thus, the feedback loop from Element E to Element A in figure II-1.

Element B.--Element B involves identification by the regulatory authority of hydrologic concerns specific to the CIA. This is a qualitative identification of the aspects of the hydrologic system most likely to be adversely affected by mining activity. By identifying hydrologic concerns peculiar to the CIA, the CHIA process

Exhibit 36

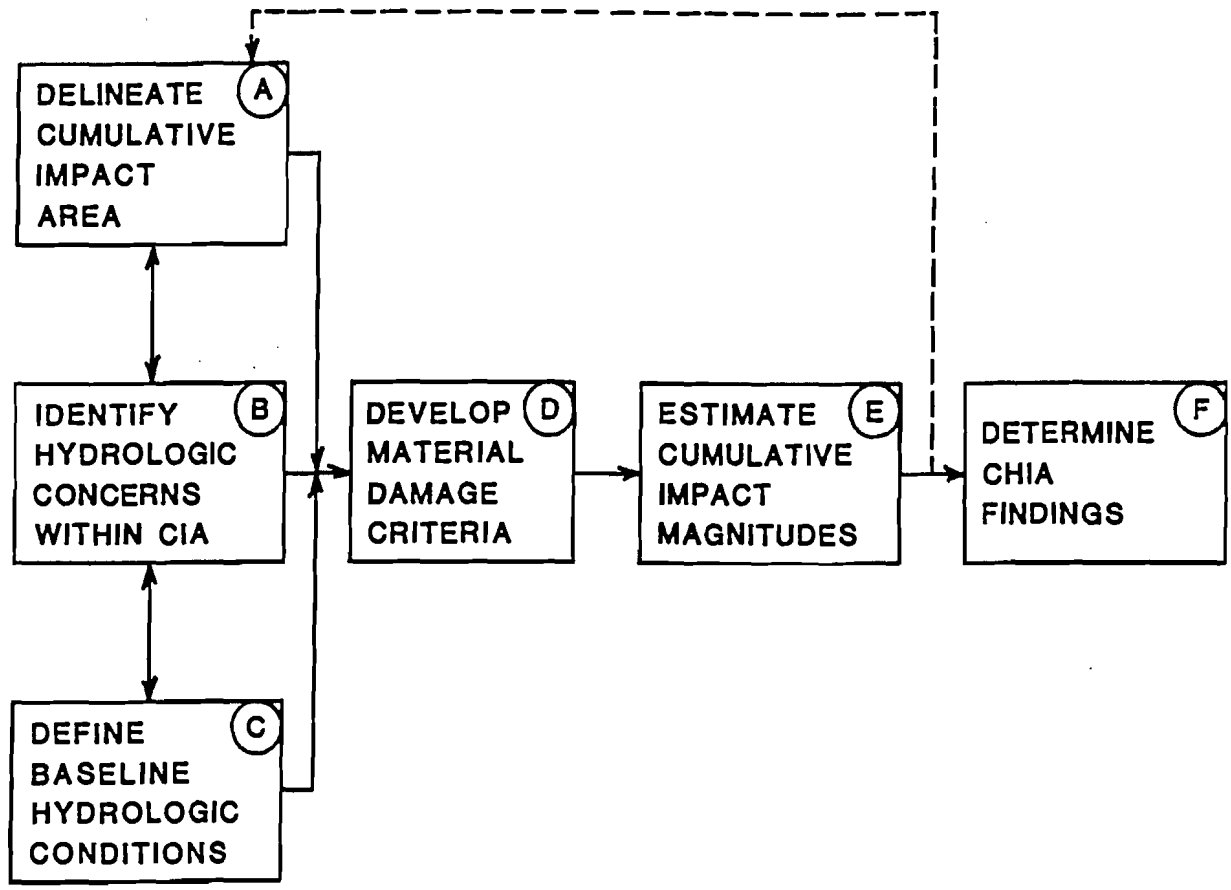

Figure II-1.--Flow diagram of basic CHIA process.

can be focused on these critical segments of the hydrologic system. The concerns can be identified from PHC data, as well as from other baseline data, historical data, or any source that raises valid questions about some aspect of the hydrology of the CIA. The specific parameters to be used to measure and evaluate the concerns, and the sites at which the concerns will be evaluated should also be identified. These parameters will be referred to as "indicator parameters" in the remainder of the guidance document. For example, a common concern associated with mining in the Western United States is increased salt concentration in the postmining ground-water supplies.

Element C.--Element C provides for the determination of baseline hydrologic conditions of the CIA. This determination should result in a description of the hydrologic system and how it functions. It should also provide the normal values of the indicator parameters at the beginning of mining. In effect, baseline conditions are indicators of the state of the hydrologic balance at the time of the analysis, and they provide reference points for evaluating the significance of future impacts (predicted values of indicator parameters) of mining.

Element D.--Under Element D, the regulatory authority establishes for the indicator parameters the threshold values beyond which material damage is likely to occur. It is here that the regulatory authority establishes what constitutes material damage for the CIA. Existing State and Federal water-quality standards should be used where applicable. Where standards are not already available, the regulatory authority will have to develop threshold values. These values normally will be in the form of maxima or minima, but, in some cases, rate-of-change limits (incremental limits) may be necessary. When, with increasing numbers of mines in the CIA, impact levels approach material damage threshold limits, the regulatory authority may wish to establish secondary limits (parameter value less than the material damage thresholds) to indicate when more rigorous and precise analysis procedures should be used.

Element E.--Element E involves estimating values that the indicator parameters are expected to attain as a result of coal mining. First, an analytical approach is adopted. If the combinational approach is used, specific analysis techniques should not be necessary because adequate impact assessments should already exist in the PHC's of the individual anticipated operations. In this case, the regulatory authority needs only to develop procedures by which the results of the individual PHC's can be rationally combined. If PHC's are not available for some of the "anticipated mining" operations, the regulatory authority must first develop PHC's or make equivalent analyses in order to use the combinational approach.

If the independent analysis approach is used, then specific techniques are necessary. Technique selection depends on many factors, but a primary consideration should be that the technique adequately account for the dominant physical conditions that characterize the subject hydrologic system. The selected techniques are applied to the total CIA using data assembled at Element C. The approach and techniques selected are extremely important to the outcome of the CHIA process and should be given careful consideration.

Exhibit 36

Element F.--The regulatory authority's final task in the CHIA process (Element F) is to determine whether the hydrologic assessment of the CIA (Elements A through E) indicates that the addition of the impacts of the proposed operation to those of the other anticipated mining may cause material damage to the hydrologic balance outside the permit area and to write a statement of these findings with all supporting evidence and rationale. The determination is the main objective of the whole CHIA process. The supporting evidence and rationale validate the determination.

The determination may be based on quantitative comparisons and/or on qualitative evaluations. Quantitative comparisons should be made whenever possible, but they need not be the sole basis for the determination. The regulatory authority has the flexibility of using qualitative factors along with quantitative comparisons to make final material damage determinations. Regardless of whether the determination is qualitative or quantitative, the rationale for the decisions must always be clearly stated.

The written statement of findings with supporting evidence and rationale should describe the actions taken to complete each of the process elements, with emphasis on justification for these specific actions or decisions. As a matter of expedience, this writing is suggested to be considered a part of each of the other elements, with the appropriate sections being completed as these elements are processed. In this way, the bulk of the writing will be completed when the analysis is completed. Then, in Element F, the statement would require only finalization. A suggested form and content for this document is given in Appendix A.

Exhibit 36

CHAPTER III

CHIA CONCEPTS

The CHIA is a novel concept for environmental protection, and all its possibilities should be explored in the process of developing working procedures for its implementation. An important first step toward compliance should be for the regulatory authority to develop a clear understanding of the language and the new terms used in the Act and regulations. This guidance document addresses the terminology in several places. The "Introduction" section defines terms not previously defined in 30 CFR 701.5. This chapter, Chapter III, expands upon, and explores in a broad and conceptual manner, the definitions of the terms "material damage to the hydrologic balance" and "cumulative impact area." These terms are further treated in Chapter IV, which suggests practical, working procedures for implementing the requirements conveyed by the terms. If the reader keeps in mind the differences in the various treatments of this terminology, the appearance of repetition should be minimized.

CONCEPT OF CUMULATIVE HYDROLOGIC IMPACTS AND CUMULATIVE IMPACT AREA

The focus of the CHIA assessments should be on the changes (type and magnitude) and conditions that are the direct result of large areas being mined by more than one operation and the possibility that these changes will result in material damage outside the permit area. In the following discussion of impacts and impact areas, the terms "mine" and "mining" refer to mining operations that are included in the definition of "anticipated mining."

To some users of this guidance document, the term "impact" may connote a severe or adverse condition. As used in this document, however, an impact is "any measurable change * * *." Therefore, a distinction is made between the occurrence of an impact and the severity of the impact. In general usage here, the term "impact" will refer only to the specific changes that are expected to occur and to the geographical area where they are expected to occur. It does not imply that the expected changes (impacts) will be damaging to the hydrologic balance; only that they may occur. Determination of the potential seriousness of the impacts is considered a separate and distinct problem in the CHIA process.

Clarification of the term "impact area" is also needed. A "hydrologic impact" is defined (see "Definitions") as "any measurable change in hydrologic parameters associated with a particular hydrologic system caused by surface and underground coal mining activities." It follows, then, that the impact area of an individual mine is the geographical area over which the mining activities cause measurable changes to the hydrologic system. The changes are expressed in terms of parameters representative of the hydrologic system. The mine's "true" impact area, then, is a composite of the subareas over which each hydrologic parameter is affected.

Exhibit 36

The only way to delineate the "true" impact area of a mine is by monitoring the representative parameters at numerous sites over the total time period during which the impacts occur (from before mining until after hydrologic equilibrium is restored after mining). Of course, the impact area would not be known until after the mining and reclamation were completed and, therefore, would not be useful for preparing CHIA's. Therefore, for PHC and CHIA purposes, the size, shape, and position of the impact areas must be estimated. The following discussion of true cumulative hydrologic impacts and cumulative impact area is offered to provide a basis for estimating the practical, "working" impact area.

"Cumulative hydrologic impacts" are the aggregate effects on hydrologic parameter values at a particular location in the hydrologic system, caused by existing and anticipated mining activities. The term is best explained by illustration. Consider the group of mines and leases depicted in figure III-1. Suppose that, at any downstream point, W, in the surface flow system, surface-water quantity and quality parameters could be monitored from a time prior to mining until the system regains equilibrium after the mining. This monitoring would provide a measure of the cumulative effects of the mining on the surface hydrology at point W. Plot A in figure III-2 shows the variation in total salt load over the monitoring period. The difference between the salt load value at any time, t, and the premining value would represent the accumulated change in salt load at time t caused by the mining. This assumes that there are no other types of development activity in the area to affect the system. Since several mines would have contributed dissolved salts into the flow system, this plot depicts the "cumulative" effect of these mines on salt load at point W. Similar measurements and plots at sites X and Y would show the cumulative impacts at those points.

From the preceding illustration, it should be apparent that the true cumulative hydrologic impacts are the net accumulated changes caused by the anticipated mining operations as integrated (combined) by the hydrologic system. The true cumulative impacts are not simple summations of the impacts from a group of individual mines selected according to rigid rules or on some arbitrary basis. Rather, they are the result of stresses on the system and their actual magnitudes can be found only by measurement. The impact values will vary, depending on where in the system and at what point in time they are measured. For CHIA purposes, the maximum expected changes are the relevant values.

As figure III-1 implies, the true impact accumulation area from several mines is not necessarily restricted to the immediate vicinity of the mines. In general, the impacts of concern will affect the quality or quantity of water in the hydrologic system, and most impacts will be transported by, or will in some way be related to, water flow through the system. Therefore, the impacts of a mine can be expected to move mainly downgradient, and the accumulation of impacts of two or more mining operations may occur at locations quite remote from their respective permit areas, or at a time far in the future. Therefore, when impacts of several mines feed into the same flow system as does the proposed mine, and irrespective of the relative locations of the mines within that system, there is theoretically a potential for accumulation of impacts.

Exhibit 36

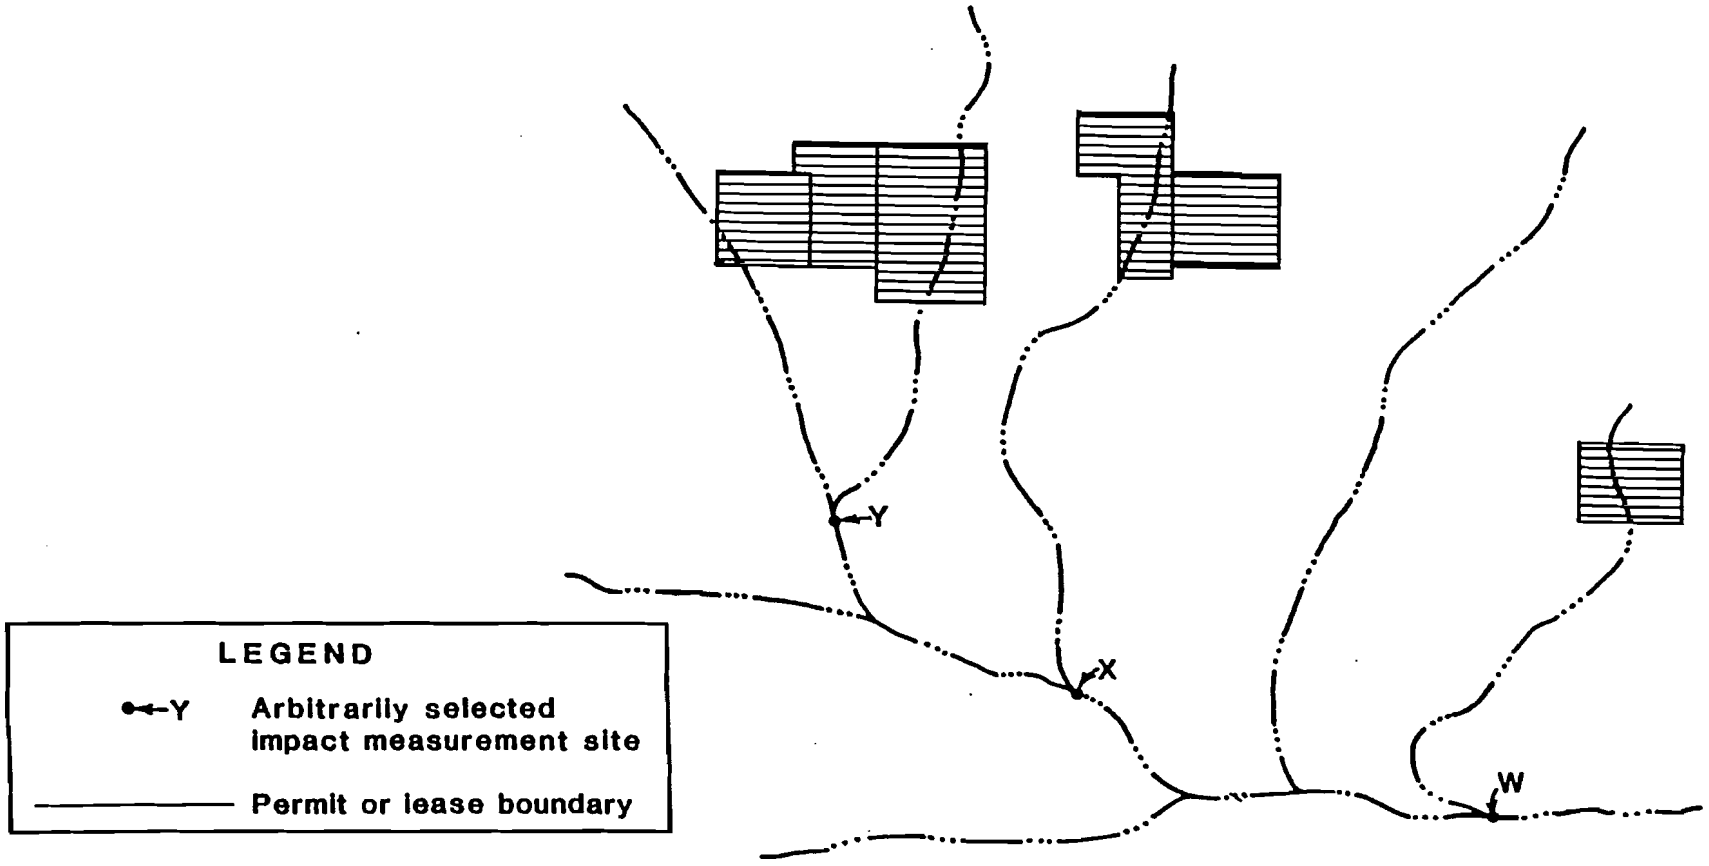

Figure III-1.--Hypothetical sites for measurement of "true" cumulative hydrologic impacts.

Exhibit 36

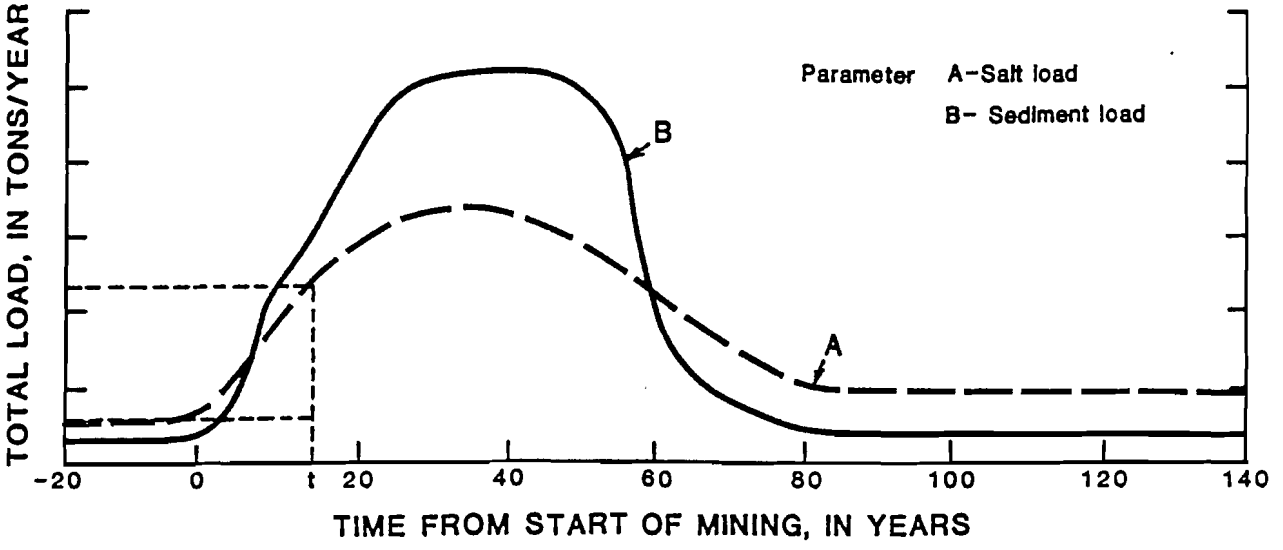

Figure III-2.--Plots of hypothetical cumulative hydrologic impacts measured at point W of figure III-1.

Exhibit 36

Following this line of reasoning, all mines within the same river system or ground-water flow system have the potential for impact accumulation with the proposed mine, and it could be argued that the CIA must extend to a point downgradient from the most downgradient mine in the river system. However, it is unlikely that Congress intended a CIA to routinely include whole river systems, as might be required if the preceding rationale were strictly followed. Therefore, the downstream extent of a CIA that is environmentally comprehensive and also satisfies the intent of the Act probably lies somewhere between the downstream boundaries of the proposed permit area and the farthest downstream mine in the river basin. The regulatory authority should develop a rational procedure for identifying this point. Preferably, the procedure would be based on hydrologic and mathematical theory and on professional judgment, rather than on professional judgment alone.

MATERIAL DAMAGE TO THE HYDROLOGIC BALANCE

The term "material damage to the hydrologic balance" may have various interpretations. The following discussion presents a conceptual interpretation of this term. The Permanent Program Regulations do not define "material damage" but do define "hydrologic balance" as "the relationship between the * * * water inflow to, water outflow from, and water storage in a hydrologic unit, such as a drainage basin, aquifer, soil zone, lake, or reservoir" (30 CFR 701.5). According to this definition, the hydrologic balance of a particular unit of the hydrologic system is the relationship of the inputs and outputs of water, and the full range of materials it may contain, to the unit. The specific relationship depends on the physical characteristics of the hydrologic unit and reflects gains and losses of output imposed by those characteristics. The balance of a hydrologic system, such as that within the CIA, can be thought of as the integrated relationship between all water inputs to and outputs from one or more hydrologic units that make up the system. These relationships can be quantified and defined by measuring the outputs and the corresponding inputs. One intended use of baseline hydrologic information is to define the existing preoperation relationships of the hydrologic system. Subsequent changes in system outflow may be considered as a measure of changes in the hydrologic balance, if the inflow is assumed to remain unchanged over the time period evaluated by the CHIA.

The concept that changes in the hydrologic balance are analogous to changes in the outputs of the system is illustrated graphically in figure III-3. Curve A represents a premining state of hydrologic balance between precipitation and runoff from a permit area. An example from the curve shows that 5 units of precipitation will produce approximately 25 units of runoff. When the area is mined, the consequent alteration of physical characteristics will result in some change in the relationship between precipitation and runoff. Curve B represents an estimate of this postmining state of the hydrologic balance. It shows that the area now produces only 15 units of runoff from 5 units of precipitation. The difference in runoff between curves A and B represents the predicted change to the hydrologic balance at a given input level as a result of mining. Quantitatively, the difference represents the change in outputs (runoff, in this case) caused by the altered physical state of the hydrologic system. This concept can be extended to all relationships used in the impact analysis. In developing an actual CHIA, quality as

Exhibit 36

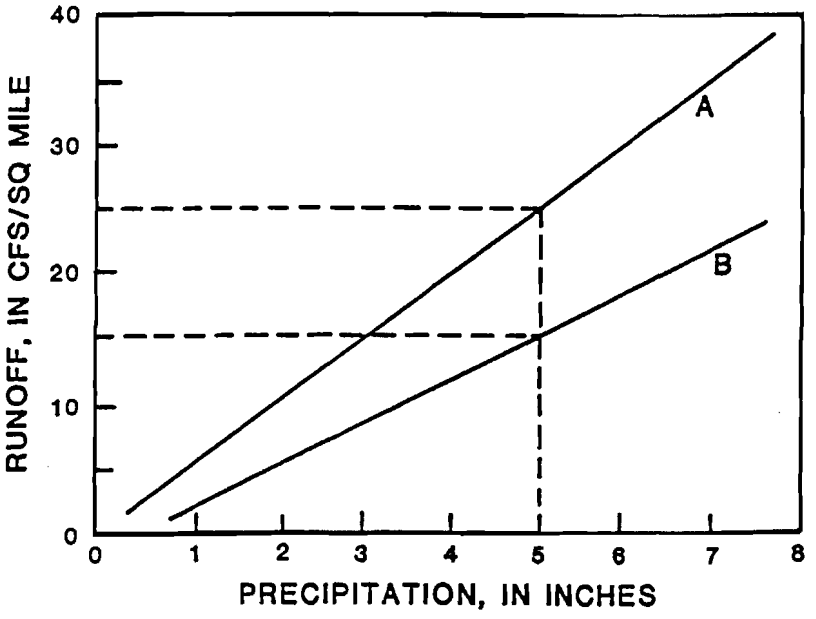

Figure III-3.--Hydrologic balance between runoff and precipitation for (A) premining conditions and (B) postmining conditions.

Exhibit 36

well as quantity relationships must be considered. The outputs discussed in the foregoing should be recognized as the parameters identified in Element B as the indices of the hydrologic concerns within the CIA.

Material damage to the hydrologic balance may be characterized by changes to the quality or quantity of surface water or ground water as measured by changes in particular hydrologic parameters or conditions. In terms of the foregoing discussion of hydrologic balance, this means that material damage occurs when postmining outputs exceed defined limits, or when the change in output which occurs in going from the premining relationship (e.g., the state of hydrologic balance) to the postmining relationship exceeds some prescribed amount. The establishment of allowable limits and of allowable increments of change for each parameter identified in Element B is the task to be accomplished in Element D. These limits are referred to in this guidance document as the Material Damage Criteria.

Exhibit 36

CHAPTER IV

ELEMENTS OF THE CHIA PROCESS

This chapter describes, in detail, the various elements that constitute the CHIA process.

ELEMENT A. DELINEATION OF CUMULATIVE IMPACT AREA

Element A deals with identification by the regulatory authority of the geographical area that the CHIA is to evaluate. The end product of this element is a delineation of the area within which cumulative hydrologic impacts of the proposed mining are expected to occur. Determination of the cumulative impact area should focus on the identification of the total area that contributes to the magnitude of hydrologic impacts outside the permit areas. Inherent in this identification process is the need to define the specific hydrologic system and to understand how it functions. Such understanding will facilitate CIA delineation, as well as the whole CHIA process, and will result in more rational and complete assessments.

OSM refers to the area which the regulatory authority must evaluate for the required CHIA as the "cumulative impact area" (CIA). The definition of CIA (30 CFR 701.5) provides the regulatory requirements for the delineation of a CIA. These requirements are very specific about the type of operation that must be evaluated but leave unclear the extent of the geographical area required for CHIA consideration. However, the parts are somewhat interdependent in that the CIA must include the impact areas of all "anticipated mining" operations, but "anticipated mining" includes only those operations that lie within the CIA. The preamble to the final rules (48 Federal Register 43956-43959, September 26, 1983) devotes considerable space to discussion of this definition and to comments received from the public relative to the definition. The reader is referred to this material in addition to the following discussion.

All Anticipated Mining Operations

The discussion of cumulative impact area concepts (Chapter III) centers on the geographical area alone. The other part of the CIA delineation process, discussed below, involves identification of the specific operations whose impacts must be included. The definition of CIA specifies the types of operations, which, at a minimum, must be included as "anticipated mining." In addition, "anticipated mining" also includes a time factor; that being, "at a minimum, the entire projected lives through bond releases of:" the above-listed types of operations (30 CFR 701.5, Cumulative Impact Area). This means that the total areas projected to be disturbed by mining and reclamation activities over the entire lives of these operations (not just the 5-year permit areas in effect at the time the CHIA is prepared) must be included in the CIA.

Of the specified types of operations, the proposed operation, existing operations, and operations for which permit applications have been submitted to the regulatory authority are most easily identified. Submitted applications are those which the regulatory authority has in hand, whether or not the application

Exhibit 36

has been certified as complete. Existing operations are those for which bond has not been released on the total mine plan area. Unpermitted operations, such as those of less than 2 acres for which a permit may not be required, are considered as existing operations and must be included in the assessment (48 Federal Register 43958, September 26, 1983). Completed operations--those for which total bond has been released prior to submittal of application for the proposed operation--need not be considered. It can be assumed that the CHIA baseline data will reflect any remaining impacts of completed operations.

The definition of Federal coal leases that must be included in the CIA needs amplification. By definition, Federal coal leases required to achieve diligent development need to be considered. More specifically, those Federal leases for which sufficient hydrologic, geologic, and mine development information is available to allow for accurate hydrologic impact assessment (such as planned mining and reclamation techniques, processes, schedules, etc.) must be considered. Federal coal leases exempt from diligence requirements and State and private leases may also be included as "all anticipated mining" if the regulatory authority deems it necessary.

All Federal coal leases and logical mining units (LMU's) issued after August 4, 1976, are required to achieve diligent development (Federal Register 33187, July 30, 1982). Federal coal leases issued prior to August 4, 1976, are required to achieve diligent development upon the effective date of the first lease readjustment after August 4, 1976. Any Federal coal lease included in an LMU is subject to the diligent development requirements imposed on the LMU (Federal Register 33187, July 30, 1982).

In addition, the amended Mineral Leasing Act (1920) requires that the leasee submit a resource recovery protection plan (RRPP) within 3 years of the effective date of a Federal coal lease. The RRPP must contain certain mine development information, as specified in 30 CFR 211.10. Leases obtained prior to August 4, 1976, are exempted from such requirements until the effective date of the first lease readjustment occurring after August 4, 1976. For the purpose of defining "all anticipated mining" in the CIA, it is suggested that the information required in the initial submittal of the RRPP for a Federal lease tract be used to satisfy the "sufficient mining development information" requirement in the definition of "anticipated mining." With this condition, only those Federal leases issued after August 4, 1976, and LMU's approved after that date for which RRPP's have been submitted and approved would have to be included in the cumulative impact area. Leases and LMU's effective before August 4, 1976, would not have to be considered as anticipated mining until they become subject to diligence and RRPP requirements after the first readjustment. Again, the regulatory authority may include, as anticipated mining, other operations, leases, and lands it deems appropriate.

In general, "anticipated mining" includes, as a minimum, all operations which have a reasonable expectation of receiving regulatory authority approval to mine and for which there is sufficient mining development information available to allow an adequate analysis (48 Federal Register 43957, September 26, 1983).

Exhibit 36

Delineation of a Working CIA

The need for a defined work area within which to conduct the CHIA is obvious. However, because it is impossible to delineate the "true" cumulative impact area before the impacts occur, the CHIA process must depend on an estimated CIA. (See Chapter III for discussion of true and working CIA's.) A CIA that is not excessively large yet accounts for all operations that may produce cumulative hydrologic impacts must be delineated. The delineation procedure that follows will help to specifically define such an area. This defined area is an estimate of the true CIA and will be called the working CIA.

An outline of the procedure is presented on pages IV-6 and IV-7. It consists of two phases and begins with consideration of a broad-scale CIA, which is subsequently reduced to a practical "working" CIA. Phase I provides for reduction of the broad-scale CIA to an intermediate area within which the working CIA can be delineated. Phase II accomplishes actual delineation of the working CIA. Once Phase I is applied to a region, the results should be generally applicable with little modification to subsequent CHIA's for the same vicinity. Phase II is the heart of the delineation procedure, will require the most effort, and should be applied to each individual CHIA separately. Both phases are necessary for a comprehensive delineation of the CIA.

To this point the CIA has been and will continue to be discussed as a single area unless otherwise stated. However, the surface- and ground-water systems are usually analyzed separately, and the impacted area of the ground-water system may very likely be entirely different in size and shape from the surface-water impacted area. Therefore, it may be advantageous for the regulatory authority to develop separate procedures for delineating surface- and ground-water CIA's. Such procedures must recognize and account for the interrelationships between the surface- and ground-water systems. The composite of these surface- and ground-water CIA's constitutes the working CIA.

Discussion of CIA Delineation Procedure

Phase I

The key to Phase I is development by the regulatory authority of specific criteria with which to test the impact significance of operations or groups of operations that are spatially and hydrologically distant from the proposed operation. These criteria can also serve to identify proposed operations that are "hydrologically isolated"; the CHIA's of such operations can be limited to the impacts of the proposed operation. The criteria should allow a quick evaluation of distant operations, but they should also be indicative of situations that may prove significant under more rigorous analysis. The criteria must not allow exclusion of operations in the immediate vicinity of the proposed operation whose impacts are likely to interact with those of the proposed operation. Once criteria have been developed and applied in a given region, the results should be applicable to subsequent CHIA's with little additional effort.

Possible approaches for developing such criteria follow; others may be equally appropriate. One approach is to compare the accuracy with which impacts can be measured at downstream sites in the surface-water system with the expected magnitudes of the impacts at the mines. By definition, a hydrologic

Exhibit 36

impact is a "measurable change." Therefore, impact magnitudes that are less than the inherent error of the measurement technique used could be considered to have insignificant accumulation potential with mines even farther downstream. Criteria based on this approach should specify, at a minimum, the parameters to be evaluated, the measurement methods to be used, and the associated ranges of measurement error.

A similar approach would use the dilution effect in the downstream direction as the basis for exclusion. At the point in the flow system where the pollutant concentrations become diluted to a predetermined level, the concentrations could be considered insignificant in a cumulative sense, and operations farther downstream could be excluded. Criteria based on this approach should specify what parameters to use for determining threshold dilution magnitudes and the threshold dilution levels.

Some States have quality standards for water entering from adjoining States. Where they exist, these standards could be the basis for exclusion criteria. It would be pointless to consider additional downstream mines if water in the system already fails to meet such standards. The regulatory authority might also take the position that if the water does meet these standards, then the State's obligations for cumulative impacts with out-of-State mines have been met. A possible drawback to this reasoning is that incentives to minimize cumulative impacts on a mine-by-mine basis are lacking until impacts have become of such magnitude that the standards are in danger of being exceeded.

Once developed, the criteria can be applied to mark the extremes of the working CIA along receiving streams common to two or more mining operations (these will be referred to as common receiving streams or common streams) in the vicinity of the proposed operation. Several limiting points may be necessary where more than one common stream originate in a probable CIA. When appropriate, upstream as well as downstream points should be located. The criteria can be applied to any logically selected point in the stream system; then to other upstream or downstream points, as the results indicate, until the criteria are satisfied; or, using a more systematic procedure, begin just upstream from the most downstream cluster of mines and proceed upstream to other clusters until the criteria are met. The delineated watershed area between the identified points is the first approximation of the working CIA.

Phase II

In Phase II, the area delineated above is refined and redelineated. The **first step** (see pages IV-6 and IV-7 for outline of procedure steps) of this phase is to identify all "anticipated mining" within the area. The types of operations that must be included have been discussed previously (see pages IV-1 and IV-2) and their identification should be routine. Identification of the downstream limit of the surface-water CIA (Step 2) simply involves locating a point downstream from the confluence of a common receiving stream with any tributary channels whose flows are likely to be affected by mining. Any stream that drains any part of a mine plan area or is close enough to a mine area to be affected by ground-water impacts should be included.

The downgradient limits of the ground-water CIA are defined in Step 3. This involves identification of the areas in which the strata and water levels in the

Exhibit 36

strata will be affected by mining or through which affected ground water may flow to reach a discharge point. Identification of strata likely to be affected by the anticipated mining operations and for which there is significant concern, and identification of aquifer recharge and discharge areas are a function of Element B and details of that process are discussed there.

The information necessary for delineation of ground-water drawdown areas and of areas through which plumes of degraded water may migrate should be available for all the anticipated operations which have submitted mine plans (PHC determination sections). For those operations for which PHC's are not available (qualifying leases), the regulatory authority will have to estimate the extent of these areas if this information is needed. Estimates based on information obtained from the PHC's of nearby operations should be adequate for most CIA delineation purposes.

Identifying those stream reaches in which the stream is losing water to the aquifer or gaining water from the aquifer may be more difficult, but this identification is important to understanding how the hydrologic system functions within the CIA. Such reaches are basically aquifer recharge or aquifer discharge (depletion) areas and therefore serve to transmit impacts from the ground to surface systems or vise versa. The PHC determinations in the individual permit applications should identify such reaches, but the regulatory authority should verify that all stream reaches important to the recharge or depletion of aquifers within the CIA have been identified.

Actual delineation of the working CIA is accomplished in Step 4. The procedure provides for separate delineation of surface- and ground-water CIA's; then, an area that encompasses both these CIA's is delineated as the working CIA.

The surface-water CIA boundary can be delineated by beginning at the downstream limits identified in Step 2.A and tracing along the natural drainage divides, or along the boundary delineated in Phase I, so as to completely encompass the impact areas of the operations identified in Step 1. The maximum upstream extent is the watershed boundary or any upstream limit identified in Phase I. It may be permissible to eliminate portions of this area. For example, if all the mining operations are on one side of a river valley, most of the watershed area on the opposite side of the river probably would not have to be included in the CIA because it is not directly impacted. However, the river valley floor and the floors of any common receiving streams must be included because these areas may be directly impacted, either by surface flows or by ground-water flows through the alluvium. The minimum working CIA should include the total watershed areas of all streams that flow across the mine plan areas of the anticipated mining operations and the proposed operation. It should also include all the area between any of the anticipated operations and the area from the operations to and including the valley floors common to receiving streams. Figure IV-1 depicts a surface CIA delineated by this procedure.

A ground-water CIA should be delineated for each impacted aquifer. The area over which a ground-water aquifer is impacted by mining basically extends from the minesites to the aquifer's discharge points. As with the surface CIA, an aquifer CIA should include all the area between the individual anticipated mining operations, as well as between the operations and the aquifer discharge points. In

Exhibit 36

addition, areas of projected potentiometric drawdown resulting from pit dewatering and production water withdrawals must be included.

Most aquifers affected by surface mining will somewhere discharge to the surface. At these places, the ground-water impacts become surface-water impacts. These discharge points can often be considered as one boundary of the ground-water CIA. The discharge areas of some regional aquifers may be so far away from the mined area that migration of degraded water to these points will take many years. The CIA boundaries for these aquifers can be taken as the estimated extent of degraded water plumes at a selected point in time after the plumes begin migration from the reclaimed spoils. Rationale for the time period used in these calculations should be discussed in the findings. The boundary of the aquifer CIA should surround the maximum extent of all degraded water plumes and drawdown cones expected to occur in the aquifer, including the areas between individual plumes and cones.

The ground-water CIA is the composite area of the individual aquifer CIA's, and, finally, the working CIA is the composite of the surface- and ground-water CIA's. Figure IV-2 depicts a ground-water CIA delineated by the outlined procedure. The working CIA, composited of the CIA's depicted in figures IV-1 and IV-2, is shown in figure IV-3.

Procedure for Delineating the CIA

(Evaluate interactively with Elements B and C)

Phase I.--Define maximum upstream and downstream extent of CIA.

Step 1. Develop criteria for excluding operations from the CIA that are spatially remote from the proposed operation but that are within the same major surface drainage system.

Step 2. Apply criteria to locate maximum extent of working CIA, both upstream and downstream from the proposed operation.

Step 3. The watershed area between these points is the first approximation of the CIA.

Phase II.--Delineate working CIA within area defined in Phase I.

Step 1. Identify all anticipated mining operations (i.e., life-of-mine areas of proposed operation, existing operations, operations with submitted applications, and Federal leases with diligence requirements) within the area defined in Phase I.

Step 2. Identify the downstream limit of the surface-water CIA.

A. Identify on a receiving stream common to two or more anticipated mining operations a point downstream from all tributary stream

channels whose flows are likely to be affected by the mining. Consider this point as the downstream limit of the surface-water CIA on that stream. Repeat on other receiving streams, as necessary.

Step 3. Identify the downgradient limit of the ground-water CIA.

A. Identify all geologic strata likely to be affected by the anticipated mining operations, including aquifers. Also, identify recharge and discharge areas for the aquifers.

B. Delineate area over which ground-water quantity and quality may be affected by the identified mines.

i. Delineate area of ground-water drawdown caused by each operation in each identified aquifer.

ii. For each identified aquifer, delineate area that ground-water pollution plume from each operation would pass through in moving from the mine to probable discharge points.

iii. Identify probable stream reaches that discharge into or receive discharge from ground-water aquifers affected by the identified mining operations.

Step 4. Delineate working CIA.

A. Surface-water CIA

i. Delineate surface-water CIA boundary along natural drainage boundaries which completely encompass all the impact areas of the operations identified in Step 2.A.

B. Ground-water CIA

i. Delineate ground-water CIA boundary to encompass the maximum extent of pollution plumes and areas of drawdown cones. Include all cones and plumes that affect or discharge to common surface streams or alluvial aquifers, or are contiguous with cone and/or plume of proposed operation.

C. The composite of the surface- and ground-water CIA's is the working CIA for the proposed operation.

The product of this procedure is a working CIA with which to begin CHIA evaluation.

Exhibit 36

ELEMENT B. HYDROLOGIC CONCERNS

The identification by the regulatory authority of hydrologic concerns (potential problems) related to the hydrologic balance and water uses that may occur or that may be compounded by the cumulative effects of the proposed mining operation and other anticipated mining operations is the function of Element B. The concerns identified in this element must have definable parameters so that material damage criteria may be established (Element D). The determination of hydrologic concerns has great significance to the CHIA process because these factors serve to define the collection requirements for baseline data, the CHIA techniques, and the determination of material damage. It must be remembered that additional or alternate hydrologic concerns may be considered by the regulatory authority to meet area-specific needs.

Baseline data that describe the hydrologic concerns in the permit area should be available in the mine-permit application. The PHC is described in the regulations and expanded in the PHC guidance document. Most concerns will be specified in the permit application, whereas some may be implied from hydrologic characteristics of the permit and adjacent areas. These concerns can be defined from the following information: (1) the location of the source of supply for all surface-water and ground-water uses, (2) the quantity and quality of water required to meet demands related to the different uses, and (3) the geomorphic processes that might be affected by changes in the water regimens. Also, publications of State agencies commonly provide information related to local or regional problems (see appendix B.1 in the appendices volume for sources of State water-quality standards) that may be applicable to specific concerns in the cumulative impact area. A literature search may be necessary to find applicable publications.

Hydrologic concerns are an expression of problems related to water use and the hydrologic balance that may occur as a result of coal mining. In order to determine the potential impact of the problems, it is necessary to select some physical or chemical parameters that are measurable and are representative of the problems.

The interrelationships between water use, hydrologic balance, and geomorphic conditions are shown in figure IV-4. Many of the hydrologic concerns that are identified will relate to more than one of the three listed factors. For example, flow rate can be related to water availability, seasonal variation, and channel erosion. The regulatory authority's objective is to identify quantity and quality parameters that will protect water use and the hydrologic balance and maintain geomorphic stability. Each factor should be considered separately.

Each water use should be identified in the cumulative impact area with the various types being grouped together. For example, irrigation uses will require water at about the same time and of the same quality. The quantity is usually related to flow rate and volume consumed per acre. The quality parameters for irrigation are usually total dissolved solids, sodium-adsorption ratio, and toxic elements, such as boron. The crops that are grown may have to be identified with respect to toxic element sensitivity in the impact area and would, therefore, have an impact on defining the cumulative impact area in Element A. Industrial and domestic water uses are quantified by diversion requirement and quality. Usually, domestic requirements are more restrictive than industrial. Domestic standards

Exhibit 36

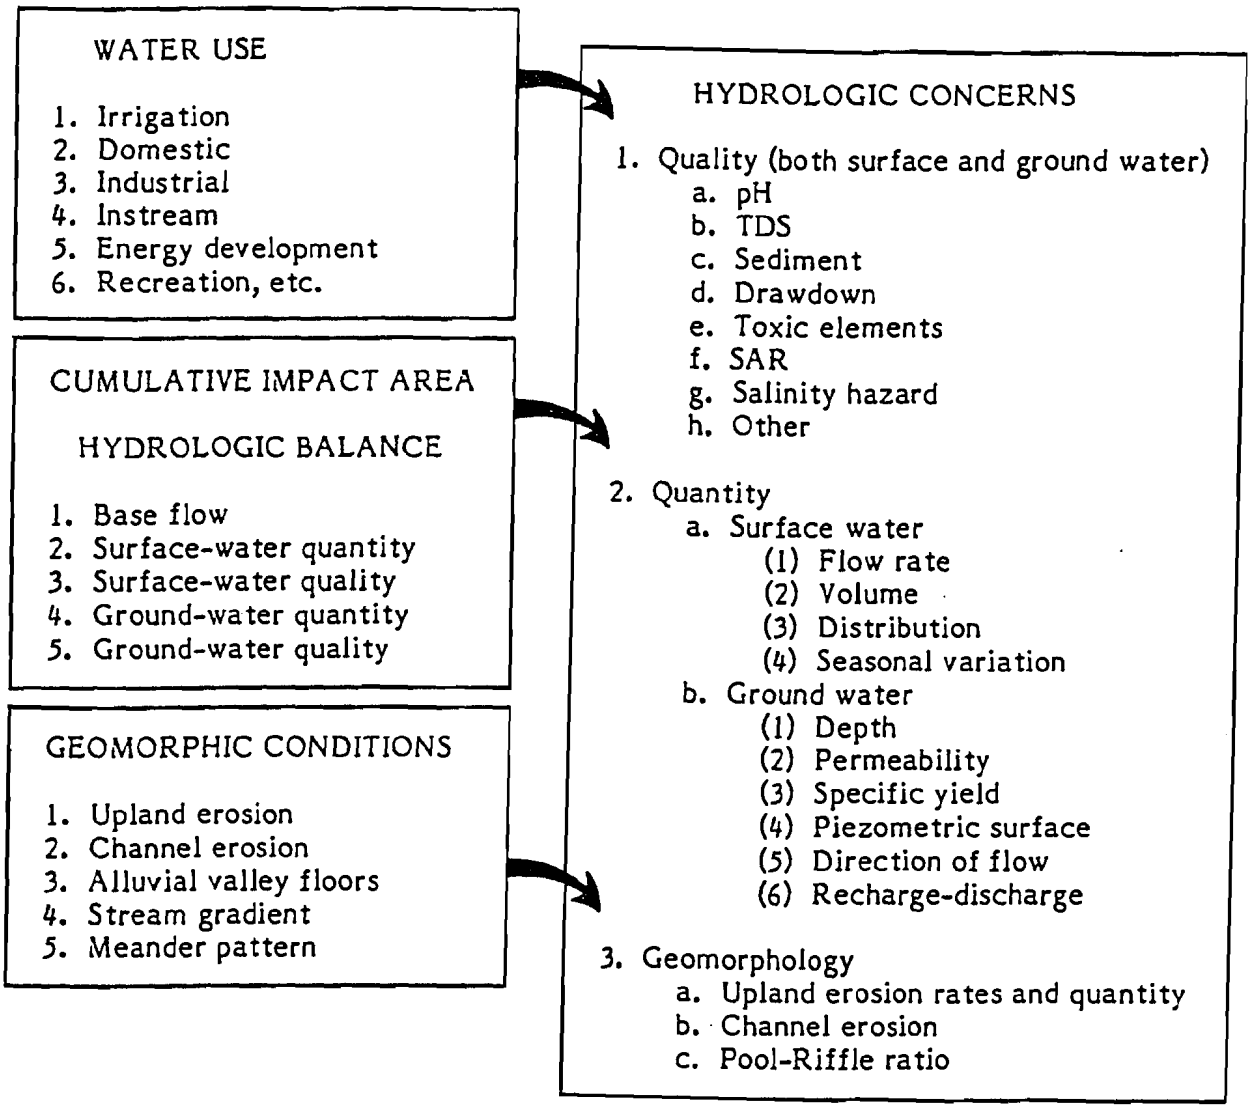

Figure IV-4.--Potential hydrologic concerns as related to cumulative impact area characteristics.

Exhibit 36

relate to total dissolved solids, sulfates, nitrites, radioactivity, hardness, sediment, pH, Fe, Mn, and bacterial quality. Usually mining will not impact on the bacterial quality and radioactivity of water. Instream use usually requires a certain minimum flow before adverse impacts occur.

Instream uses, such as fish propagation, may also limit maximum temperature and pH ranges. These values are dependent upon species present. Unique situations may require other considerations, such as have been determined by the U.S. Fish and Wildlife Service for endangered species in the Upper Colorado River basin. They have determined that any withdrawal of water constitutes material damage to the Colorado River squawfish and the humpback chub. They have also specified a way that the impacts can be mitigated at this time to allow continued withdrawals from the streams.

The hydrologic concerns differ greatly in the different coal regions of the United States. This is because the potential impacts of coal mining are dependent on the hydrologic conditions, such as rainfall amounts, temperature, water uses, geomorphic conditions, and geology. For example, typical hydrologic concerns in areas associated with the coal fields of Western United States may include but not be limited to the following:

1. Reductions in the quantity of available surface water and ground water may be critical because existing supplies in the region are relatively scarce and commonly are completely appropriated under State water rights administration. Available supplies may be reduced as a result of changes in surface runoff conditions or lowering of ground-water levels. Beneficial changes can also occur, such as reducing runoff peaks through increased infiltration and increasing base streamflow through increased ground-water discharges.

2. Increases in total dissolved solids (TDS) or sodium-adsorption ratios (SAR) in surface water or ground water may cause critical production losses where supplies are used in irrigation of crops.

3. Increases in the concentration of total suspended solids (TSS) may cause destruction of aquatic habitat or the loss of reservoir storage capacity due to siltation.

4. Changes in flow rates or suspended solids load of a stream can change the erosional balance, which may cause geomorphic instability. The adverse impact may be lowering of ground-water levels because of the downcutting of channels acting as drains which result in the ground-water level being lowered below the plant rooting depths.

5. Changes in water quality may be critical where an increase of one constituent may adversely affect water uses, such as increased concentrations of boron, selenium, iron, or manganese.

Some examples of hydrologic concerns included in the CHIA for areas in Western United States are as follows: (1) Operations of coal mines in Wyoming would lower the ground-water level and reduce the yield from domestic and livestock wells, and (2) mining operations in the Yampa River basin of Colorado would increase the total dissolved solids in streamflow due to the increased

concentrations in surface runoff and in ground water draining from the disturbed areas. These impacts must be assessed, as discussed in Element E, and evaluated for material damage,as discussed in Element F. These are many of the concerns that must be considered by the regulatory authority.

Typical examples of hydrologic concerns in areas associated with coal mining in the Eastern United States may include but are not limited to the following:

1. Changes in the chemical composition of streamflow due to the addition of acid mine drainage (e.g. total iron, total manganese, and pH) may cause deleterious effects in water used for public supplies and maintenance of aquatic organism populations.

2. Increases in the sediment load from the disturbed areas of mines may cause destruction of aquatic habitat in streams and ponds.

3. Changes in conditions affecting surface-water runoff may add to the flood hazard of a watershed.

4. Disturbances of overburden due to mine excavation may increase the availability of some chemical constituents that cause deleterious effects in water (e.g., total iron, manganese, aluminum, total dissolved solids, etc.).

An example of hydrologic concerns included in the CHIA, for mining along the Shavers Fork River in West Virginia, focused on a set of conditions (acidity and iron) that related to probable degradation of the chemical quality of surface water. These parameters were identified as being critical to fish production.

These are typical hydrologic concerns and include only a small number of possibilities. At each specific site and cumulative impact area, the hydrologic concerns must be determined on the basis of water usage in the area, existing water-quality standards, and local hydrologic conditions.

When the hydrologic concerns are being defined for a specific impact area, it is recommended that an inventory be made of all water uses which includes identification of sources, quantity and quality requirements, quality, type of use, and any known or existing water related problems. Water-quality standards and water-quantity requirements associated with the identified water users should also be evaluated. This type of approach provides an effective means of determining the hydrologic concerns that are important in terms of protecting the hydrologic balance and associated water uses. A similar inventory should be made regarding the geomorphic characteristics important to water uses that may be impacted by mining, such as alluvial valley floors, riparian zones, pool-riffle ratio, and sinuosity.

Table IV-1 has been included as a quick check to determine whether proper information has been evaluated to identify hydrologic concerns for the cumulative impact area identified in Element A. If this process is followed by the regulatory authority, it should protect the water resource values with respect to use, as

Exhibit 36

affected by water availability and water quality. The information presented in table IV-1, although not an exhaustive list, is an example of some of the steps the regulatory authority should complete in order to identify the hydrologic concerns. It may be expanded or reduced to suit area-specific conditions and considerations.

Table IV-1.--A partial list of types of information to define and evaluate hydrologic concerns

1. Define and quantify existing and projected water uses related to:
   a. Available surface-water supply.
   b. The quality of surface water in the basin.
   c. Available ground-water supply.
   d. The quality of ground water in the basin.

2. Describe existing and potential hydrologic problems related to:
   a. Concerns identified in mine-permit application.
   b. Concerns identified in previous CHIA studies.
   c. Problems identified in regional studies by State agencies.
   d. Water-quality problems that could be created by the chemistry of the overburden.
   e. Changes in runoff characteristics that cause geomorphic instability.

3. Select representative parameters for quantifying hydrologic concerns in order to evaluate changes and assess impacts on the hydrologic balance.

Table IV-2 contains the hydrologic concerns for a hypothetical example for the Black Hole mine. It lists the hydrologic concerns, the physical or chemical characteristics, and the specific parameters to use as a measure of the impact with respect to material damage. Procedures for identifying material damage threshold values are presented in Element D.

Exhibit 36

Table IV-2.--Hydrologic concerns for Black Hole example mine CHIA

Concern	Physical-chemical characteristics	Specific parameters
	Surface water	
Damage to fishing stream	Mean flow	Mean monthly discharge.
	Low flows--rate and duration	7-day, 10-year discharge ($7\text{-}Q_{10}$).
	Temperature	Degrees Celsius.
	Alkalinity, acidity, pH	$CaCO_3$ equivalent, pH.
	Suspended solids	Concentration at $7\text{-}Q_{10}$.
	Salts	TDS, sulfate ion.
Reservoir--fishing and irrigation	Stream inflows	Minimum annual volume.
	Alkalinity, acidity, pH	$CaCO_3$ equivalent, pH.
	Sediment	Annual volume.
	Suspended solids	Concentration during storm inflow.
	Ground Water	
Municipal wells	Water level in aquifer A	Percent of baseline saturated thickness.
	Water level in aquifer B	Percent of baseline saturated thickness.
	Salts	TDS.
	Geomorphology	
Potential upland headcutting	Hillslope gradients	Average slope, percent.
	Channel gradients	Maximum slope, percent.

Exhibit 36

ELEMENT C. BASELINE HYDROLOGIC INFORMATION

The assembly and evaluation of hydrologic baseline information by the regulatory authority is the function of Element C. The purpose of this information is to characterize the hydrologic system and define imposition of changes by the proposed mine operation. Much of the needed hydrologic and geologic information should be available in the mine-permit applications. Details of collecting and assembling these data are discussed in "Guidelines for a Probable Hydrologic Consequences Determination." Additional baseline data needed for parts of the cumulative impact area outside the permit boundaries must be obtained from other sources, such as the U.S. Geological Survey publications or other Federal and State data collection agencies. With the data presented in the PHC portion of the individual mines and other available data, the regulatory authority must be able to describe the hydrologic system sufficiently to understand the ground-water and surface-water interactions with respect to "anticipated mining" and the hydrologic concerns identified in Element B. The description should at a minimum describe the components of the hydrologic balance that must be protected. The baseline data should provide a basis for assessment of mining impacts with respect to the hydrologic concerns and be used to determine material damage. Establishment of material damage values or thresholds for the hydrologic concerns is covered in Element D.

Appendix C.1 provides potential sources of data from each State that may be useful to the regulatory authority to supplement baseline data contained in the PHC portion of the permit application. Data from outside the permit areas necessary to perform the CHIA must be available to the regulatory authority. For this reason it is essential for each regulatory authority to identify available hydrologic data associated with coal-producing areas of the State. When additional baseline data are required but are not site specific or are not contained in the permit applications, they must be obtained from other available sources, such as Federal and State agencies. The needed baseline data may also be provided by the mining company to expedite permit processing. These data requirements need to be identified as early as possible in the permitting process. It is essential that the information be sufficient to clearly define the hydrologic system, provide required data for analysis of the impacts, and provide a sound basis for assessment of material damage.

Data availability can be a major factor in selecting downstream boundaries of cumulative impact areas. For example, a long-term USGS stream-gaging station that collects both quantitative and qualitative data would provide good baseline data and control for the assessment of impacts. Additionally, the regulatory authority can use future data collected at the station as a check to evaluate the accuracy of the CHIA's and to monitor actual impacts of mining with time. The shorter periods of records collected at the minesites can be correlated with the longer records. These correlations can be used to describe the seasonal variation and to project both high- and low-flow values.

The duration and frequency of sampling required for baseline data should be based on the hydrologic concerns and the variability of the data. For example, streamflow changes rapidly during intense rainfall events. Usually, water-quality parameter values change with the discharge. Hydrologic data covering these situations are important to the understanding of the hydrologic balance of the cumulative impact area for determining the cumulative impacts.

Exhibit 36

Baseline data required to define surface-water systems commonly include both quantitative and qualitative information. In order to determine the adequacy of baseline data, it is necessary to describe the hydrologic systems in the cumulative impact area and to describe the type of information needed to define the functions and importance of those systems to the hydrologic balance. Existing baseline data from the permit application should be evaluated with respect to the methods of collection and analysis and the lengths of record. Other sources of hydrologic information also should be investigated, such as the Bureau of Land Management, U.S. Geological Survey, State Engineer, State water-quality agencies, etc. Apparent data deficiencies with respect to coverage, period of record, quality, etc., should be identified. The location and method of data collection for all planned monitoring sites set forth in the permit application should be evaluated with regard to applicability for mining and postmining information. Data related to streams may include quantitative values of average weekly or monthly flows, flow duration, flood-frequency distribution, and low flows. Data related to the quality of water in streams should include concentrations of dissolved constituents (particularly those elements or compounds having health, use, or regulatory limits that are associated with the hydrologic concerns), and the concentration and volume of suspended sediment (annual load or basin yield). Data associated with the use of surface water should include the location and rate of all diversions, the changes in diversion rights during periods of reduced streamflow, the quality standards in relation to the principal users, the rate and volume of use in relation to seasonal requirements, and the quantity of water exported from the basin. These baseline data must reflect the hydrologic concerns identified in Element B with respect to quantity and quality parameters.

Baseline data required to define ground-water systems commonly include a description of the lithologic, structural, and hydrologic characteristics of geologic units within the aquifer and overburden systems, the rate and direction of water movement as defined by the water table or potentiometric surface, the rate and direction of water movement between aquifer units or between the aquifer and associated streams, and the location and rate of recharge or discharge. Some of these baseline data may require measurement and testing, such as determining the aquifer properties of porosity, permeability, hydraulic conductivity, transmissivity, specific yield, and storage coefficient.

Data related to the quality of ground water generally includes the concentration and areal distribution of dissolved constituents, with particular emphasis on those elements or compounds having health, use, or regulatory limits. Additional data may be obtained for determining the quality of water contributed to the aquifer from recharge, the direction and rate of chemical transport, and the associated diffusivity, dispersivity, or geochemical reactions that could occur within the geohydrologic system.

Other data related to the use of ground water include the location and source of supply from all wells and springs, the rates of daily and seasonal withdrawals, and the quality of water in relation to the standards required by the principal users. Additional data should be obtained for determining the return flow to the aquifer or stream and the losses through evaporation and transpiration.

The baseline data should be collected at sites (ground water and surface water) located with respect to the impact areas, the anticipated mining and whether or not they can also be used as impact evaluation sites. It is imperative

Exhibit 36

that these sites be near the mining operation to reflect the hydrologic changes. Also, the points must be readily accessible for current and future data collection in order to monitor actual conditions. Data obtained at the evaluation must be reflective of the identified hydrologic concerns and must be quantifiable in terms of the criteria established for material damage. When future monitoring data are available for comparison with estimated values, verification of results can be used to improve the predictive capabilities of the regulatory authority.

Tables IV-3, IV-4, and IV-5 have been included for use to evaluate the adequacy of the baseline data. These tables should not be construed as providing exhaustive or mandatory lists. The regulatory authority should carefully review these tables and modify them to meet site-specific conditions. Table IV-3 covers surface water, table IV-4 covers ground water, and table IV-5 covers the geomorphic conditions that relate to erosion and stream channel stability. Both the upland and channel erosion are of concern and must be considered in the determination of material damage. The regulatory authority must determine how important the geomorphic considerations are with respect to each mining environment.

Table IV-3.--Baseline hydrologic data useful for characterizing the surface-water system

1. Description of drainage basin in relation to runoff.
   a. Total area, topographic relief, basin length, and average basin slope.
   b. Precipitation records that include monthly or seasonal data for snow pack accumulation and rainfall.
   c. Geologic characteristics that affect runoff or streamflow.
   d. Chemical and physical properties of the overburden.
   e. Soil characteristics from soil surveys with respect to infiltration, runoff, and erosion.
   f. Summaries of vegetation types and land use.

2. Description of streamflow characteristics.
   a. Type of streams (perennial, intermittent, or ephemeral).
   b. Streamflow data collected and tabulated to describe mean annual and mean monthly discharges.
   c. Streamflow related to frequency and duration of floods to include:
      (1) Floods of 2-, 10-, 25-, and 100-year recurrence.
      (2) Flows of different frequency and duration for structure design.
   d. Nature of frequency and duration of low flows related to water use:
      (1) Quantitative diversion rights.
      (2) Low-flow water quality related to stream standards and water user needs.
      (3) Annual low flows and period of occurrence.
      (4) Relate low flows to normal base, mean annual, and high flows.
   e. Water quality characteristics with respect to seasonal flow:
      (1) Major ions (Ca, Mg, Na, K, HCO_3, CO_3, Cl, SO_4, TDS).
      (2) Trace elements (Fe, Mn, As, Hg, B, Pb, Zn, Ag, Cu, Cr, Ba, etc.).
      (3) Other (temperature, pH, suspended solids, settleable solids, bacteria)

Exhibit 36

Table IV-4.--Baseline hydrologic data useful for characterizing the ground-water system

1. Physical description of aquifer (or aquifers) in relation to the geohydrologic framework of the area.
   a. General description of aquifer units in relation to other stratigraphic units.
   b. Physical description of aquifer and associated confining beds as indicated from test holes, drillers' logs, and geologic maps to include: (1) extent, (2) thickness, (3) lithology, (4) structure, and (5) type of rock.

2. Hydrologic description of aquifers
   a. Description of aquifer in terms of well yields and water use.
   b. Description of confined or unconfined aquifer conditions.
   c. Definition of water table or potentiometric surface as determined from test holes and observation wells.
   d. Delineation of saturated thicknesses, direction of water movement, and areas of recharge and discharge.
   e. Determine gain or loss of base flow in streams in relation to associated ground water.
   f. Water movement between aquifer units and between the aquifer and streams.
   g. Aquifer properties determined by testing that include porosity, permeability, hydraulic conductivity, transmissivity, specific yield, and storage coefficient.

3. Chemical properties of water in the aquifer.
   a. Major ions (including Ca, Mg, Na, K, HCO_3, CO_3, Cl, SO_4, TDS).
   b. Trace elements (including Fe, Mn, As, Hg, B, Pb, Zn, Ag, Cu, Cr, Ba, etc.).
   c. Other (temperature, pH, bacteria).

4. Characteristics of overburden
   a. Physical destruction of resistant rocks into an erodible aggregate.
   b. Potential chemical constituents from the disturbed overburden that may affect the water quality (acidity, alkalinity, salinity, and other toxic elements).

Exhibit 36

Table IV-5.--Baseline hydrologic data useful for characterizing the geomorphic stability

1. Basin characteristics related to sediment discharge.
   a. Description of basin in terms of area, length, slope, etc.
   b. Describe geologic characteristics that affect runoff and sediment yield.
   c. Summarize the type and extent of different soils with respect to erodibility.
   d. Summarize the type and extent of vegetation and land use.
   e. Describe channel conditions prior to mining (bedrock bottom, stream bottom, armored, bank conditions, riparian, etc.)

2. Stream characteristics related to sediment discharge.
   a. Type of stream (perennial, intermittent, or ephemeral) in relation to general flow characteristics.
   b. Define nature of flow related to frequency and duration of 2-, 10-, and 25-year floods.
   c. Describe such stream channel characteristics as width, depth, gradient, sinuosity, etc.
   d. Obtain samples of suspended sediment and bed load related to a broad range of stream discharges.
   e. Estimate hydrologic characteristics of ungaged streams on the basis of channel geometry (methods have been described by USGS for most Western coal areas).

3. Erosion and sediment potential in mined areas:
   a. Describe probable effects of erosion and sediment yield during the mining and reclamation phases.
   b. Estimate flow and sediment yield from 2-, 10-, and 25-year floods for design of sediment control structures.
   c. Relate proposed drainage design to geomorphic stability of mined areas after reclamation.

Exhibit 36

ELEMENT D. ESTABLISHING CRITERIA FOR DETERMINATION OF MATERIAL DAMAGE

Section 507(b)(11) of the Act requires a determination of probable hydrologic consequences caused by mining and reclamation operations, both on and off the minesite. However, the CHIA process for permit approval or denial under Section 510(b)(3) of the Act requires that these impacts be evaluated to determine whether the proposed operation has been designed to prevent material damage to the hydrologic balance outside the permit area. Therefore, the regulatory authority must have and must include in the assessment report the criteria by which the potential for material damage can be assessed. These criteria are needed for comparison with the quantitatively or qualitatively predicted impacts of mining that will be obtained through the process outlined in Element E. The product of Element D will be a set of site-specific values for selected parameters used to measure the material damage at each of the predictive points identified in Element B. The criteria should be established prior to completing the projection of impacts in Element E.

There are two bases for the development of these criteria. One is the evaluation of material damage in terms of the effects on the hydrologic system. For instance, a logical extension of the discussion of hydrologic balance concepts (Chapter III) would be to define material damage in terms of the statistics of the premining relationship (A in fig. III-3). For example, if the increment of change from premining to postmining conditions exceeds one standard deviation, the regulatory authority may determine that that change constitutes material damage. The regulatory authority may determine that some other deviation is a more appropriate threshold. Another example would be to express material damage in terms of the proportional disturbance of the cumulative impact area (i.e., material damage will occur if more than a defined percentage of the area is disturbed). Basing material damage criteria on the characteristics of the system is a plausible approach, but it may present difficulties in establishing workable criteria.

The other, more obvious approach is to establish material damage in terms of specified water uses. It is a common regulatory practice to focus on designated uses. However, material damage criteria based on water use should consider both instream and out-of-stream requirements. This means that water-contact recreation, fish habitat, and the needs of aquatic organisms must receive equal consideration with industrial, domestic, and agricultural uses. Although either approach is acceptable, and in some cases the use of both may be desirable, regulatory authorities will probably base material damage criteria on water use considerations.

Discussion of Procedure for Defining Material Damage Criteria

The material damage criteria, of course, cannot require less than the existing laws, standards or regulations. Therefore, the **first step** in developing these criteria is to assemble all existing standards and determine which apply to the cumulative impact area and to the identified hydrologic concerns. Most established standards relate to water quality and its effect on specific uses. Water quantity generally is regulated through water rights laws.

On the Federal level, the Environmental Protection Agency is the major source of standards on water quality. At the State level, several agencies may

Exhibit 36

have established standards relating to water quality, rights and use. Appendix B.1 in the appendix volume lists the primary agencies in each State that are possible sources of existing water-quality standards. Counties and cities may also have established standards for water protection and use, especially in metropolitan areas, and should be considered a possible source of existing water standards. It may be expedient to develop an exhaustive listing of standards during the initial cumulative hydrologic impact assessment so that subsequent impact assessments would require only the addition of newly established or modified standards.

After all of the applicable water use standards that apply to the cumulative impact area have been assembled, it should be determined which of the hydrologic concerns and associated parameters identified in Element B are not covered by these standards and which concerns are only partially covered. Also, it may be determined that some of the existing standards are not as stringent as the regulatory authority deems necessary, thus requiring new standards. At this stage, it is assumed that the identified concerns and associated parameters address all the required and desirable aspects to be assessed in the hydrologic system, particularly ground-water and surface-water quality and quantity, and any concerns for the geomorphic stability of the cumulative impact area.

The second step of Element D is the development of criteria for the concerns that are not adequately covered by existing standards. In any given region, standards for an identified concern may be lacking. Concerns that are most likely to lack standards are those relating to ground water and geomorphology. Few States have standards that apply to ground water, and probably none have standards that apply directly to geomorphology. Because entities other than the SMCRA regulatory authority may be trying to resolve many of the same issues (such as agencies that regulate sanitary landfills and toxic waste disposal areas), such agencies should be contacted for suggestions regarding the development of needed criteria. In fact, it would be advisable to develop a statewide policy on protection of hydrologic resources prior to the time specific standards are needed. Then all State-developed standards would have a common basis, which would minimize the possibility of conflict between material damage criteria and the requirements of other regulatory agencies.

One of the more difficult and crucial tasks in the CHIA process is the development of material damage criteria for concerns that have no existing standards, or for which existing standards are not sufficiently comprehensive or stringent. These criteria should be developed cautiously because they may become precedents for establishing the State or areawide standards. Because the criteria must be tailored to regional needs, only general guidance can be provided here.

SMCRA specifically requires the assessment of cumulative impacts "particularly upon water availability * * *" (Section 507(b)(11), and by implication requires that the available water be of adequate quality for the uses designated by the regulatory authority. Development of criteria for limiting changes in surface water discharges commonly will be based on use requirements that are specified by existing water rights. The quantity requirements should consider the probable postmining uses and existing uses, including instream uses and the variation of water quantities used throughout the year. The effects of changed discharge regimes on channel stability also should be considered. Increases in peak discharges may create a flooding potential that could result in channel degradation. On the other hand, a diminished flow regime may cause sediment deposition in

Exhibit 36

stream channels, an undesirable condition for most instream water uses. On the assumption that water rights require approximate maintenance of premining water quantities and that increases or decreases in stream discharges may cause changes in channel morphology, material damage criteria should be designed to maintain the flow regime within a small percentage of the baseline quantities.

The major concerns about the cumulative impacts of the mining on ground-water availability tend to focus on the maintenance of streamflows and pumping requirements. The drawdown of the potentiometric surface in the vicinity of the mine is a common impact of mining on the ground-water system. Thus, it is logical to express material damage criteria for ground-water quantity in terms of the potentiometric surfaces affected. Because high water tables also can cause problems in some areas, the criteria may need to address both rises and declines in the potentiometric surface. The development of these criteria then becomes a matter of determining how much change in the potentiometric surface can be sustained without causing material damage to the hydrologic balance of the ground-water system.

Although ground water and surface water are presented as separate entities in this guidance document, it is imperative that the relationship between them be understood and considered in setting limiting criteria. Some items that should be considered are the interrelationships of surface and ground water, long-term rate of recharge to the aquifers, rate of recharge to the reclaimed spoils, rates of recharge relative to rates of use, and the possible impedence of ground-water movement by the reclaimed spoil material.

The increased public concern during the past decade and a half for the quality of the nation's water supplies has led to the establishment of water quality standards by various regulatory agencies. These standards generally are based on the maintenance and protection for specified water uses. Although standards for surface water are most numerous, some States also have established standards for protection of ground water. Material damage criteria for both ground-water and surface-water quality can be developed, in many cases, from existing standards; several sources of information are available to the regulatory authority for guidance. The regulatory authority in nearby States may have established standards for similar concerns. Another source of information is a compilation by McKee and Wolf (1963) regarding the water-quality criteria promulgated by State and interstate agencies as well as legal application of such criteria. Also, EPA (1976) has provided information on the toxic levels of many water polluting substances relative to specific uses. In situations where the aquifer discharges into the surface stream system, the effects of this discharge on the quality of surface flows should be considered in developing ground-water material damage criteria.

Geomorphic concerns probably will focus on channel and hillslope erosion most often. The most likely areas of cumulative concern are increased sediment loads in the streams, the possibility of channel downcutting with its attendant dewatering of alluvial aquifers, and dissection of the land surface with gullies. Criteria for addressing these problems probably should focus on limiting channel and hillslope gradients in the reclamation areas. Hillslope gradients which are within approximate original contour requirements (30 CFR 816.100-106) may not be adequate in terms of erosion potential. In the Western United States, landscapes commonly are carved in layers of erosion-resistant rock that keep stream gradients relatively steep. After the mining process breaks up these

Exhibit 36

supporting layers into a variety of smaller fragments, stable gradients for both hillslopes and channels are likely to be different from the premining gradients. The material damage criteria must assure erosively stable slope gradients relative to expected postmining conditions (i.e. vegetative cover, particle-size distribution of reclaimed overburden, etc.).

Step three involves establishment of criteria for any aspects of material damage assessment that have not been categorized. A possible example of this type is the consideration of whether incremental change limits are needed for some parameters.

There is a possibility that the impacts of a single mining operation may "use up" the total allowable change from baseline levels to the maximum allowable limit. To prevent this possibility, it may be necessary to set incremental change limits for some parameters. However, actual changes should already be at a minimum if the permitted operations are, in fact, designed to minimize the impacts to the hydrologic balance, as required by the regulations.

The nature of other hydrologic concerns may dictate that limits be set on the time-rate of change of certain parameter values. For example, some species of aquatic life may be able to survive relatively high water temperatures, but the rate of change of the temperature must be commensurate with the organisms ability to acclimate to temperature changes. The acclimation rate will differ with species and rate-of-change limits may be necessary to assure survival of the specific species. Dissolved oxygen content is another parameter for which rate-of-change limits may sometimes be necessary. The need for both types of incremental limits should be considered in the process of developing material damage criteria.

Step four of Element D suggests that the regulatory authority the design of a specific set of material damage criteria for each evaluation site identified in Element B. Site-specific criteria are necessary because each site could have a different set of conditions to be evaluated. The design of these criteria sets should be a relatively simple part of the process if Steps 1 through 3 have been properly completed. EPA (1983, Chapter 11) has published guidelines for deriving site-specific water quality criteria. The regulatory authority may wish to use these EPA quidelines to develop site-specific material-damage criteria, or to use them as a pattern for its own guidelines. The product of this step and of Element D is a listing of the material damage criteria for each parameter identified at each evaluation site.

Once criteria have been established for the coal-producing areas of a State, they should be applicable to subsequent CHIA's without additional developmental effort. Periodic review and updating should assure that the correct criteria are available at any time.

Procedure For Defining Material Damage Criteria

The following steps are suggested as a process for establishing material damage criteria:

1. Assemble existing State, Federal, and local standards which apply to the expressed hydrologic concerns (product of Element B).

a. Source of standards.

(1) U.S. EPA.

(2) State agencies.

(3) City and county agencies.

b. Identify parameters not adequately addressed by existing standards by comparing existing standards and identified parameters.

2. Develop limiting values for parameters associated with hydrologic concerns not covered by existing standards.

a. Water quantity.

(1) Consider any quantity change defined by applicable water rights.

(2) Consider needs of probable uses.

(3) Consider possible channel stability problems resulting from discharge changes.

b. Water quality.

(1) Consider standards used by surrounding States.

(2) Consider quality requirements for present and potential uses.

(3) See U.S. EPA (1976) and McKee and Wolf (1963) for suggested limits of specific constitutients relative to use.

c. Geomorphology

(1) Consider need for reduced channel and hillslope gradients in the postmining environment.

3. Develop any additional criteria considered necessary for an adequate assessment of material damage.

a. Need for incremental change (or time rate of change) limits.

4. Establish a site-specific set of material damage criteria for each predictive point identified in Element B. These sets of criteria are the product of Element D.

a. Apply appropriate criteria from lists developed in Steps 1 through 3.

Exhibit 36

ELEMENT E. ANALYSIS OF CUMULATIVE HYDROLOGIC IMPACTS

Analysis of the hydrologic system with the imposed stress of the anticipated mining to determine its probable impacts and their magnitudes is the goal of Element E. More specifically, the regulatory authority's task involves estimation of the magnitudes of changes that the indicator parameter values can be expected to experience as a result of mining. Accomplishment of this task may best be achieved by first selecting an analytical approach, then selecting the specific techniques and methodology to be used, and, finally, making the analysis.

Two basic analytical approaches have commonly been used to date in the development of CHIA's. One approach is to combine the results (estimated values of indicator parameters) presented in the PHC portions of individual mine plans into composite impact values for the CIA. Use of this approach requires the regulatory authority to develop PHC's for any "anticipated mining" operations for which PHC's are not available (leases, 2-acre exemptions, etc.). The other approach is to make an independent hydrologic analysis of the CIA, using the data provided in the permit application package and in the PHC portions of other applicable mine plans, as well as pertinent data from any other sources. In a given situation, one or the other of these approaches may be appropriately used.

The basic difference between the two approaches is **not** a difference of specific techniques used with each approach; rather, it is one of how selected techniques are applied and by whom. The PHC of each mine operation is normally determined by a different analyst using a different specific set of analytical techniques. Under the combinational approach, the actual combining of these PHC results to obtain the cumulative impacts would involve yet another set of techniques and another analyst (that is, the regulatory authority). Each analyst is likely to make his own assumptions about the hydrologic system. The combination of results obtained from such unrelated bases may invite severe criticism if not rejection. With the independent analytical approach, the same set of techniques would be applied over the whole CIA by the same analyst(s). Therefore, the independent approach could generally be expected to give the most consistent, uniform, and accurate results. From a strictly hydrologic standpoint, the independent analytical approach would be valid in all cases. Use of the combinational approach would be most appropriate early in the development of an area when cumulative impacts could be expected to be small.

Once an analytical approach is adopted, suitable hydrologic estimation techniques can be selected. If the combinational approach is used, specific analytical methods and techniques are not needed because estimates of impacts should already exist in the individual PHC's. However, suitable procedures for combining parameter values are needed because the simple addition of values is not a valid combinational procedure for some hydrologic parameters. For example, flow routing procedures are necessary for combining the peak discharges of two streams, and a discharge-weighted average procedure is needed to determine the concentrations of substances at different locations in the stream system. Therefore, for the combinational approach, the regulatory authority needs to select or develop valid procedures by which results of the individual PHC's can be combined.

If the independent analytical approach is used, then appropriate analytical methods and techniques must be selected. Technique selection depends on many

Exhibit 36

factors, but a primary consideration should be that the technique adequately account for the dominant physical processes occurring in the hydrologic system being evaluated. The required degree of accuracy is another important consideration. In some cases, a worst case analysis may be adequate. However, when values of the indicator parameters approach the material-damage threshold levels, more rigorous and accurate techniques may be needed to verify that the material damage thresholds are not violated.

Methods for predicting cumulative impacts may be classified into the following broad categories:

1. Qualitative methods.

2. Empirical equations and statistical correlations.

3. Physical process models of the hydrologic system.

Qualitative methods are those which provide for systematic evaluation of qualitative data inputs and predict a range of output values. They rely heavily on the judgment of the user, who should be a competent hydrologist and highly knowledgeable about the method and the CIA being assessed.

The second category includes a wide range of techniques, equations, and statistical correlations by which values of various hydrologic parameters, under specified conditions, can be calculated. The universal soil loss equation (Wischmeier and Smith, 1965), the Theis equation (Theis, 1935), and the Muskingum flow routing equation (McCarthy, 1938) are examples of techniques in this category. Brief discussions relative to the specific uses of these and other methods in categories 2 and 3 can be found in appendix D.1.

A complete hydrologic analysis would require application of one or more of these techniques in proper order. Thus, the Theis equation would be used to calculate aquifer transmissivity and storage coefficients from pump test data, and these parameters would, in turn, be used to calculate aquifer flow rates and the extent of drawdowns. For CHIA analysis, the appropriate methods would be systematically applied to all mine operations in the CIA, giving appropriate consideration to possible effects of adjoining operations. These calculations can be facilitated by use of programmable hand-held calculators or minicomputers. Programs for many of these methods are generally available (Croley, 1977; OSM, 1981).

The final category of techniques is comprised of hydrologic models which simulate the physical processes in the hydrologic cycle with mathematical equations. In all but the simplest hydrologic systems, the equations governing the system processes are either too numerous or too complicated to be solved by direct mathematics. Therefore, the high speed computational capabilities of digital computers are usually needed to solve the equations.

Models provide the analyst with a means of integrating the responses of interrelated processes of the hydrologic system. In this way, all processes of the system can, in theory, by analyzed with a single procedure. Because all components of the system are automatically and systematically considered, the model and its solutions should more nearly reflect real physical systems than does

Exhibit 36

the piecemeal application of individual category 2 techniques. However, the underlying concepts of the individual models and the availability of data are also extremely important to the analysis outcome. In any case where the data base is extensive enough to allow adequate calibration and verification of the models for each set of watershed conditions to be modeled, then physical process models should give excellent results and their use should be strongly considered for that particular CHIA analysis.

Hydrologic models have been designed to accomplish a wide variety of analyses. To date, the need for a single model that analyzes all aspects of the hydrologic cycle has been limited. The complexity of such a model would tax the computational abilities of even today's high-speed computers. Therefore, most physical process models are limited to a particular segment or segments of the hydrologic cycle. Some model the surface-water processes; others, the ground-water system. Still others deal with water pollutants and their transport through the system. A comprehensive surface-water model would include routines for modeling the dilution and transport of water-quality constituents, as well as the generation of upstream and upland runoff volumes and stream discharge rates.

Models also vary in the degree of capability. Some will generate water volume input (surface runoff or aquifer recharge) and route this water into and through the stream channel or aquifer systems. Others only route through the system water quantities calculated by other methods. The same alternatives are available for water quality models.

Another division of model characteristics is between long-term or continuous models and those that only simulate individual storm events. Event models simulate the effects of selected storms on a given set of antecedent conditions. Several simulations using selected antecedent conditions for critical periods of the hydrologic cycle would be necessary for a CHIA analysis. Continuous models account for the cumulative effects of precipitation, evapotranspiration, soil moisture storage, pollution buildup, and so forth; therefore, changes in antecedent conditions are automatically and continuously updated during a simulation run. A CHIA assessment done completely by modeling would require a full range of model capabilities.

Whatever techniques or combinations of techniques are selected, the analytical process must have the capability of predicting water quantity and quality changes (changes in availability) under seasonal conditions. It should also have the capability of determining magnitudes of changes and of routing those changes through the system to the downgradient boundary of the CIA. The time span for the analysis period should cover the mining, reclamation, and postreclamation phases in order to determine maximum impact magnitudes, when the maximums occur, and the rates of recession from the maximum values.

The following is a partial list of considerations that may be useful to the regulatory authority in selecting the appropriate methods and techniques for an independent analysis of cumulative hydrologic impacts:

1. Desired accuracy and precision of results.
2. Available baseline hydrologic data and information.
3. PHC analysis results for anticipated operations,

4. Previous hydrologic studies in the CIA.
5. Identified hydrologic parameters.
6. Time and resources available for the analysis.

Qualitative review of these factors by a hydrologist with experience and knowledge of analytical methods should indicate which general categories of methods are appropriate for the CIA to be assessed. Evaluation of the available hydrologic data is a critical factor, as it affects not only which specific methods can be successfully used but also the accuracy of results that can be achieved with that method. Also, each technique is based on certain assumptions about the conditions of the hydrologic system. Application to systems with conditions significantly different than the assumed conditions can seriously affect the accuracy of the technique, and this factor should be an important consideration in the selection of techniques.

A problem with many of the methods for projecting impacts occurs when the characteristics of the hydrologic system are changed by the mining. Most hydrologic prediction methods must be calibrated and verified if they are to give reliable results. Only with calibration and verification can the accuracy of a method be determined. Calibration involves adjusting fixed-value parameters until predicted outputs closely simulate or "fit" previously measured outputs of the system. Once a "good" fit is obtained, the method is said to be calibrated for the system from which the measured data were obtained. Verification involves using the adjusted parameter values with different input values for the system and comparing the measured outputs with the predicted outputs. However, if the system subsequently is altered, then the method is no longer calibrated and the accuracy of its predictions is unknown. For predicting impacts of coal mining, fixed-value parameters are usually calibrated to premining conditions. After the system is disturbed by mining, accuracy of results are unknown, unless the method has also been calibrated in a similar physiographic and climatic area under similar mining conditions. From calibrations under similar mining conditions, model parameter values can be selected to represent the mining conditions.

Use of physical process models requires sufficient data to calibrate and verify the models for each set of watershed conditions to be modeled. If a model can be satisfactorily calibrated and verified to establish parameters values for the existing and anticipated land use conditions over a physiographic region, coal region, or CIA, then this "precalibrated" model can probably be applied repeatedly within that region for a reasonable cost. However, if the model must be recalibrated for each application, its use may not be cost effective.

After selection of necessary methodology, it is applied according to good hydrologic practice and professional judgment. If results indicate that impacts extend beyond the working CIA boundary, the boundary delineation should be adjusted and the analysis modified accordingly.

Procedure for Analysis of Cumulative Hydrologic Impacts

1. Select analytical approach.
   a. Combinational approach.
   b. Independent analytical approach.
2. Select specific techniques and methodology.

Exhibit 36

a. Qualitative methods.
b. Empirical equations and statistical correlations.
c. Physical process models.

3. Analyze CIA for cumulative hydrologic impacts.

ELEMENT F. DETERMINATION AND STATEMENT OF FINDINGS

The final task in the CHIA process (Element F) is to determine whether the hydrologic assessment of the CIA (Elements A-E) indicates that the additional impacts of the proposed operation may cause material damage to the hydrologic balance outside the permit area and, then, to write a statement of these findings, giving all supporting evidence and stating the rationale used. This determination is the main objective of the whole CHIA process. The supporting evidence and rationale validate the determination.

The determination may be based on quantitative comparisons and/or on qualitative evaluations. A quantitative determination is a comparison of analytical estimates for the defined indicator parameters (product of Element E) with the corresponding material damage threshold values for these parameters (product of Element D). A qualitative determination is a judgment determination by the regulatory authority based on all available evidence. For this final determination, the minimum acceptable evidence consists of an adequate PHC evaluation for the proposed operation and for each "anticipated mining" operation within the CIA. Whenever possible, the quantitative approach should be used, but qualitative determinations may also be appropriate. Regardless of whether the determination is qualitative or quantitative, the rationale for the decisions should must always be clearly stated.

Both approaches should probably be used for most determinations. Certainly, quantitative comparisons are most defensible. However, estimating future values of hydrologic parameters is uncertain at best, as is the task of clearly defining what constitutes "material damage" and what does not. For a variety of reasons, one cannot be certain of the correctness of answers provided by hydrologic estimating procedures. Also, different procedures may result in a range of values that straddle critical levels. The natural variability of hydrologic processes may necessitate that damage levels cover ranges rather than single, precise values. To make material damage determinations solely by comparison of estimated values to single-value criterion ignores the fact that natural forces are variable. Quantitative comparisons can be used, but they should not be the sole basis for the material-damage determination. The regulatory authority should use qualitative factors along with quantitative comparisons to make final material-damage determinations.

Exhibit 36

The following two-part procedure is suggested for accomplishing Element F:

I. Determine potential for material damage.
   A. Make quantitative comparisons of estimated parameter values with the applicable material-damage criteria assembled in Element D.
   B. Make qualitative comparisons of the parameters for which quantitative evaluation is not appropriate.
   C. Make the final determination of whether impacts from the proposed operation accumulated with the impacts of other anticipated operations may cause material damage to the hydrologic balance outside the permit area.
II. Prepare a statement of CHIA findings.
   A. Introductory information.
   B. Documentation to justify actions.
   C. Statement of findings.

Discussion of Procedure for Determination of Material Damage Potential

Despite the uncertainties of quantitative hydrology, it remains the most defensible means of assessing cumulative hydrologic impacts and should be used at every possible opportunity. The procedure is to compare the predicted magnitudes of the defined indicator parameters (product of Element E) to the corresponding material-damage criteria thresholds for these parameters (product of Element D). This comparison should indicate the potential for material damage to the hydrologic balance outside the permit area. Any necessary conditions for comparison should be spelled out as part of the identification of hydrologic concerns (Element B). For instance, the flow conditions under which total dissolved solids concentrations are to be evaluated should be considered as part of the information needed to characterize the concern for salt loading. The specific wording of these criteria becomes especially important when, with each additional mine, cumulative impact magnitudes approach critical levels. If damage conditions are clearly identified as part of the concern, then the material-damage criteria and the estimated values for the indicator parameters (Element E) can be stated in similar terms and units, and quantitative determinations should be relatively straightforward.

When first estimates indicate that material damage thresholds may be exceeded, the regulatory authority may wish to reevaluate the impact prediction procedures used. Some kinds of modifications to the estimating procedures may be appropriate. For example, worst case conditions are commonly assumed as a means of simplifying the estimation process. It is common CHIA practice to assume that the maximum impacts of all the mining operations within the CIA will occur at the same time. When an analysis based on this assumption indicates potential material damage, a reanalysis using the actual timing sequence of the mining operations may reduce the impact estimates to nondamage levels. Such adjustments are acceptable and proper. However, it would be difficult for the regulatory authority to justify reevaluations in which individual input parameter values are adjusted to obtain favorable output magnitudes.

Qualitative analysis may enter the process at two levels. The first is in determining the magnitudes of the indicator parameters and comparing these

Exhibit 36

values to the material damage criteria. The second is in making the final determination of whether impacts of the proposed operation accumulated with the impacts of the other anticipated operations will result in material damage to the hydrologic balance outside the permit area. In the first case (Step I.B of procedure), the analyst applies professional judgment to all available evidence, which may include analytically derived, as well as qualitative, information, to arrive at a material damage determination for each indicator parameter. In the second case (Step I.C), the regulatory authority considers the comparisons made in Steps I.A and I.B, and any other relevant factors to arrive at a CHIA permitting decision. In either case, the rationale used in making the qualitative determination is, in effect, the methodology. Thoroughly document this rationale either directly or by reference, just as analytical methods would be described, as this rationale is the primary defense against potential challenges to qualitative evaluations.

Qualitative estimates allow the regulatory authority to consider all relevant factors in making the final determination. Also, in early development stages of a coal field, while there are few operating mines and minimal impacts, qualitative evaluations may be wholly adequate. However, as the number of operations increases, increased use of quantitative procedures is recommended. But even when the CHIA is mostly quantitative, the regulatory authority should have, when making the final material damage determination, the option to qualitatively consider factors which are not amenable to the more mechanical quantitative comparison approach.

If the determination is negative (material damage to the hydrologic balance is probable), and the regulatory authority determines that no further evaluation of the determination is warranted, the negative finding is reported, granting of a permit is delayed, and the CHIA process is finished for the time being. Mitigating actions by the company to further minimize impacts of the proposed mine would be handled outside the CHIA process as part of the overall permit processing procedure (fig. II-1).

Preparation of Statement of Findings

The second part of Element F involves writing of a statement of findings with supporting evidence and rationale. This statement should describe the actions taken to complete each of the process elements, with emphasis on providing the justification for these specific actions or decisions. It should also document the assessment findings as to whether the addition of the proposed operation to the other anticipated mining will cause material damage to the hydrologic balance outside the permit area. For expediency, preparation of the written statement should be considered a part of each of the other elements, with the appropriate sections being completed as these elements are processed. In this way, the bulk of the writing will be completed when the analysis is completed. Then, at Element F, the statement would only require finalization and the writing of an executive summary. A suggested form and content for the CHIA document is given in Appendix A.

At a minimum, the statement should cover three broad topics. The first is introductory information, which should include why this specific CHIA is necessary (new application, modification, and so forth), and a very brief statement of other mining activity in the immediate area. It should mention any previously prepared CHIA's for the area that are incorporated in the present effort, and it should

Exhibit 36

specify any significant difference between approaches used in the present and previous efforts. The statement should also include any information of a general nature that adds to the understanding of the situation and conditions dealt with in this CHIA.

The second is a thorough discussion of actions taken in the evaluation of each element. This discussion will comprise the bulk of the statement and should reflect how the assessment was done and the reasons for specific actions and decisions. The discussion of each element should touch on three basic points:

1. It should document all parts of the analysis that are significant to the outcome of the element product. A partial list of appropriate topics would include the analytical approach used to evaluate the element, the specific methods used, assumptions made, specific parameters used or excluded, appropriate maps and illustrations, description of the portion to the system being analyzed, any exceptions made to the normal procedure, and applicable statutory and regulatory requirements. Any topic necessary to convey what actions were taken in the evaluation of the element and how they were accomplished should be included in this discussion.

2. The discussion of each element should emphasize the justification for each specific decision made during the evaluation of the element. The justification of decisions is an integral facet of the CHIA process. The rationale for using one option over others, and exceptions to normal procedure should be thoroughly documented. Any decision or action may be challenged in the subsequent phases of the permitting process; therefore, the regulatory authority should have legally and scientifically valid reasons for those actions.

3. The discussion of each element should include an illustration or listing of the product resulting from the evaluation of the element. The desired element products have been described in this guidance document in the discussions of the individual elements. For example, a map showing the delineation of the CIA should be a standard illustration for Element A of these statements. The locations of evaluation sites, a partial product of Element B, should also be shown on this map. The listing and discussion of the element products should clearly describe those products and their use to the remainder of the assessment.

The final topic to be addressed in the findings statement is a statement of conclusions and the findings relative to the potential for material damage to the hydrologic balance. This finding is the ultimate objective of the assessment. The discussion should summarize the major reasons for the finding and state any special conditions or stipulations that the finding is contingent upon. Any significant differences from previous CHIA's in the area and the probable reasons for the differences should be noted. Upon completion of the statement, an executive summary should be prepared for general use and for inclusion in the permit application package.

APPENDIX A

RECOMMENDED CHIA REPORT CONTENT

The final product of the cumulative hydrologic impact assessment is a report that fully documents all aspects of the study and its findings. The report must stand along without the permit application or the permit decision document. The outline that follows suggests a generally acceptable list of contents for a CHIA report. However, it may not include all items that require discussion for a particular study. The exact report contents are site dependent, and, therefore, this outline should be modified as necessary. However, report topics should include all the major steps of the CHIA process. The report should, among other things, thoroughly describe the subject hydrologic system, discuss the adequacy of the data set used, provide the rationale for delineation of the CIA, state hydrologic concerns for the CIA, describe and justify the methods and techniques used, define damage criteria, and generally document and justify each decision made in the course of the study and each conclusion drawn from the study.

REPORT CONTENT

(Note: Materials shown in parentheses indicate the types of items that should be discussed under the indicated topic headings.)

I. Executive summary
II. Introduction
III. Discussion of CHIA process elements
    A. Cumulative impact area
        1. Maximum upstream and downstream extent of CIA
            (a. Discuss criteria used to evaluate significance of spatially remote operations)
            (b. Discuss application of criteria and resulting CIA extremes)
            c. Delineate watershed area between these points on suitable map.
        2. Delineate watershed area between these points on suitable map
            (a. Specify anticipated mining operations and locate on map)
            (b. Discuss process of delineating surface-water CIA)
            (c. Discuss process of delineating ground-water CIA)
            (d. Show working CIA on suitable map.
    B. Hydrologic baseline conditions in the CIA
        1. Adequacy of available hydrologic data
            a. Surface-water data
            b. Ground-water data
        2. Characterize the hydrologic system
            a. General description
            b. Surface-water system
                (i. Describe surface-water system)

Exhibit 36

III. Discussion of CHIA process elements--Continued
B. Hydrologic baseline conditions in the CIA--Continued
2. Characterize the hydrologic system--Continued
b. Surface-water system--Continued
(ii. Quantify surface flows)
(iii. Quantify surface-water quality)
(iv. Inventory surface-water usage, location, and quantity)
c. Ground-water system
(i. Describe ground-water system)
(ii. Quantify ground-water flows)
(iii. Quantify ground-water quality)
(iv. Inventory ground-water usage, location, and quantity)
C. Hydrologic concerns and associated indicator parameters
1. Surface-water concerns
a. Identify concerns
(i. Discuss rationale for inclusion of each concern)
b. Indicator parameters used to evaluate surface-water concerns
(i. Discuss reasons for selection of specific parameters)
c. Impact assessment sites
(i. Discuss selection of sites where impacts are to be assessed)
(ii. Locate sites on map of CIA (Use map prepared in step III.A.1.c))
2. Ground-water concerns
a. Identify concerns
(i. Discuss rationale for inclusion of each concern)
b. Indicator parameters used to evaluate ground-water concerns
(i. Discuss reasons for selection of specific parameters)
c. Impact assessment sites
(i. Discuss selection of sites where impacts are to be assessed)
(ii. Locate sites on map of CIA
D. Material damage criteria
1. Existing water-quality standards
2. Existing water-quantity standards
3. Development of limiting parameter values for concerns inadequately covered by existing standards
4. Site-specific material damage criteria
(a. Prepare list of criteria for each parameter at each site)
E. Assessment of cumulative impacts of mining on indicator parameters
1. Mining methods used within the CIA
(a. Describe the mining methods being used)
(b. Discuss effects of various mining methods on hydrology of the CIA)

III. Discussion of CHIA process elements--Continued
    E. Assessment of cumulative impacts of mining on indicator parameters--Continued
        2. Surface water
            a. Predictive methods used
                (i. Discuss reasons for using these methods)
                (ii. Discuss assumptions of the methods
                (iii. Discuss data requirements of the methods
                (iv. Discuss procedure used to calibrate method)
            b. Projected values of indicator parameters at identified surface-water impact sites--long- and short-term impacts
                (i. Discuss difference in procedure to obtain short-and long-term parameter values)
                (ii. Quantity parameters for each site)
                (iii. Quality parameters for each site)
        3. Ground water
            a. Predictive methods used
                (i. Discuss reasons for using these methods)
                (ii. Discuss assumptions of the methods
                (iii. Discuss data requirements of the methods
                (iv. Discuss procedure used to calibrate method)
            b. Projected values of indicator parameters at identified ground-water impact sites
IV. Determination and statement of findings
    A. Determination of material damage potential
        1. Surface water
            a. Comparison of projected values with material damage criteria
                (i. Discuss comparison procedures used)
            b. Potential for material damage to the surface-water system
        2. Ground water
            a. Comparison of projected values with material damage criteria
                (i. Discuss comparison procedures used)
            b. Potential for material damage to the ground-water system

APPENDIX B

EXAMPLE CHIA FINDINGS REPORT

This example is offerred to show the kinds of information that should be included in a CHIA findings statement. Because examples tend to simplify real conditions, they may not address all topics that should be addressed for a specific real-world site. This example is no exception. Therefore, the specific topics addressed and the specific way they are addressed should not be construed as the only ones that need to be presented, or that this is the "best way" to present them. Especially the results, conclusions, and lines of reasoning leading to the conclusions, as presented here, may not be valid for a specific real situation. Only the actual conditions of the specific CIA should govern how and what should be presented in a findings statement.

CUMULATIVE HYDROLOGIC IMPACT ASSESSMENT FOR THE BLACK HOLE MINE

INTRODUCTION

Coalo Energy Company has submitted an application for a permit to mine its leasehold lying in portions of sections 9, 10, 11, 14, 15, 16, and 17, T. 51 N., R. 71 E., in Anchor County. This is the first permitting application for the mine, which is known as the Black Hole mine. There are two presently active mines in the immediate area (Prairie Chicken and Mud Hen), one recently completed mine (Old Crow), and several lease tracts. A CHIA was prepared approximately 1 year ago for the Prairie Chicken mine, and all applicable information from that document was used in the present effort.

DELINEATION OF THE CUMULATIVE IMPACT AREA

Maximum Possible Extent of CIA

The major river basin (river that discharges into the ocean) associated with the proposed Black Hole mine is that of the Coal River. Within the Coal River basin, coal is being mined in four widely separated areas (fig. B-1). Three of the areas are located on tributaries to the Gold River, which is tributary to the Coal River. The fourth area lies adjacent to the Coal River valley. The mines in these four areas include all operations whose impacts could possibly accumulate with those of the proposed operation.

A CHIA was conducted about 1 year ago for the Prairie Chicken mine, which is located in the same area of development as the proposed mine (Area I, fig. B-1). That assessment determined the maximum downstream extent of the CIA for the mines in Area I to be at the mouth of the Padre River (Point A, fig. B-1). The determination was based on the dilution of estimated total salt load from each of the mines in the Coal River basin. The analysis showed that the increased salt load in the Coal River at Point C would be less than the error inherent in methods available for measuring total salt loads. Therefore, it was concluded that the

Exhibit 36

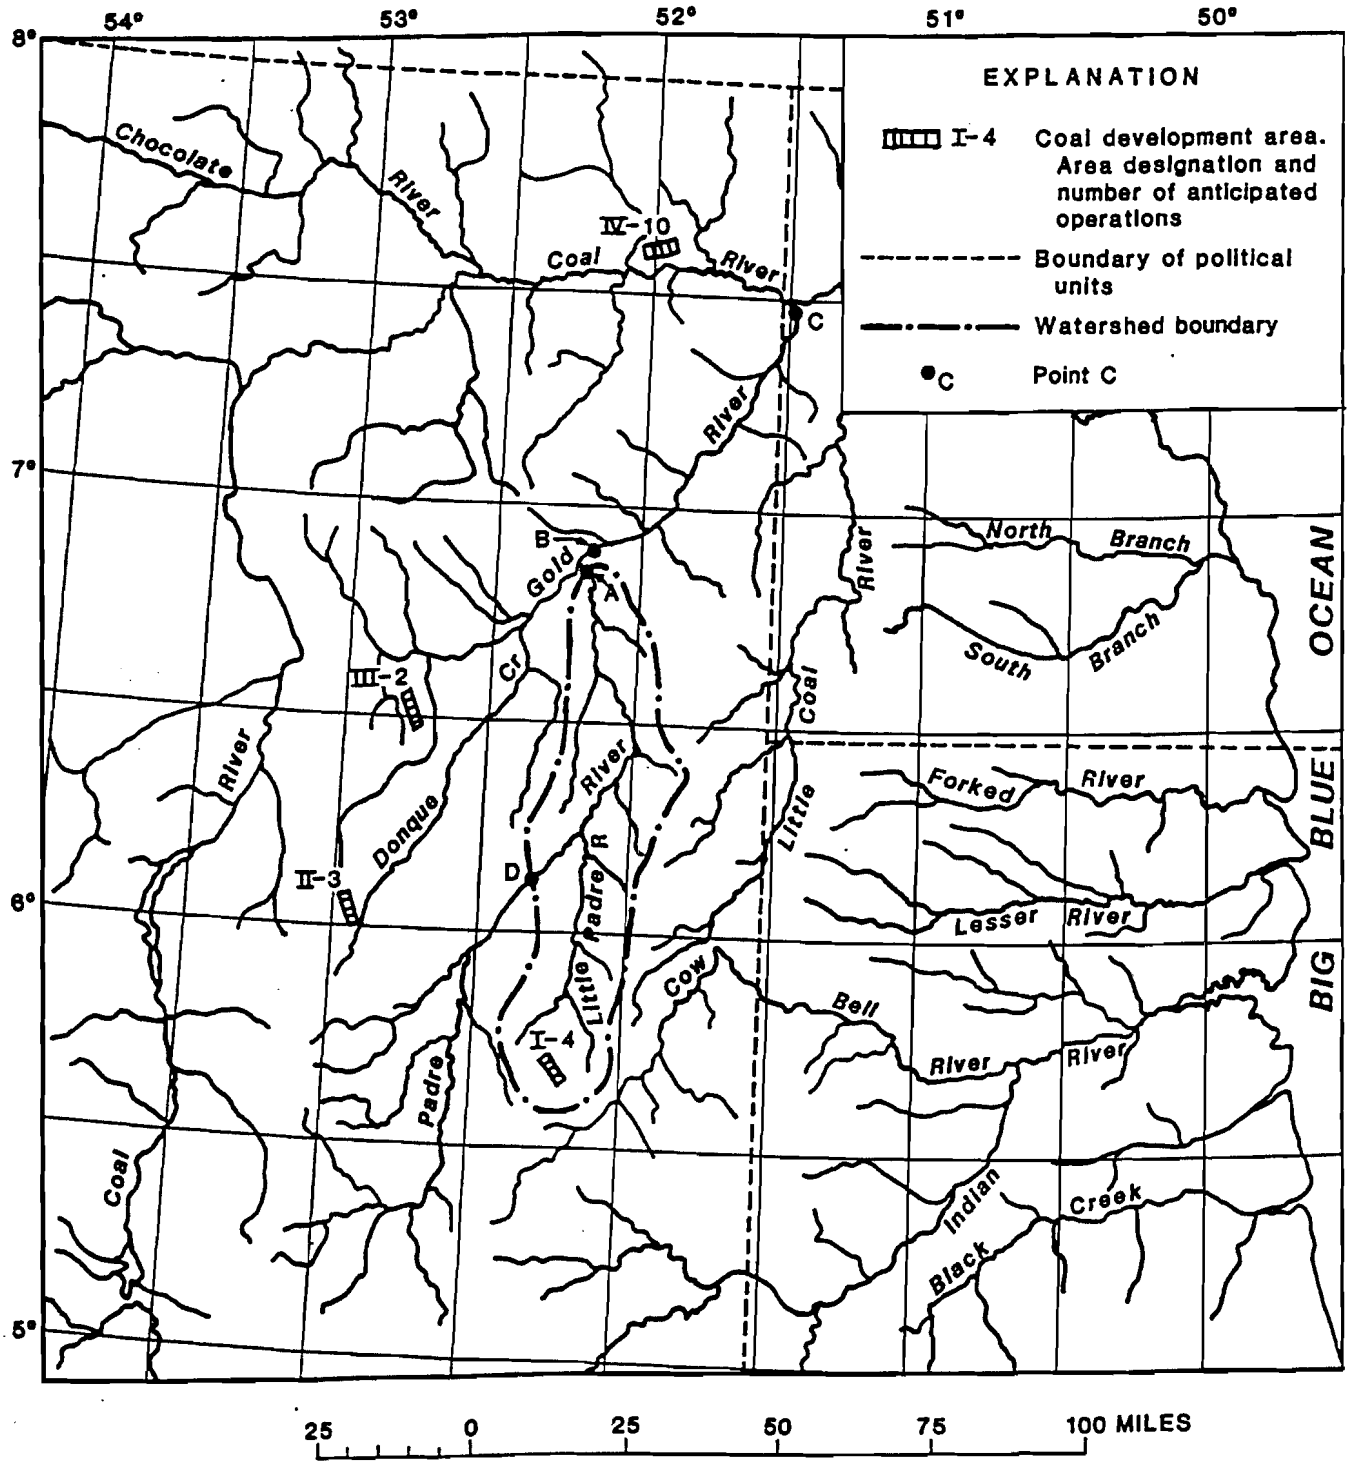

Figure B-1.--Map of the Coal River basin, showing maximum extent of cumulative impact area for the proposed Black Hole mine.

Exhibit 36

increased salt load delivered to the Coal River below Point C and contributed by the mines in the Gold River basin, is not great enough to be considered as an accumulated impact. Calculations support the same conclusion at Point B. (See CHIA for Prairie Chicken mine.) The additional salt load contributed by the proposed mine is not likely to require a different conclusion. Therefore, Point A was considered the maximum possible downstream extent of the surface CIA for this CHIA.

The maximum upstream extent of the surface CIA is marked by the watershed boundaries of East Fork Padre River and the lower Padre River. The upper Padre River basin was excluded because it contains no mines. Any effects of the upper Padre River on the CHIA can be input at the point of truncation (Point D).

Working CIA

All mining operations and leases in Area I, including completed operations, are shown in figure B-2. Operation 4 is the proposed Black Hole mine. Operation 1 was officially completed on November 30, 1979 (date of final bond release), and is no longer considered a mining operation. Operations 2 (Mud Hen mine) and 5 (Prairie Chicken mine) are active mines. Operation 6 is a leased tract for which an approved RRPP is available. Operations 3, 7, 8, and 9 are leases for which RRPP's have not been submitted. By definition, operations 2, 4, 5, and 6 must be considered as "anticipated" mining operations for CHIA purposes.

Pussy Cat Creek is the farthest downstream tributary whose precipitation and snowmelt discharge events are likely to be affected by these operations. Therefore, Point X was considered as the downstream limit of the CIA for surface-water analysis. The watershed above Point X was delineated as shown in figure B-2, and this area was considered to be the surface CIA. Although operations 1, 3, 7, and 8 lie within this CIA, they are not required to be included as "anticipated" mining. The regulatory authority has received no indication that permit applications will be submitted for any of these operations in the near future. Therefore, they were not included as anticipated operations for this CHIA. The areas that these operations occupy were included in the analysis as integral parts of the hydrologic system, but it was assumed that they would not be disturbed by mining and, therefore, would not directly affect the magnitudes of impacts for this particular CHIA.

The geologic strata that could be affected by the anticipated mining are the overburden, Quaternary sediments (valley alluvium), the coal seam, the shale formation under the coal, and a sandstone formation beneath the shale. The regional dip of these strata is 1° to 2° W. The coal outcrops along a line generally trending northwest to southeast.

The overburden is a member of the Wachou Formation and consists of interbedded siltstone and claystone. These materials are generally uniformly textured and moderately to well cemented. Most of the permeability of these materials is due to fracturing. The fractures contain small amounts of water that is sometimes used for domestic livestock. Overburden water is recharged by infiltration in upland areas. It generally moves through the overburden from south to north and discharges into the underlying coal seam and into the alluvium along the stream valleys.

Exhibit 36

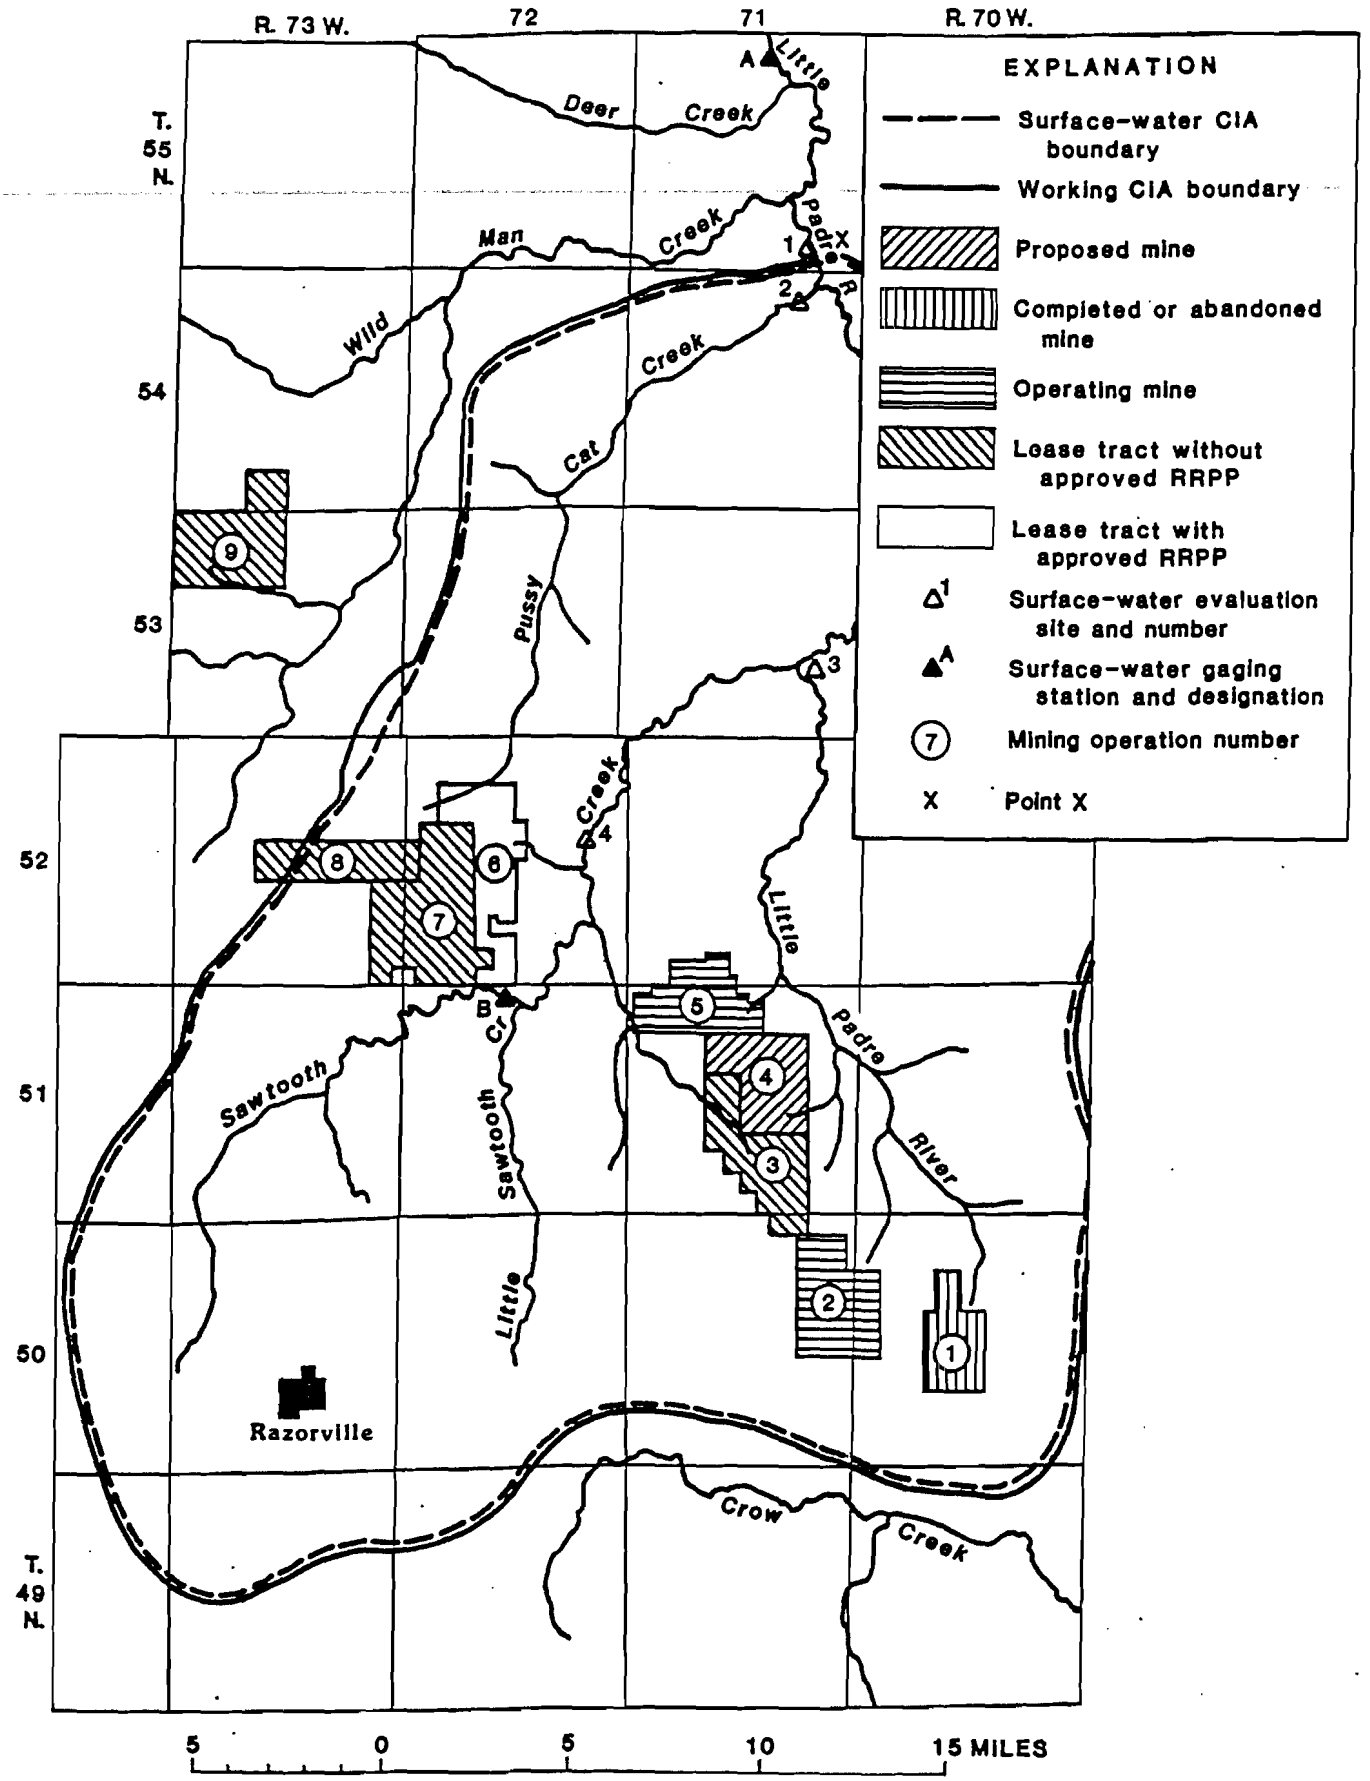

Figure B-2.--Anticipated mining operations associated with the proposed Black Hole mine, and surface-water CIA and ground-water CIA.

Exhibit 36

Quaternary sediment deposits are found along the larger stream valleys in the area. These deposits consist of both streamlaid and colluvial materials and serve as the main discharge area for the coal aquifer. Here, the water is either consumed by evapotranspiration or discharged to the surface farther downstream in the system.

The coal seam averages 80 feet in thickness and contains significant quantities of water. The coal is saturated through its entire thickness and is under artesian pressure. The coal's permeability is due to fracture systems and varies greatly over the area. Yields of wells in the coal vary from 1 to 10 gallons per minute. The coal is recharged along its outcrop and by some leakage through the overburden. It discharges into the Quaternary deposits along the stream valleys.

Immediately beneath the coal is a consistent layer of dense claystone that varies from 2 to 10 feet in thickness. This material (the underclay layer) is an effective barrier to water movement between the coal and the underlying rocks. Other sub-coal rocks are 500 to 700 feet thick and consist mainly of well-cemented shales. There apparently are only a few fracture zones in these rocks. Although these rocks contain some water, yields to wells are generally too small to be useful. For this analysis, these rocks and the underclay layer were considered to be significant aquacludes. The overburden, the coal, and the valley alluvium aquifers are referred to as the near-surface ground-water system. All strata below the coal were considered to be part of the deep ground-water system.

Ample volumes of potable water are available from the Deep Sands aquifer directly beneath the shales. This aquifer is composed of poorly cemented medium sand and is 700-800 feet thick. It crops out 50-60 miles east of the permit area along the eastern edge of the structural basin. The outcrop is the aquifer's main recharge area. The aquifer is confined; its potentiometric surface is approximately at the level of the land surface, and it slopes to the north-northwest at about 0.00009 foot per foot. There are no points within 100 miles of the permit area where this aquifer is known to discharge directly to the surface. However, some upward leakage to the alluvium along the Padre River is probable.

The short-term impacts of the mining on the near-surface ground-water system of this area are dewatering of the coal and overburden in and adjacent to the mine pits. Longer term impacts include the increased mineralization of water in the resaturated spoils and migration of this water off the permit areas and through the system. For the purpose of delineating the working CIA, estimated extent of life-of-mine drawdowns as submitted in the permit applications of operation 2, 4, and 5 were used. For operation 6, the drawdowns in the coal and overburden aquifers were assumed to extend from the permit boundary the same distances as those for operation 2. These drawdown zones are shown in figure B-3 and represent estimated drawdowns of more than 5 feet.

Likewise, paths that the mineralized water will follow in moving from the resaturated spoils to probable discharge points were adopted from the respective permit applications. However, because the aquifer discharge points are so near the permit areas, the pollution paths are all within the coal aquifer drawdown zones and, therefore, were not delineated in figure B-3. The delineation of the ground-water CIA for the overburden and coal aquifers (near-surface system) is shown in figure B-3. A composite of the cumulative impact area for the surface water system and that for the near-surface ground-water system constitutes the working

Exhibit 36

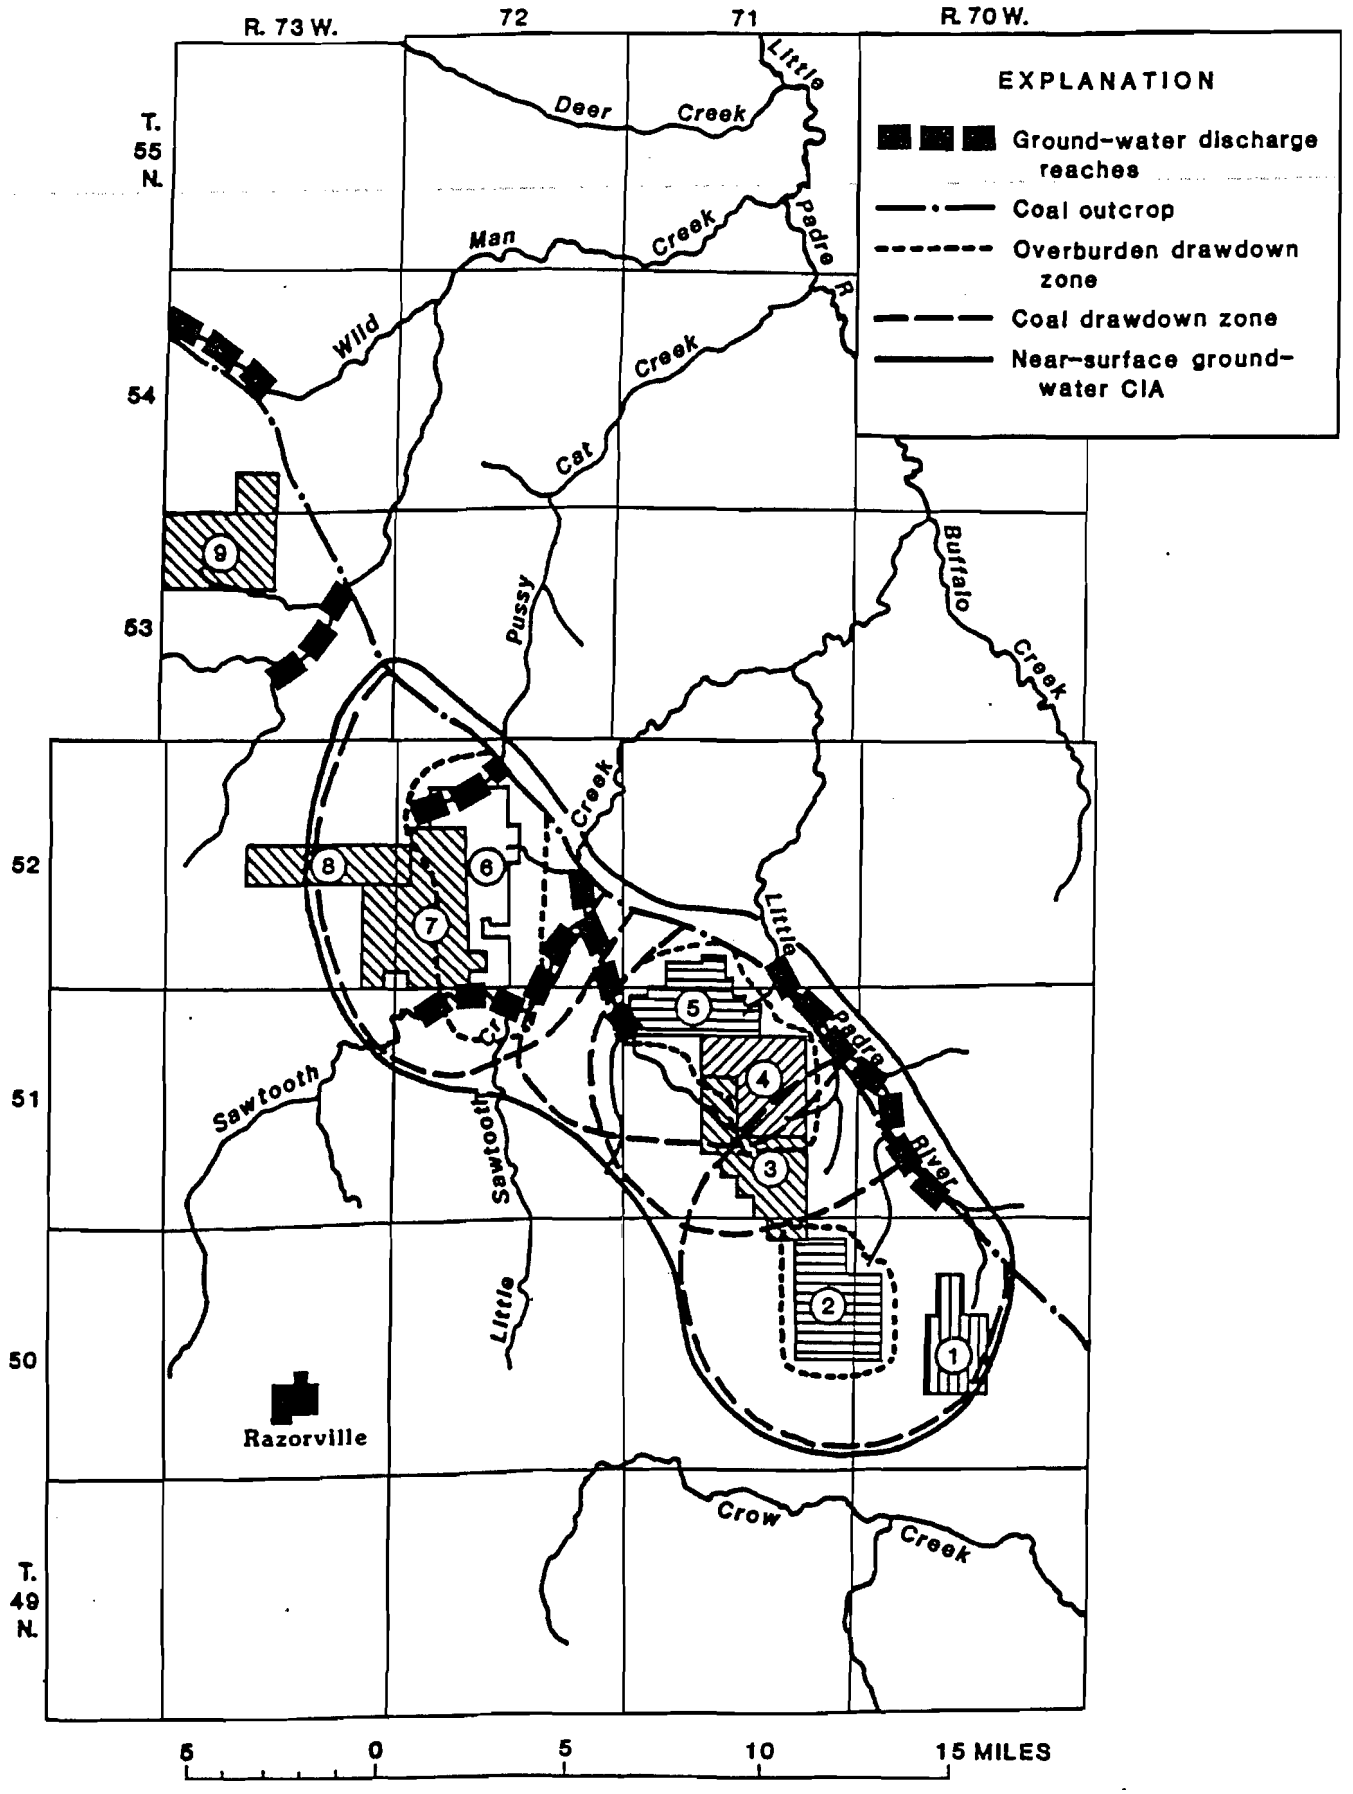

Figure B-3.--Estimated drawdown zones in near-surface aquifers, and near-surface ground-water CIA.

Exhibit 36

CIA. The working CIA was delineated by overlaying figures B-2 and B-3 and is shown in figure B-2.

The area of cumulative impacts in the Deep Sands aquifer was delineated and analyzed separately from the above impact area because this aquifer is, to a large degree, isolated from the near-surface hydrologic system by intervening aquacludes. Operations 2, 4, and 5 obtain some water by pumping from this aquifer. However, the permit applications for these operations do not show the extent of anticipated drawdown zones resulting from such pumping. Only the drawdowns expected at the wells are given.

For the purpose of delineating the cumulative impact area of these wells, drawdown zones were estimated with the Theis nonequilibrium formula for a confined aquifer. Transmissivity and storage coefficient values of 2,000 gallons per day per foot and 0.0002, respectively, were used. These values are the maximum values found in the individual permit applications. The wells were assumed to be pumped one-half the time over a 30-year period at a rate of 250 gallons per minute. The resulting composite drawdown zone is shown in figure B-4. This delineation represents drawdowns greater than 20 feet. The travel paths of contaminants through the Deep Sands aquifer are not represented in this delineation because the possibility that the mining operations would degrade this water is highly remote. The introduction of contaminants through the wells penetrating the aquifer is the only way such degradation could occur. If this should occur, immediate heavy pumping at the culprit well should remove the offending contaminant before it could significantly spread through the aquifer.

BASELINE HYDROLOGIC CONDITIONS

Baseline hydrologic information is needed to define the hydrologic system as it exists prior to mining of the proposed operation. This definition provides a base from which to project the probable impacts of the "anticipated mining," including the proposed operation, upon the CIA.

The streams draining the CIA are shown in figure B-2. Two long-term streamflow records are available in this area. Nineteen years of continuous water and sediment discharge records have been collected on the Little Padre River at Station A (fig. B-2). In addition, water temperature, pH, electrical conductivity, total dissolved solids, sulfate ion, total iron and total manganese concentrations have been measured on a monthly basis for the past 5 years. Also, one water sample per year has been analyzed for 17 additional chemical constituents. This record provides good definition of the 2-, 10-, and 25-year peak discharge, low flow characteristics, and the water quality at that site.

Eight years of continuous water discharge records have been collected on Sawtooth Creek at Station B (fig B-2). The same water-quality parameters that have been measured at Station A have been measured at Station B for 2 years. The records at these two sites form the basis for estimation of premining flow characteristics at evaluation sites 1-4.

The streamfow record at Station B was extended in time using the methods suggested by Searcy (1960), and the long-term record at Station A. In addition, a series of discharge measurements have been made at the four evaluation sites over

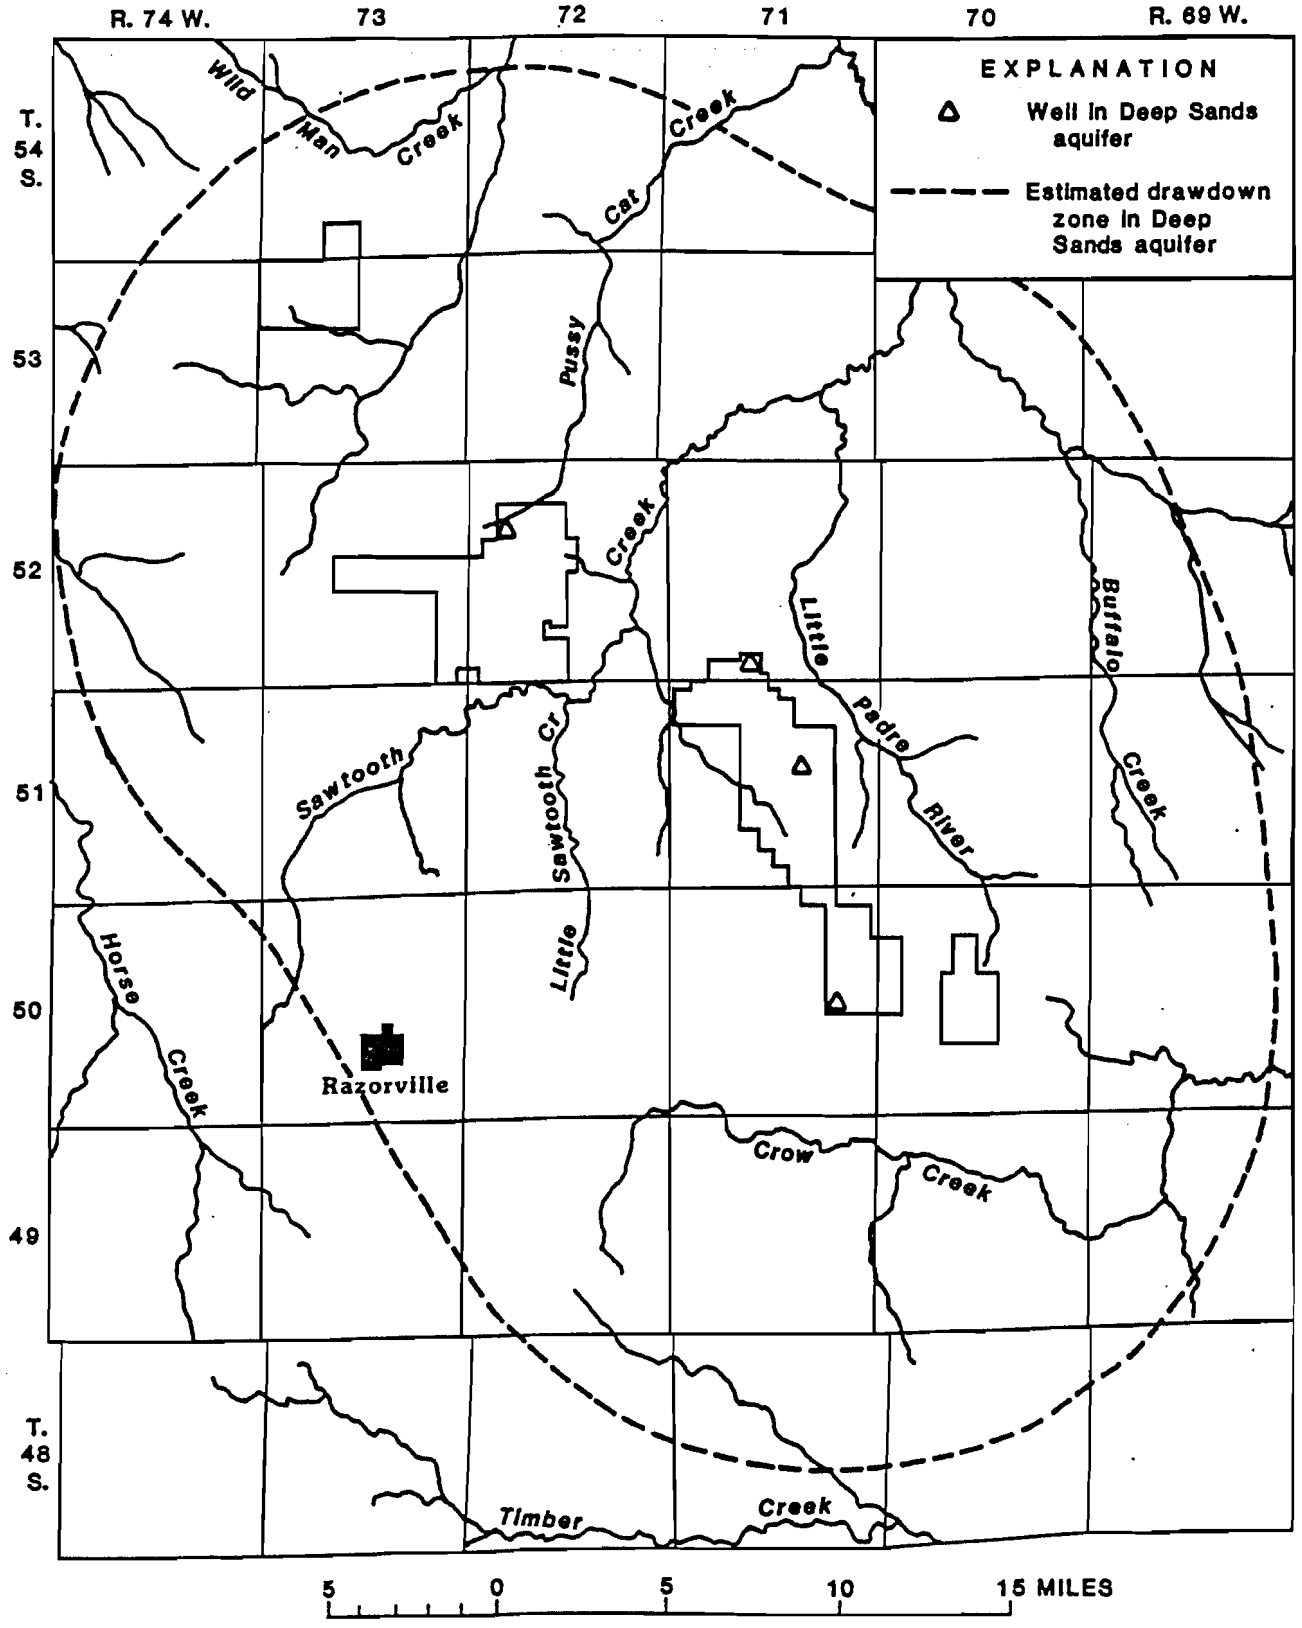

Figure B-4.--Cumulative impact area of Deep Sands aquifer.

Exhibit 36

the past 2 years. A regression equation for each evaluation site was developed with these measurements. The measurements at sites 1 and 2 were related to coincident discharges at Station A, whereas the measurements at sites 3 and 4 were related to the extended record at Station B. Using the regression equations, the flow characteristics at the four evaluation sites were estimated. The flow characteristics of these same evaluation sites were first estimated for the Prairie Chicken mine, The values were then established as base values from which to calculate material damage thresholds to be used in all subsequent CHIA's that include these evaluation sites. The base mean monthly discharges (Qmm) and average monthly 7-day low-flow discharges (7Qam) are listed in table B-1.

Table B-1.--Base discharge rates established by regulatory authority for CHIA evaluation sites*

(All values are in cubic feet per second. Qmm = Mean monthly discharge; 7Qam = Average monthly 7-day low-flow discharge)

*Baseline discharges for Prairie Chicken mine were basis for these values. Base discharges will be used for all subsequent CHIA's that include these evaluation sites.

Exhibit 36

MATERIAL DAMAGE CRITERIA

The criteria for determining material damage potential of surface coal mining has been previously established and justified by the regulatory authority and was used to make such a determination for the Prairie Chicken mine CHIA. The same criteria apply to the Black Hole mine and are restated here.

Except for the area occupied by the city of Razorville, all land within the CIA is used for agricultural purposes, mainly livestock grazing, and this is the most likely postmining land use in the foreseeable future. Therefore, the regulatory authority has determined that the land and waters of the CIA should be restored and maintained to support this use, in particular livestock grazing, and the material damage criteria applied are based on that premise.

The applicable material damage thresholds for all surface hydrology evaluation sites shown in figure B-2 are listed below.

Site	Parameter	Material damage threshold
All	Average monthly 7-day low-flow rate (7Qam).	50% of 7Qam base rate, Mar. 1-Aug. 31.
All	Mean monthly discharge rate (Qmm).	±50% of Qmm base rate, Mar. 1-Aug. 31.
All	Total dissolved solids.	5,000 mg/L.
All	pH	4.5-9.0.
All	Sulfate ion	3,000 mg/L.
1	Manganese	1.0 mg/L.
2,3,4	Manganese	2.0 mg/L - Average of daily values for 30 consecutive days.
All	Total iron (Fe)	6.0 mg/L.

For the months of September through April, streamflows within the CIA are too small for any useful purpose and the regulatory authority has determined that material damage to streamflow quantity cannot occur during that period of the year.

IDENTIFICATION OF HYDROLOGIC CONCERNS

The objective of this CHIA is to determine the probable cumulative hydrologic impacts of the anticipated mine operations within the CIA delineated in the preceding section of this report. Impacts on the quality and quantity of the surface and ground water, with particular emphasis on the availability of water, are addressed as required by SMCRA. The following discussion identifies the critical hydrologic system segments that were analyzed, the specific parameters analyzed, and the points in the systems at which the parameters were evaluated.

The climate of the area is semiarid. Mean annual precipitation is about 16.0 inches. About one-third of this occurs during the months of May and June. Potential evaporation exceeds 50 inches per year and about 15 inches of the annual precipitation is lost to evapotranspiration. Of the remaining inch, about 0.3 inch runs off the surface, and the rest infiltrates.

Exhibit 36

The topography of the CIA consists of gently rolling hills of low relief. Topographic features were formed by streams eroding into the nearly flat lying Watchou Formation. The stream channels form dendritic drainage patterns. Upper reaches of most stream channels carry only ephemeral flows. Lower reaches that are eroded into or through the coal may carry intermittent or very small perennial flows derived from the coal aquifer. Between storm- or snowmelt-produced runoff events, this water normally stands or very slowly flows through a series of large pools. Maximum relief between valley floors and adjacent ridges is about 150 feet. Total relief of the CIA is about 500 feet. Premining hillslope gradients range from zero to 40 percent and average 6.5 percent. Eighty percent of the slope gradients are less than 10 percent.

The primary use of water in this area is for livestock and wildlife. Water for this purpose is obtained from wells in the overburden or coal, and by retention of surface runoff in small reservoirs. There have been some attempts at irrigation, but, in general, there is insufficient supply of water from the near-surface system, and it is too poor in quality for successful irrigation. The three available mine plans all indicate grazing as the postmining land use, and it is reasonable to assume that the postmining land use for operation 6 will also be grazing. There has been limited domestic use of ground water from the overburden and coal aquifers, although State and U.S. Public Health standards indicate the water to be unsuitable for human consumption. The best water for human consumption is obtained from the Deep Sands aquifer, which lies 800-1,000 feet below the land surface. The two presently operating mines each have a well tapping this aquifer. The city of Razorville obtains most of its water supply from five wells tapping the Deep Sands aquifer. The wells are located about 25 miles due west of the proposed Black Hole mine.

The concentrations of total dissolved solids in the few samples of surface runoff obtained to date range from 1,060 to 3,200 mg/L. Major constituents are manganese, sodium, calcium, and sulfate. The pH ranged from 7.0 to 9.2. The concentrations of total dissolved solids in ground-water samples range as follows: Overburden, 1,100 to 3,600 mg/L (calcium magnesium sulfate); coal, 800 to 3,800 mg/L (sodium sulfate bicarbonate); Deep Sands, 275 to 1,500 mg/L (sodium calcium bicarbonate sulfate). Concentrations of iron, sulfates, and nitrates in these aquifers frequently exceed drinking water standards.

A direct effect of the anticipated mining is to remove and replace the coal aquifer with fragmented and dewatered overburden material in a broken strip across the CIA. This will cause a redirection toward the reclaimed spoils of the water flow patterns in the coal and overburden adjacent to the reclaimed pits. Until these spoils are resaturated, they constitute a major discontinuity or barrier to the movement of this water toward its present discharge points in the stream valley alluvium.

A subsequent direct effect is that water moving into the reclaimed spoils will become more highly mineralized because of the increased surface area of the fragmented material. Once these spoils are resaturated and flow patterns revert to premining patterns, this highly mineralized water will move into and through the downgradient coal and overburden to the stream valley alluvium and, eventually, into the surface streamflow.

It is obvious from the above physical descriptions of the CIA, of the occurrence of water therein, and of the direct effects of the mining on the hydrology that the major concern relative to the cumulative effects of mining on the hydrology of this area is for the maintenance of already limited amounts of water in the near-surface system available for present uses (i.e., livestock and wildlife watering). This means that the quantity, quality, and distribution of water presently obtained from surface runoff and from the coal and overburden aquifers must be maintained or be made available at present levels. Drawdowns in the coal and overburden aquifers may affect perennial and intermittent streamflows. These drawdowns may also affect some of the wells that now provide water for livestock. An additional concern is that the withdrawal of water from the Deep Sands aquifer for mining-related uses not affect the water supply to the Razorville wells or the cost of pumping that water.

In order to address these concerns, the specific objectives of this CHIA are (1) to determine the change in quantities of water reaching the off-permit stream system, (2) to determine the change in the quality of water that resaturates the reclaimed spoils and eventually reaches the surface-water system and to evaluate the time needed for the spoils to resaturate and for the water to subsequently reach the stream system, (3) to evaluate any change in sediment load to the stream system during and after mining and reclamation, and (4) to determine the effect of the mine wells on the city of Razorville's wells.

The specific parameters used to evaluate each of the stated objectives were as follows:

- Surface-water flow parameters: Mean monthly discharge rate (Qmm) and average monthly 7-day low-flow rate (7Qam).
- Ground-water flow parameter: Drawdown of potentiometric surfaces due to pit seepage.
- Water-quality parameters: Total dissolved solids concentration, sulfate ion concentration, total manganese concentration, total iron (Fe) concentrations, and monthly sediment load.

Surface-water parameters were evaluated at the sites shown in figure B-2. All parameters were evaluated at each site except that low-flow rates were only evaluated at sites with intermittent or perennial flows. Ground-water discharge rates to valley alluvium were evaluated as changes in streamflow rates along the ground-water discharge reaches shown in figure B-3. Water quality parameters were evaluated at all flow evaluation sites and within the projected ground-water drawdown zones.

(READER NOTE: For the sake of brevity, the remainder of this CHIA example will address only the water quantity impacts to the surface hydrology system. However, an actual CHIA **must** address all concerns identified in Element B.)

ANALYSIS OF HYDROLOGIC IMPACTS

The combinational approach was selected for this analysis. The same approach was used for the Prairie Chicken mine CHIA and that assessment showed by wide margins that there was little possibility that the analyzed parameters would exceed material damage thresholds. The only real difference in conditions

for the two assessments is that an additional year of data is now available and a PHC analysis for the Black Hole lease area is available, whereas many estimates were applied to that area in the previous CHIA. The additional data tends to confirm the parameter values estimated for operation 6, and those same values will also be used for this CHIA.

Projected maximum changes in Qmm and 7Qam discharges were obtained from the hydrologic analyses (PHC's) of the individual maine plan applications. These values are listed in tables B-2 and B-3, respectively. Next, these dischargechanges were routed to the four impact evaluation sites. This was done by simple summation at each evaluation site of all nonsummed discharge change values, or of evaluation site sums immediately upstream from the summing site. Thus, the values for site 3 are the sums of discharge change quantities from mine operations 2, 4, and 5 (2-LP, 4-LP, 5-LP, tables B-2, B-3). This routing procedure was considered adequate in this case because discharge changes were routed rather than the total stream discharge, and, therefore, it was not necessary to account for incremental discharge changes (due to nonmining increases or depletions) from within the intervening stream reach. Also, this routing procedure does not account for discharge changes caused by changes in stream channel geometry (width, depth, gradient, roughness) within the stream reach. However, the procedure should give conservative discharge estimates.

The routed Qmm and 7Qam discharge changes are listed in tables B-4 and B-5, respectively. These are the maximum discharge changes expected at the evaluation as a result of the anticipated mining.

POTENTIAL FOR MATERIAL DAMAGE

The material damage threshold values for surface discharge parameters are calculated from base discharges set by the regulatory authority. The base discharge values are the Qmm and 7Qam discharges determined for each evaluation site at the time that the Prairie Chicken CHIA was prepared.

The material damage criteria set damage thresholds at 50 percent of the base discharge values. Thus, the total allowable discharge change (Qa) from base values is ±50 percent of the base discharge. The base discharge values are listed in table B-1. The Qa values (allowable discharge changes before material damage occurs) are listed in tables B-4 and B-5. The projected changes (Qc) due to anticipated mining are also shown in tables B-4 and B-5. Comparison of the corresponding Qa and Qc values indicates the potential for material damage. In this case, the comparison shows that 40-60 percent of the allowable change values remain, thus indicating no potential damage to surface water quantities due to the anticipated mining.

Exhibit 36

The above-listed Qc values are conservative in that it was initially assumed that the maximum impacts of all the mines would occur at the same time. In reality, the maximum impacts of Operations 2 and 6 will probably occur some years apart, meaning that larger percentages of the allowable changes remain than is indicated by this analysis.

On the basis of the preceding cumulative hydrologic impact analysis, the regulatory authority has determined that the cumulative impacts of the Black Hole mine will not cause material damage to the hydrologic balance that affects surface-water quantities.

Table B-4.--Mean monthly discharges: Estimated maximum changes and allowable changes at evaluation sites

(All values are in cubic feet per second. Qa = Allowable discharge changes before material damage occurs. Qc = Estimated maximum discharge changes. Qc values for Site 1 are sum of values for Sites 2, 3, and 4. Qc values for Site 2 are sum of values 6-PC from table B-2. Qc values for Site 3 are sum of values 2-LP, 4-LP, 5-LP from table B-2. Qc values for Site 4 are sum of values 4-ST, 5-ST, 6-ST from table B-2. NA - Not applicable)

Dave – it looks like we do have some genus-level data (see attached).

Please take a look when you get the chance and give us your thoughts. Is this data set suitable for calculation a bioassessment score with Plains MMI or RIVPACS?

Thanks

Pete

This only contains data from the 1978 survey. I've yet to add the 76 and yet to be found 73 survey. Some of the genus names may need to be untangled as these could really be family or group names.

No, We're not looking for an impairment call.

What we want to do is compare existing assemblages to these historic assemblages using appropriate metrics.

I understand the assemblages indicate lower water quality. The question is…can a bioassessment score (MMI and/or O/E) be calculated on these assemblages? If no, why not? If yes, let's make it happen.

It appears that what I thought was a simple technical request apparently has implications beyond our need to assess condition.

Thanks. I realize it's out of your hands, but I do appreciate your assistance. I spoke with Eric, and will attempt to follow-up at the mgmt level.

Hello!

I've reviewed the data, and here's some thoughts:

I've organized the data by sampling location and date to get an idea of what you're seeing in the macroinvertebrate communities at those locations. The samples are not very diverse, and some samples do not have very many inverts. If we were using these data in any kind of macroinvertebrate indicator of water quality, the samples would all be rated low.

I spoke with Eric Urban about this, and he told me that any kind of impairment determination is beyond the scope of what you need in the Coal Program. He told me the best way I can help you is to describe what taxa are there, and that's it.

I hope this helps!

REVISION HISTORY

Revision No.	Date	Modified By	Sections Modified	Description of Changes
1	10/21/2004	DF, MB, BB	4,5,7, Appendices, Attachment 1	Quality Assurarnce procedures were added. The taxa list (Appendix 3) was updated The site visit field forms (Attachment 1) were updated.
2	09/08/2006	DF, MB, MS, BB	1,2,5,6,7, Appendices	The Montana Observed/Expected (a.k.a. RIVPACS) Model and Multimetric Indices (MMIs) were added. The Appendices were relabeled by letter instead of number. The taxa list (Appendix A) was updated. The Glossary of metrics was updated for the MMIs. Appendix D was added to the SOP.
3	03/15/2012	DF, MM, KM, BB	All	The scope of the SOP was refined to include which river segments were unwadeable and beyond the scope of the sampling protocols. The justification for the index sampling period was slightly modified. The coldwater O/E model and Bray Curtis (BC) Index were added. The MMIs were removed. The rarefaction instructions to prepare the data for the MMIs in Appendix C were removed and replaced with example outputs from both O/E models. The code to calculate the coldwater O/E model and instructions on how to use it was added as Appendix D. The laboratory subsampling procedures were updated to require that the labs submit their SOPs, and use unbiased subsampling procedures.

Exhibit 34

1.1 SCOPE AND APPLICABILITY

The methods described herein are used for collecting and analyzing macroinvertebrate data from wadeable streams (1st order or higher) by or for the Montana Department of Environmental Quality (DEQ). Benthic macroinvertebrate data collected on large rivers is beyond the scope of this method. **Table 1-1** lists those large river segments.

Table 1-1. Non-wadeable river segments within the state of Montana

River Name	Segment Description
Big Horn River	Yellowtail Dam to mouth
Clark Fork River	Bitterroot River to state-line
Flathead River	Origin to mouth
Kootenai River	Libby Dam to state-line
Madison River	Ennis Lake to mouth
Missouri River	Origin to state-line
South Fork Flathead River	Hungry Horse Dam to mouth
Yellowstone River	State-line to state-line

1.1 GENERAL CONSIDERATIONS

Prior to conductiong a benthic macroinvertebrate survey, determine the specific data quality objectives (DQOs) and the information sought. DQOs can be qualitative or quantitative statements developed to specify the quality of data needed to support specific decisions and conclusions about the information sought. The DQOs should be documented in a Sampling and Analysis Plan or Quality Assurance Project Plan.

1.1.1 Index Period

The index period is the period of time that samples should be collected to minimize seasonal variation.

- The index period for Montana is generally the summer (June 21 to October 1), following runoff loeb (Richards D.C., 1996; Loeb and Spacie, 1994). Eastern Montana streams may be sampled May 1 to October 1.
- Sampling may occur outside of the index period, however this may reduce certainty that the data are comparable to historical data, reference conditions or indices (see discussion below).

The index period noted above was the temporal basis for reference conditions used in the development of the Observed/Expected (O/E) model. However, even within this index period, extreme runoff or summer drought conditions could affect these periods; professional judgment must be used when considering sampling schedules. Sampling macroinvertebrates during high flows, besides being potentially unsafe, is likely to increase sampling variance due to the difficulties associated with sampling these waters using the methods described herein.

When monitoring for trends at a particular site, minimize seasonal variation by sampling as close as possible to the same date each year.

Exhibit 34

1.1.2 Site Selection

Sampling requirements including the total number of sampling sites their location in the study area, and the spatial and temporal independence are outlined in each DEQ pollutant-specific assessment method. Some of the assessment methods do not require any biological samples to be collected for assessment decisions. Refer to the assessment method when determining the sampling design in order to achieve an appropriate assessment of the stream. Always consider potential constraints to collecting representative samples such as site access when selecting sites. Document any necessary changes due to site access restrictions.

The study design should specify requisite site specifications for the study. For example, many study designs use the riffle environment as the specific point of comparison between streams. A *rationale* described in the Sampling and Analysis Plan (SAP) for determining representative riffles for the anticipated stream types would be a *site selection specification*.

Although riffle areas with cobble substrates are generally the most diverse and productive habitat type, these may not be representative of the predominant type of habitat in the stream. If so, the study design should describe the variety of habitats, the rationale for representative sampling, and the various appropriate sampling techniques for the study.

There is ample evidence that the presence of lakes, impoundments, bridges, road crossings, and bedrock or large-boulder dominated substrates affect benthic invertebrate community composition; therefore, sampling sites should be located as far from these as is practical, *unless the objective of the study is to measure their localized influence*.

Always sample sufficiently upstream from the confluence of major tributaries or receiving waterbodies to minimize their influence on study sites. Otherwise, consider the mixing zone of the two waterbodies and select sites downstream of the confluence that are well mixed, and represent both the biological community and water quality conditions.

1.1.3 Sample Collection Methods

DEQ employs a semi-quantitative Environmental Monitoring and Assessment Protocol (EMAP) reach wide sampling technique to collect samples in a known area allowing the estimation of population density, in addition to diversity and abundance.

1.1.4 Checklist of Recommended Field Supplies

- ❑ Field Meter (pH, Spec. Conductance, DO)
- ❑ Macroinvertebrate sample bottles (1 liter wide mouth poly)
- ❑ Lab markers, external labels, clear tape, Parafilm-M
- ❑ Internal labels (paper)
- ❑ Sampler (D-frame net)
- ❑ Field notebook
- ❑ Field data sheets (Site Visit Form, Photo Documentation Form, Site Map Form)
- ❑ Camera
- ❑ GPS unit
- ❑ 95% Ethanol preservative
- ❑ 500 um sieve for washing and sorting out large objects
- ❑ Pencils

Exhibit 34

- ❑ Clipboard
- ❑ De-Ionized Water
- ❑ Hip boots or waders
- ❑ Maps
- ❑ Dishwashing brush
- ❑ Hard or soft-sided Coolers to store samples
- ❑ Small soft-sided coolers to transport samples

2.0 SAMPLE COLLECTION PROCEDURES

The following section discusses sample collection procedures used to sample macroinvertebrates in streams and wadeable rivers not listed in **Table 1-1**.

2.1 PRECAUTIONS

Care must be taken when looking for suitable sampling sites not to disturb the substrate or habitat in areas where samples might be collected. A sample collected where the substrate has been disturbed by walking may not be representative of the community.

Be sure to transfer the entire sample to the bottles. Only fill each bottle one-half to three-quarters full with sample to leave room for preservative. Capture all bugs by thoroughly cleaning off all large rocks and sticks. Excluding large rocks prevents grinding damage to bugs during transport. Discard cleaned rocks and sticks.

Pack and store collection bottles carefully and securely in order to protect the sample jars and prevent the loss of contents during transport or shipment.

2.2 SAMPLE LABELING

Accurate labeling of sample bottles is important to preserve critical information. Attach a preprinted label to the jar clearly identifying the sample (location, date, number of bottles, method of collection and sample number). Use pre-printed, fill-in-the-blank labels to help ensure that the sample information is complete.

2.2.1 Sample Containers and Preservation

Collection jars: 1-liter wide-mouth polyethylene bottle. (Note: It may be necessary to use more than one 1-liter polyethylene bottle.)

Use 95% ethanol (ETOH) to preserve the macroinvertebrate samples. . Please remember that ETOH is flammable! The drawback of using ethanol is that the fluid composition of the sample needs to be dominated by ethanol to properly preserve the sample. Because of this, try to keep as much water out of the sample jar as possible, and fill the sample bottle only one half with sample and the remainder with ETOH to fill the bottle completely. Split the sample using an additional bottle(s) if necessary, and be sure to correctly label the bottles using a numeric sequence (i.e. 1 of 3, 2 of 3, 3 of 3).

Exhibit 34

2.2.2 Sampling Quality Control

2.2.2.1 Field Replicates

Field replicates are collected to measure total method error and should always be included in the sampling design at a predetermined frequency (usually 10%).

Field replicates are two or more samples, collected side-by-side or consecutively, at the sampling site. Replicate samples should be taken at places that are very similar in terms of depth, substrate, composition, and slope. ***Always collect samples from downstream to upstream to avoid sample contamination***. Replicates are processed in the laboratory as discrete samples. They are compared directly to the original samples. Any difference represents total method error (e.g., heterogeneity of site, reproducibility of sampling technique, sorting error, and identification error).

Relative Percent Difference (RPD) is used to evaluate results differences between two replicate samples.

$$RPD = \frac{(result1 - result2)}{(result1 + result2)/2} \times 100$$

The results of replicated samples (i.e. O/E model results) should be < 20% RPD, however, each project must state its required replicate precision criteria based on project DQO's.

2.2.3 Benthic macroinvertebrate sampling methods and protocols

A variety of other sampling methods are available from EPA, USGS, and other organizations. It is beyond the scope of this SOP to discuss all available sampling methods, or the applicability of sampling design for determining the health of benthic macroinvertebrate communities using the Data Analysis and Interpretation tools presented in Section 5 of this SOP.

When sampling methods other than those listed in this SOP are used for water quality assessments by or for DEQ, the SOP(s) for the alternate methods must be attached or cited in the project's Quality Assurance Project Plan (QAPP) or Sampling and Analysis Plan (SAP). Any known (documented) or assumed comparability to the methods in this SOP should be cited or documented in these Quality Assurance (QA) documents.

2.2.3.1 Environmental Monitoring and Assessment Protocol (EMAP)

Currently, the DEQ Reference Project uses EMAP sampling protocols to identify and assess reference sites (Peck, 2006). These data were included in the compiled reference data collection used for the O/E models. Therefore, EMAP methods are considered valid sampling techniques for use with the tools presented in Section 5 of this SOP.

2.2.3.1.1 Reachwide Sample

The EMAP sampling protocol requires that a kick sample be collected at each of 11 transects (A though K), sampling from downstram to upstream along the reach; these kick samples are composited to obtain a sample that is representative of the entire reach. Collect each kick sample at each transect (A through K) at the assigned sampling point (left, center, or Right). Position a 500um D-frame kick net within a representative portion of the designated channel location and hold the net vertically upright with the base of the frame in contact with the substrate and the open portion of the net facing into the flow. See **Figure 2-1** for a conceptual diagram of the EMAP reach, and where to collect each macroinvertebrate

Exhibit 34

kick sample. Note: if a sampling location that is unsafe to wade to is encountered, try to find a safer location either up or downstream approximately 1 meter of that location. Switch to another position (i.e., R.L,C) on the same transect if moving up or downstream to collect the sample isn't possible. Return to the initial sampling pattern at the next transect after the kick is collected. Here are some important points to consider when collecting macroinvertebrate samples:

- *Thoroughly* inspect and clean (with stream water) the net after each sampling event to ensure that all organisms have been removed to prevent contamination between sites. Consider the following procedures to ensure that all organisms are removed from the net and placed in the jars:
  - Rinse large rocks, sticks, and other debris into the net and thoroughly inspect them prior to discarding.
  - Use a small plastic spoon to scoop the sample into the sample jar.
  - Inspect the entire inner surface of the net and use clean forceps to carefully remove any organisms clinging to the net and place them into the sample jar.
  - Dump the contents of the net into a 500 um sieve, rinse stream water through the sieve to clean the sample of fine sediment and transfer the sample into the jar.
  - Elutriate each kick sample to separate the organic and inorganic portions before you transfer it into sample jars; this should help protect the soft-bodied macroinvertebrates from damage caused by inorganic material in the sample jar during sample transport and storage. Elutriate by submerging portions of the sample in a 5 gallon bucket containing some water, vigorously swirl the sample in the water to separate the organic and inorganic portions of the sample, then decant the floating material into the 500 micron sieve and transfer from the sieve into the sample jar. Repeat this process several times until almost the entire organic portion of the sample has been removed. Then transfer the inorganic portion to different sample jars and submit these along with the organic portions to the analytical laboratory.
  - When sampling a pool with little to no flow, follow the same procedure except use your hands or feet to push the sample into the net. If encountering a slackwater area choked with vegetation, sweep the net through the vegetation for 30 seconds over the $0.09m^2$ sampling location.
  - Add enough ETOH to submerge the debris in each sample jar as soon as the material from each kick is added to the jar to prevent damage or loss of some taxa by opportunistic predators.
  - Spray organisms clinging to the net with a dilute (10%) ammonia or (95%) EtOH solution to detach them from the net. Partially immerse the net in the stream to concentrate the detached organisms at the base of the net and/or use forceps to transfer organisms directly into the jar.
  - To collect replicate samples using the reachwide approach, simply collect replicate kicks at each transect at another location on the same transect. For example, if the regular sample is collected following the Right, Left, Center pattern, the replicate sample could either be collected following the Left, Center, Right or Center, Right, Left pattern.
  - Always check all of the sampling gear between sampling events to make certain all organisms were removed. This prevents sample contamination between sites and prevents biased biological assessments

Exhibit 34

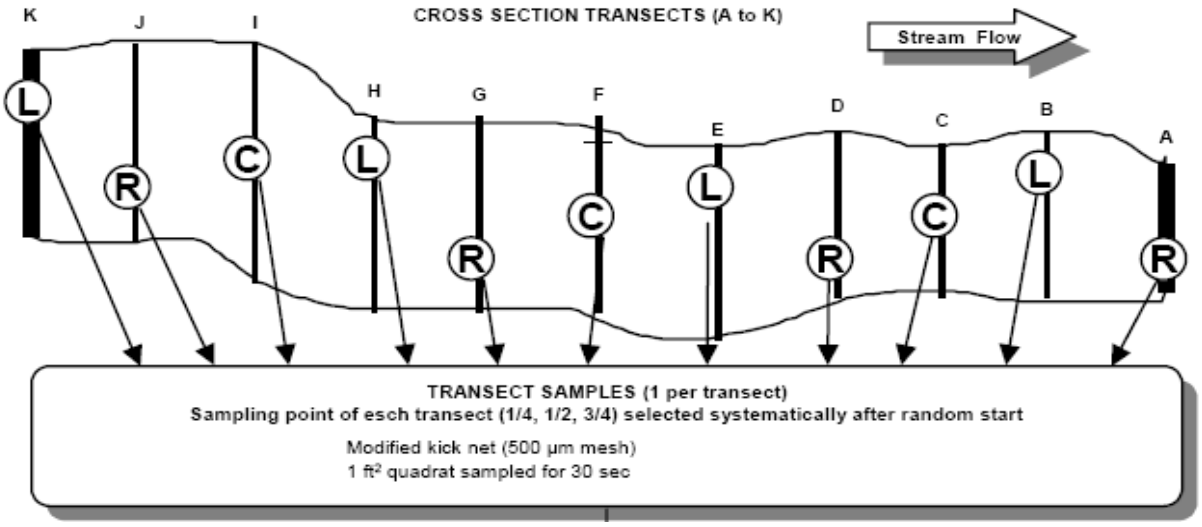

Figure 2-1. Sampling locations for the reachwide benthic macroinvertebrate sample within the sampling reach (adopted from Peck et al. 2006).

2.3 SUPPORTING FIELD DATA

Macroinvertebrate sample sites are described by metadata recorded at the time of sampling as well as any field observations taken at the time of sampling. Use the Site Visit Form (**Attachment 1**) to record metadata (GPS lat/long in decimal degrees, NAD 83) for the sampling site and record sample identifiers.

Digital photographs should be taken of the sampling site (upstream, downstream, and the site itself) and of the substrate sampled. Record metadata for the photos on the Photo Point Form (**Attachment 2**). As a back-up to digital photos, a sketch of the sampling site is recommended, along with an indication where the sample was taken at the site. A Site Sketch Form is included in this SOP (**Attachment 3**).

3.0 SUBSAMPLING & SORTING

Subsampling is using a representative portion of the field-collected sample for analysis. Sorting is the physical separation, counting, and grouping of organisms from the debris collected in the sample. All macroinvertebrate samples collected by and for DEQ should follow an unbiased subsampling procedure to achieve a target subsample count of 500 $\pm$ 10% organisms.

It is important to understand the objectives of the project when selecting subsampling techniques. If the intention of the study is to measure population density (i.e., quantitative sampling), sort the entire sample. Full sample sorts can be used for samples collected by semi-quantitative collection methods if the study requires that all organisms are identified. However, full sample sorts are more time consuming for the taxonomist, adding additional expense to each sample.

Exhibit 34

3.1 PRE-SUBSAMPLING METHODS

To get a relatively even distribution of organisms prior to subsampling or sorting, remove large debris from the sample. There are two approaches to this sample clean up. The debris can be removed from the sample (picking) or the sample can be removed from the debris (elutriation).

3.1.1 Picking detritus

Picking the debris from the sample involves rinsing out fine material, removing large rocks, woody debris and setting them aside. Picking and rinsing should be performed in a 500 um sieve with a gentle stream of water to prevent splattering. Large rocks and sticks must be thoroughly scraped, rinsed and examined prior to setting them aside. The remaining sample is placed in an appropriate sized Caton tray for subsampling and sorting.

3.1.1.1 Elutriation

Elutriation is basically an extraction of the organisms from the substrate remaining in the sample. This technique works best when the substrate is inorganic material such as sand, pebbles, and rocks. Samples with a large amount of organic material are not amenable to this extraction. Field elutriations can be performed to reduce the number of jars a field crew transports to the macroinvertebrate laboratory or to separate soft-bodied macroinvertebrates from the course material in a sample.

Dump the sample into a 5-gallon bucket and fill the tray with water. Swish the sample around in the tray to liberate organic material and bugs from the substrate. The organic material and organisms should float in the water. Pour the water and all floating material and organisms into a 500um sieve. Add more water and repeat the process until no more organic material remains in the tray. Note: A 10% magnesium sulfate solution can be used instead of just water to increase the efficiency of the elutriation.

Once the sample is separated, use a magnifying lamp to check the inorganic portion of the sample for snails, clams, stone cased organisms, or any other organism too heavy to have floated. Have a fellow technician take a second look to verify that all organisms were removed. Any organisms found in the inorganic fraction must be added to the organisms in the sieve so they may be included in the sort. If a large number of organisms are found remaining in the inorganic fraction, the elutriation technique is not appropriate and the sample fraction in the sieve must be recombined with the inorganic fraction and sorted as a whole.

3.2 SUB-SAMPLING AND SORTING

The techniques for subsampling and sorting vary slightly between the contractors used by DEQ. Rather than describing (in detail) each contractor's specific method, DEQ requires that each contractor documents their procedure in a SOP, which includes the following components:

- Magnifying glass or microscope used for subsample and sort. (Specify power)
- Standardized sorting bench sheets
- Random selection of cells
- Last cell chosen
- Quality Controls to determine sorting efficiency or precision

SOPs must be submitted to DEQ as part of the contractor qualification process.

Exhibit 34

3.2.1 Sorting Quality Control (QC)

3.2.1.1 Relative Percent Difference in Enumeration (RPDE)

DEQ evaluates the precision of sample counts taken for the subsamples by calculating the relative percent difference of enumeration (RPDE). The RPDE is the standard formula used to evaluate how well a laboratory performs by comparing a sample result versus the result generated by a second laboratory evaluating the same sample (American Public Health Association, et al., 1998). Calculate the RPDE by comparing results from two independent laboratories or taxonomists using the formula:

$$\text{RPDE} = \frac{\left| \text{Sample Result}_1 - \text{Sample Result}_2 \right|}{(\text{Sample Result}_1 + \text{Sample Result}_2)/2}$$

where *sample result*$_1$ is the number of organisms in a sample counted by the first laboratory, and *duplicate result*$_2$ is the recount by the second taxonomist or laboratory (adapted from Standard Methods 20th Ed. - 1020 B (American Public Health Association, et al., 1998)). The purpose of this calculation is to highlight those samples where counts differ substantially and to focus attention on obtaining better consistency.

The measurement quality objective (MQO) for RPDE is 10%. Values for individual sample comparisons exceeding the MQO (> 10%) require an examination to determine causes of the difference. Upon completion of this investigation, DEQ will communicate when and if the RPDE exceeds 10% to the taxonomic contractor and QC taxonomist(s). This will occur as a conference call and/or e-mail correspondence with the contractor(s).

4.0 TAXONOMY

4.1 TAXONOMIC IDENTIFICATION

Consistency in macroinvertebrate taxonomy is critical for final site assessments and interpretation. It is the responsibility of the taxonomist to communicate the composition of samples to those personnel performing data entry, and to be able to defend taxonomic results to the ultimate data analysts. DEQ encourages taxonomists to identify specimens to the *lowest practical taxonomic level*. However, DEQ also understands that specimen condition (damage, early instar, poor slide mounts) may force the taxonomist into an unavoidable situation of having to leave identification at more coarse levels (e. g., family instead of genus). With the limitation of organism condition in mind, DEQ will judge consistency of data based on historical hierarchical levels that have been achieved, resulting in the Montana Master Taxa list (**Appendix A**).

Count vs. non-count specimens. In general, all specimens in the subsample should be identified and counted by the taxonomist, including pupae. However, there are several exceptions known as non-counts, which include:

- Empty mollusk shells (lacking soft tissue)
- Worm fragments lacking the anterior (head) end
- Body parts NOT INCLUDING at least the head and thorax
- Surface dwellers such as Collembola, Gerridae, and Veliidae

Exhibit 34

- Incidentally-collected terrestrial specimens

Some hierarchical inconsistency in taxonomic data is dealt with during coding and analysis (see **Section 5.2**). During development of the Observed/Expected (O/E) models (**Section 5.5**), operational taxonomic units (OTUs) are specified to reduce the influence of ambiguous taxonomy. The complete Montana taxa list with OTUs and other attributes is available from DEQ as a table within the DEQ macroinvertebrate database and as **Appendix A**. A template for tracking identification and enumerations is provided as **Appendix B**.

4.2 QUALITY CONTROL FOR TAXONOMY

All QC activities, including specification and response to corrective actions, should be completed *prior* to initiation of data reduction (metric calculation and indicator analysis). The aspects relevant to taxonomic data quality are: accuracy and precision (Stribling, et al., 2003).

4.2.1 Accuracy

Accuracy is defined as the nearness of a measurement to a specified analytical truth. For taxonomy, there are several options that can be used as the analytical truth, including:

- Museum-based type material (holotype, paratype, or other; the original specimen or series of specimens on which the original description of a species is based),
- The most current and accepted taxonomic literature (dichotomous keys with illustrated, diagnostic morphological characters), or
- A reference collection, verified by an independent taxonomic specialist.

Type material is usually found in museums, and direct interaction with museum curators is required to use it for comparisons. Thus, it is often not feasible, or even necessary, for routine monitoring and assessment programs or projects (Stribling et al. 2003). Contractors must provide at least one reference collection per year that can be verified by a qualified, independent macroinvertebrate taxonomist. Depending on the magnitude of an individual project, a project-specific reference collection may be requested by DEQ; what the reference collection is intended to represent will be determined by DEQ. Whether the reference collection is annual or project-based, specimens included in it are intended to represent the original taxonomist's concept of the morphological basis of each taxon. Verification of the reference collection, by DEQ staff or independent laboratories or taxonomists, documents the morphological and nomenclatural understanding of the original taxonomist. This will provide DEQ with some assurance of the contract taxonomist's use of up-to-date nomenclature (with the Integrated Taxonomic Information System [ITIS] as the standard), as well as verifying their understanding of the morphological bases of taxonomic groupings.

4.2.2 Precision

Precision is defined as nearness of different measures of the same property. Simply stated, it is a measure of consistency and repeatability; for production taxonomy (Stribling et al. 2003), quantification of taxonomic precision provides the ability to document and communicate the quality of taxonomic data within a project, or within a laboratory over time. Taxonomic precision is evaluated by direct comparison of the results (list of taxa and number of individuals of each) of a randomly-selected sample that is processed by 2 taxonomists or laboratories. Once a sample is identified by the primary taxonomist (T1), it is sent to an outside, independent taxonomist (T2), who re-identifies the entire (sub)sample. The sample should be sent to T2 blind, that is, without any identification labels associated

Exhibit 34

with the material. Each taxonomist will be provided with a hierarchical target list (standard level of effort for each taxon) and "counting rules" (need to be included as attachments). The total set of randomly-selected subsamples is a subset of the total number of samples collected for:

- A single project,
- Multiple projects within a sampling year, or
- >1 projects over several sampling years.

If multiple taxonomists within a project or laboratory have each identified enough samples, the subset can be stratified among the taxonomists so that specific checks can be made on individual taxonomists. Generally, and as a rule-of-thumb, the subset of samples can be approximately 10% of the total sample lot. For example, if a project has a total of 30 samples, there should be 3 samples randomly selected that will be re-identified by an outside/independent taxonomist. It is recommended that there be at least 3 samples selected and re-identified for sample lots of ≤ 30. For large programs or projects, say > 500 samples, it may be unnecessary to have 50 samples re-identified, but that decision will be made by DEQ.

Using the final results by the taxonomists, precision is quantified for both specimen enumeration and taxonomic identifications for each of the QC or re-id samples.

4.2.2.1 Percent Taxonomic Disagreement (PTD)

Use the formula below for determining Percent Taxonomic Disagreement (PTD):

$$PTD = \left[1 - \left(\frac{comp_{pos}}{N}\right)\right] \times 100$$

Where: $comp_{pos}$ is the number of agreements, and N is the total number of organisms in the larger of the two counts (Stribling et al. 2003).

Three types of taxonomic errors are illuminated by this comparison process: 1) straight disagreements, 2) hierarchical differences, and 3) missing specimens. Effort will be made during the side by side comparison of individual samples to specify the types of differences that are observed, and which types predominate in each sample. The lower the PTD value, the greater is the overall taxonomic precision, indicating relative consistency in sample treatment. For the 2006 field season and beyond, an MQO for PTD ≤ 15% is established. Values for individual sample comparisons exceeding the MQO (> 15%) will prompt a more detailed examination of those individual samples to determine the cause or causes of the difference in counts. PTD results as well as parsing of the difference types will be used by DEQ to develop corrective actions. Corrective actions related to taxonomic disagreement will be forwarded in writing to the taxonomy laboratory responsible for the primary identifications. The corrective actions will require that the contractor(s) correct the entire sample lot, or only the 10% subset that were the QC samples.

4.2.2.1.1 Bias

Bias is defined as statistical or method error caused by systematically favoring some outcomes over others and can be characterized as the degree of departure from a true value. Taxonomic bias exists if there are consistent misinterpretations of dichotomous keys or morphological features, poor processing of samples (e.g., poor slide-mounting techniques), or inadequate optical equipment. There is no specific

Exhibit 34

MQO established for bias but it may be a factor in the review of accuracy, which is described as low bias (directional error) and high precision.

4.2.3 Corrections to database

Any corrections to DEQ databases will be handled by the DEQ QA Officer, who will work directly with the DEQ MT-eWQX Coordinator and the DEQ macroinvertebrate specialist, who are responsible for the MT-eWQX and EDAS databases, respectively.

5.0 DATA ANALYSIS AND INTERPRETATION

Data analysis and assessment of biological integrity should be performed following the six steps listed here and described in **Sections 5.1 – 5.6**.

1. Transfer sample data from laboratory output to a reliable database
2. Reduce sample data
   a) condense to proper OTUs
   b) exclude taxa marked
   c) artificially reduce large samples
3. Compile site information (predictor variables) and identify site classes
4. Calculate the Montana-specific version of the Hilsenhoff Biotic Index (HBI)
5. Calculate a Observed/Expected(O/E) Model Result
6. Assess site biological integrity through interpretation of index results

Most of these steps are considerably simplified by using EDAS (Tetra Tech and Montana Department of Environmental Quality, 2006), which can be obtained from DEQ along with its User's Manual (Tetra Tech, 2006). Compiling site information (step 3), calculating the O/E model (step 4), and the interpreting the results (step 5) are accomplished using other technologies and procedures described below.

5.1 TRANSFER SAMPLE DATA

Benthic macroinvertebrate taxa lists with individual counts should be transferred into EDAS (Tetra Tech 2006a) or another database in which taxa can be associated with the taxonomic attributes used in calculating metrics and predictive models. EDAS includes a function that automates import of taxonomic data after the data are properly formatted in a spreadsheet. With any data transfer procedure, the accuracy of the transfer should be checked to assure 100% accuracy.

5.2 REDUCE SAMPLE DATA

5.2.1 Operational Taxonomic Units (OTUs)

For each taxon in a sample taxa list, the OTU must be determined. OTUs are identified in the Benthic Master Taxa table of EDAS. This is the level of identification at which taxonomic counts are condensed for calculations, for O/E (predictive model) calculations[1]. For instance, midges (Diptera: Chironomidae) have OTUs at the subfamily level because this is the level at which all agencies in Montana reliably

[1] Note: OTUs are not considered taxonomic target levels. Future DEQ macroinvertebrate tools may require different taxonomic requirements. Therefore, macroinvertebrate taxonomy should include identifications at the lowest practical taxonomic level, as stated in **Section 4-1**.

Exhibit 34

identify them. Numbers of individuals in multiple taxa identified at a more detailed level are summed within a sample if the OTU is at a more coarse level. OTUs for metric calculations include family and order level identifications. OTUs for predictive models exclude family and more coarse identifications for some taxa groups.

5.2.2 Excluded Taxa

In calculations of metrics that are counts of taxa (richness metrics), only those taxa that are unique within each sample should be counted. Ambiguous taxa are excluded from taxa counts. Such taxa include family level identifications within a sample that also includes genus level identifications from the same family. Likewise, order or coarser identifications may be ambiguously unique and should be excluded. Such exclusions should be made after converting taxa and individual counts at the appropriate OTU level. In EDAS, 'Excluded Taxa' are automatically marked as they are imported. Excluded taxa can also be marked manually. Within each sample, every OTU taxon that defines a group that is also represented by another OTU taxon identified at a more detailed taxonomic level should be marked for exclusion from metrics that count unique taxa.

5.2.3 Re-Sampling

Random re-sampling is the process by which samples larger than the target subsample size are reduced to the exact target subsample size. Random re-sampling generates a list of taxa and their abundances that would occur if the original sample had identified only the target number of individuals. Such a list is necessary for the predictive model, in which presence and absence of taxa for a standard sample size is required. It contrasts from rarefaction, which gives a probability for every taxon, but does not reduce the list of individuals or taxa.

In EDAS, random re-sampling is accomplished by assigning a random number to each individual in an oversized sample, ordering the list by the random numbers, and selecting the top 300 individuals to represent the new sample. By this method, some individuals and perhaps some uncommon taxa are eliminated from the list. Because it uses random number generators in determining the final list of taxa, random re-sampling can result in different taxa lists every time it is executed.

5.3 IDENTIFY SITE CLASSES

5.3.1 Predictor Variables

Site classes for the predictive model (O/E) are not distinct, but are calculated as probabilities within the model. Both indices require predictor variables for site classification (**Table 5-1**). These variables can be derived by associating geographically referenced data with the coordinates and delineated watersheds of each site. While it is possible to derive predictor values through map analysis, watershed delineation and spatial analyses are best performed with a Geographic Information System (GIS), such as ArcGIS 9.x or 10.x. The GIS analysis is outlined in Chinnayakanahalli et al. (2006). The basic GIS analytical procedures include the ***association*** of Station IDs with waterbody names with ***geographic*** coordinates, loading the spatially referenced stations into the GIS program, verifying station locations, delineating catchments using Digital Elevation Models (DEMs), and intersecting station points and catchments with the appropriate predictor data layers.

Exhibit 34

Table 5-1. Predictive variables associated with each sampling station.

Variable (EDAS name)	Description	Model	Data Source
Latitude (GIS_LAT)	Latitude (decimal), confirmed during delineation	O/E 2005; 2011	GIS or map
Longitude(GIS_LONG)	Longitude (decimal), confirmed during delineation	O/E 2005	GIS or map
Area (SQ_KM)	Catchment area (km^2)	O/E 2005; 2011	GIS or map
Basin (Columbia River Basin)	Within the Columbia River Basin (1 = yes, 0 = no)	O/E 2005	GIS or map
Air Temperature (TMAX_PT)	Annual mean of daily maximum temperatures at the site between 1971-2000 (C x 10, e.g., 14.4 degrees C = 144)	O/E 2005	PRISM database[a]
Standard Deviation of the elevation within the watershed (ELEVsd_WS)	The standard deviation of the digital elevation model data within the watershed	O/E 2011	GIS
Air Temperature (TMAX_PT_2011)	Annual mean of daily maximum temperatures at the site between 1961-1990 (C x 10, e.g., 14.4 degrees C = 144)	O/E 2011	PRISM database[a]
Julian Day (DAY)	Numeric Day of the year (1-365)	O/E 2011	Calendar
Mountains (Mtn1)	Classified as a coldwater stream (1 = yes, 0 = no)	O/E 2011	ARM[b]

5.4 CALCULATE MACROINVERTEBRATE INDICATOR RESULTS

5.4.1 Calculate the Montana-specific Hilsenhoff Biotic Index (HBI)

The HBI metric represents the relative sensitivity of the sample to nutrient perturbation. It is calculated as the average tolerance value of all individuals in the sample (excluding those without tolerance values). The range of the Biotic Index values is 0-10, 0 being sensitive and 10 being pollution tolerant. The biotic index values are listed in the "TolVal" column in the Master Taxa List in **Appendix A**. The HBI results are calculated using a weighted average:

$$HBI = \sum (ni \; x \; ai)/N$$

Where:
"n" is the number of individuals in a taxon, "i";
"a" is the index value assigned to that taxon;
N is the number of individuals in the sample with a Biotic Index value.

5.4.2 Calculate Observed/Expected

The O/E models are calculated as the ratio of the number of taxa observed (O) in the collected sample to the number expected (E) in that site type (Feldman and Jessup, 2012). The O/E ratio is calculated from sample taxa lists and predictive variables that are either uploaded to a website that runs the model or via the coldwater O/E model built using the R statistical language. The website is maintained by the Utah

Exhibit 34

State University's (USU) Western Center for Monitoring and Assessment of Freshwater Ecosystems (http://www.cnr.usu.edu/wmc/). The R code for the coldwater O/E model is detailed in **Appendix D**. Details for generating uploadable files from EDAS and running either of the models are available in the EDAS User's Manual (Tetra Tech 2010) and on the website. An explanation of the theory and processes of the model is included in Feldman and Jessup (2012).

5.5 VALIDATING MODEL OUTPUTS

Output from either O/E model provides information to determine the validity of the values (see **Appendix C**). Validity is dependent on having a minimum sample size after data reduction and, for the O/E, on model recognition of the combination of predictor variables. Sample sizes for the O/E may be different for the same sample because the O/E discounts some coarse taxa identifications (see **Section 5.2**). To determine whether the O/E could recognize the combination of predictor variables, refer to the website results labeled 'outlier'. An outlier O/E test result indicates a site that is outside of the experience of the model and the O/E value may be unreliable.

5.6 INTERPRET THE OBSERVED/EXPECTED INDEX

The interpretation of benthic macroinvertebrate data is a component within the broader Water Quality Assessment Method (Montana Department of Environmental Quality, 2011). Depending on the availability and rigor of other biological data, benthic macroinvertebrate data *may not,* be used exclusively for aquatic life and fisheries beneficial use support determinations. With this in mind, this section of the SOP uses the terms: "pass", or "fail" in relation to the biological model test in the context of the biological component within an established water quality assessment method (**Appendix D**).

The O/E model is used with established assessment methods to determine the integrity of the macroinvertebrate community. The O/E models are used to test how far a given macroinvertebrate community deviates from those sampled at reference sites.

O/E values in **Table 5-4** indicate when a macroinvertebrate sample either passes or fails the biological model test. Note: some DEQ stressor-specific assessment methods apply different O/E thresholds in a different manner than those presented in **Table 5-4** (see Suplee and Sada de Suplee, 2011). Follow the guidelines in those assessment methods when using the biological indicators for stressor-specific assessments. Otherwise use the thresholds in **Table 5-4**.

Table 5-4. Biological test thresholds based on O/E results.

O/E Model	Region (stream setting)	Pass	Fail
2005	Eastern MT (plains)	$\geq$ 0.80	< 0.80
2011	Western MT (mountain/transitional)	$\geq$ 0.90	< 0.90

5.6.1 Bray-Curtis Index

A supplemental measure to the O/E model is the Bray-Curtis Index (BC) (Van Sickle, 2008). The BC index is derived from some of the same information used to calculate the O/E score. It can be a useful tool for discerning counterintuitive O/E results. The BC Index is most helpful whenever a high (i.e. good) O/E score results from a sample collected from a known stressed stream. Occasionally this occurs when certain stressors (e.g. excess nutrients) cause some taxa to be **replaced** by other taxa that are more tolerant of the stressors, resulting in a high O/E score in a stream with high stressors. The BC Index

Exhibit 34

shows when new taxa have replaced others taxa above and beyond what the O/E model expected to measure in a given stream.

The formula for the BC Index is the sum of the absolute differences in the number of presence/absence (1,0) of observed taxa (O) minus their associated probabilities of capture (P) divided by the total sum of the O + P values:

$$BC = \frac{\sum|O - P|}{\sum(O + P)}$$

Note that the O is the formula above is not the raw count of individuals from a taxa group (e.g., 15 *Tricorythodes sp.* out of 100 total individual insects counted in a sample). Rather, it is a dummy variable indicating whether or not even a single individual of the taxa in question was observed in the sample (o no, 1 yes). The BC Index is scaled in the opposite direction than the O/E model. The BC scores will range between 0 and 1; a score of 0 means that no taxa replacement has occurred, and 1 means that all of the taxa have been replaced with other taxa**.** Use the BC Index ***only*** to help guideyour assessment decisions when you believe you are getting an incorrect O/E score. It is not meant to trump or replace the O/E score, just to clarify it. Van Sickle (2008) reported that the BC Index was more sensitive to several stressor gradients based upon nationwide datasets. You can use it to show when a community is shifting before the O/E model will react to the stressor.

5.6.1.1 How the BC Index Can Be Helpful

Table 5-6 shows a hypothetical macroinvertebrate sample collected from a stream with a high measured stressor (e.g., a fine sediment source) upstream of the sampling location. For demonstration purposes, this is an extremely small sample (five taxa). Remember that the "E" in the O/E formula is the sum of the probability of capture values for all of the taxa in a sample.

Table 5-6. A hypothetical example that demonstrates the O/E calculation, the absolute difference for the hypothetical observed (O) and expected (P) taxa, and sum of O and P for 5 taxa (adopted from Van Sickle 2008).

Taxon	O	P	|O - P|	(O + P)
1	1	0.1	0.9	1.1
2	1	0.3	0.7	1.3
3	1	0.8	0.2	1.8
4	0	0.9	0.9	0.9
5	0	0.9	0.9	0.9
	O = sum =3	E= sum = 3	Mean = 0.72; sum = 3.6	sum = 6

In this scenario, taxa 4 and 5 were expected by the model to be in the sample (i.e., probability of capture = 0.9; however, they were not collected, therefore O = 0 for both taxa. Taxa 1 and 2 were very unlikely to be collected, yet they were collected (O = 1 for each taxon). The probability of capture rates for taxa 1 and 2 was 0.1 and 0.3, respectively. The O/E score in this scenario = (3/3) = 1, and at first blush, this could be interpreted as a reference quality stream supporting a healthy macroinvertebrate community. In the example, however, recent habitat observations of high fine sediment deposition suggested an impairment really is occurring at the stream but it was not detected by O/E. The BC Index = 0.6 (3.6/6.0). This means that 40% of the taxa in this sample were replaced by rare, potentially tolerant, taxa. With

Exhibit 34

this combination of O/E and BC scores, you can say that the macroinvertebrate community was in the process of adjusting to the instream changes in stressor levels.

5.7 REPORTING RESULTS

Reports written for the DEQ following the methods described herein require:

- The EDAS output and a concise one paragraph ecological interpretation. The ecological interpretation includes a description of the invertebrates found in the sample and what their presence represents in terms of water quality.
- Taxonomic lists of macroinvertebrates, including tolerance values and functional feeding group designations used for each taxon. Taxa lists should include class, order, family, genus, and species designations where possible. Taxa lists should follow the taxonomic classification scheme shown in **Appendix A** to facilitate DEQ quality assurance activities.
- Copies of taxonomic bench sheets should be included (Taxa List Template example provided in **Appendix B**.)
- Number pages on all reports, including appendices.
- A clear and concise summary of findings and conclusions.
- Clearly document the dates samples were collected in any written report.
- If an internal reference is developed for the analysis, describe the internal reference used.
- Clear documentation of the proportion of sample subsampled.
- Submit data both in hard copy and in electronic form (EQUiS/WQX Compatible).
- If any further analysis is needed in which the O/E models cannot be used, contact David Feldman; Water Quality Standards Section; Montana Department of Environmental Quality, PO Box 200901, Helena MT 59620- 0901 (406)-444-6764, dfeldman@mt.gov or the current biocriteria specialist for the state of Montana.

APPENDIX C - EXAMPLE OUTPUT FOR THE OBSERVED/EXPECTED MODELS

The following page shows an example output table from EDAS (Tetra Tech 2006a). These are used to illustrate index results for samples. The EDAS output result comes as a direct output saved as an MS Excel (2003) spreadsheet (**Table C-1**). The spreadsheet contains all of the relevant sampling location information and O/E values. EDAS can also generate Multimetric Index values if a project requires them (not shown in the example).

Exhibit 34

Table C-1. EDAS output table example.

APPENDIX D - MONTANA DEPARTMENT OF ENVIRONMENTAL QUALITY BENTHIC MACROINVERTEBRATE OBSERVED/EXPECTED MANUAL

D1.0 Introduction

D1.1 Background

This manual is intended to guide users in creating and applying predictive models of observed and expected (O/E) benthic macroinvertebrate taxa in samples from streams in Montana. O/E models have been developed in 2005 and 2011 by consultants to the Montana Department of Environmental Quality (DEQ). With this guidance and associated software, development of new models and application of existing models should be possible for DEQ staff.

The O/E model is an assessment tool that can be used to determine the degree to which a sample contains the number and type of taxa expected after considering relevant characteristics of each site's environmental setting. Literature on the O/E predictive models is abundant, and the theories behind the responsiveness of the models to stress can be reviewed in those articles (Clarke et al. 1996, Clarke et al. 2002, Clarke et al. 2003, Hawkins and Carlisle 2001, Hawkins et al. 2000, Hawkins and Norris 2000, Hawkins et al. 2009, Hubler 2008, Van Sickle et al. 2005, Van Sickle et al. 2006, and Van Sickle et al. 2007). The Bray-Curtis (BC) index is used as a secondary indicator and its development and application are also presented in this document. It is developed using theories similar to the O/E index (Van Sickle 2008).

D1.2 Purpose and Goals

This document is intended as a guide for developing, interpreting, and applying O/E and BC indices. It is especially tailored to the needs of DEQ in assessing benthic macroinvertebrate conditions in streams of Montana. Following the steps of this manual should allow DEQ staff to calibrate new predictive models, interpret the model output, and apply developed models for assessment purposes.

D1.3 Data organization and software

Data for analyses must conform to DEQ standards for sample collection for taxa and other data standards for reference designations and predictor data. The necessary information for development and application of the O/E and BC indices include two types: One of taxonomic composition in samples and another of site and sample characteristics (predictors) for the sampling locations. DEQ uses the Ecological Data Analysis System (EDAS) for generating macroinvertebrate indicator of water quality results. EDAS is also used to generate taxonomic and predictor data in formats that can be used for model development and application. Some formats require further manipulation after export from EDAS. In this manual, we assume that the analyst is familiar with EDAS and its functions. Specific format for analyses will be described in following sections.

The instructions include references to existing software. While some details on the use of the software are provided, analysts are expected to have basic knowledge of the software and can investigate software application issues through other manuals specific to those programs. The software referenced most often includes Excel (Microsoft Corporation), PC-ORD (McCune and Mefford 2006), R (http://www.r-project.org), Statistica (StatSoft, Inc.), and "SubSample.exe" (a DOS program). Alternative software could be used for some steps of the analyses.

Exhibit 34

D2.0 Applying an Observed/Expected model

Once the O/E and BC models are built on calibration data and saved, they can be applied to test data. Test data are samples from any site that was not used as a reference sample in the model calibration. This could include samples from reference-quality sites sampled in years following the calibration effort or from sites that have some know degree of disturbance.

D2.1 Required files and scripts

The files required to calculate O/E scores from an established model include 2 data files and multiple R scripts. The taxa and predictor matrix should have the same format described for model building. Taxa identifiers should be the 8-character OTUs, predictors must include all predictors used in the models, and records for the taxa and predictor files must have the same sample identifiers in the same order. The same predictor file used for model building can be used for model application, where the 'RefCalVal' field includes 'test' designations. Only the sample identifiers and the model predictors are required in the test predictor file, but the other fields can be included as well.

The model can be applied either at the end of the 'model.build.V4.1.R' script or from the 'model.apply.V4.1.R' script. During its execution, the script calls on other files, including 'model.predict.v4.1.r', 'MyModel.Version1.Rdata', and 'assess.one.sample.4.1.r'. If new data are prepared for calculation of O/E and BC scores, first create the taxon and predictor files as described above. Then run the 'model.apply.V4.1.R' script as described below.

The required fields in the predictor files are as follow. All spellings and cases must be exact.

SampID	Also called BenSamp-Rep (rename to SampID)
RefCalVal	With allowed values 'Calib', 'Valid', or 'test' (case sensitive) (optional field)
ELVsd_WS	Standard deviation of Elevation in the watershed
GIS_LAT	Latitude
JulianDay	Sequential day of the year (cold only)
log_sqkm	logarithm of watershed square kilometers (also called 'log_km2' [rename])
Mtns1	Designation of the mountains ecoregions (1), or not (0)
Tmax_PT	Maximum monthly average temperature at the point (also TMAX_PT_2011)
FFP_PT	Frost-Free Period Point (For Warm-Water model only)
WDmin_PT	Minimum number of wet days (For Warm-Water model only)

There are alternate names for two variables because these were also used in the 2005 O/E model. In the case of Tmax_PT, the value is calculated differently among models, so that in EDAS the value is labeled Tmax_PT_2011, but it is recognized in the model as 'Tmax_PT'.

D2.2 Running model application R code

The model application R code is named 'model.apply.V4.1.R'. The code is run in sections so that errors can be corrected sequentially (and to avoid wasting time running subsequent erred sections). In the next report section, the code for the cold-water model is contained in text boxes. It is recommended that the code be run in the blocks between bullets as shown below. All model development files should be kept

Exhibit 34

in one file folder (or "directory"). Retaining distinct runs in separate directories is a good idea when experimenting and interpreting.

- Introduction and set-up.

```
# R code modified to allow application only (cut out much of the building steps)

# Ben Jessup and Dave Feldman modified original code by John Van Sickle, US Environmental
Protection Agency;
#Version 3: For application of an existing model (established through the model.build.v4.1 script)

##################################################;

## First clear the workspace
rm(list=ls())

#load required packages;
library(gtools); library(MASS);
library(cluster); library(Hmisc);
require(scatterplot3d)
require(maps)

# change directory based on where have script and data files (EWL)
#  but to keep code the same subsititute with "getwd"
# change the working directory to the correct one using "setdir". Notice that the filepath uses "/"
setdir ("C:/working directory")
 myDir <- getwd()
```

- Load the predictor file and display example data, which should be in the same directory as the script.

```
# STEP 1 -- INITIAL SETUP -- Input and organize the bug and predictor data;
# The exact code for this step is very particular for each data set, ;
# but similar operations will need to be done on every data set;
# Data setup below is an example which contains both reference and nonreference sites;

################################;
# Input data are predictor data and a (site x taxa) matrix of abundance for all bugs;
# Predictor data file must include a column to identify the calibration, validation and test sites;

# Step 1a - Read and organize predictor data;
# Input the predictor data, tab delimited. Use the sample/site ID as the row name;

# Import Data
myFile = "data.cold.preds.tst.tab"
predall=read.delim(myFile,row.names=1)

head(predall); #look at 1st 5 rows, all columns;
dim(predall); # number of rows and columns;
```

Exhibit 34

- Load the bug file and display dimensions of the file (# rows and # columns)

```
## Step 1b - Input the assemblage data (bug data), as a site-by-taxa matrix;
# The bug matrix is the result of fixed-count subsampling and matrify or cross-tab functions;

bugall<-read.table(paste(myDir,"data.cold.bugs.tst.tab",sep="/"),row.names="SampID",
        header=T,sep="\t");
dim(bugall)
```

- Make sure that the predictor and bug files have records in the same order, with the same identifiers.
- If records are aligned, “true” will appear for every record.

```
## Step 1c - Align bug and predictor data, by site/sample;
#check sample(row) alignment of bug and predictor data;
row.names(bugall)==row.names(predall);
# If samples are not aligned, fix by aligning bugs data to predictor data;
bugall<-bugall[row.names(predall),];
#check alignment again -- alignment OK;
row.names(bugall)==row.names(predall);
```

- Change taxa abundance to presence/absence.

```
#Create a Presence/absence (1/0) matrix (site by taxa) for the bugs;
bugall.pa<-bugall;
bugall.pa[bugall.pa>0]<-1;
```

- The following lines are mostly informative.
- The source and load lines call on scripts and files that should be in the same directory as the script.
- The last line displays taxa names.

Exhibit 34

```
# Step 7 (continuation of steps in model.build.v4.1) - Making predictions for new (test) data.
# first, source the prediction script and also load the desired model;
 source("model.predict.v4.1.r");
 load('MyModel.Version1.Rdata');

 # User must supply a sample-by-taxa matrix of taxa abundance or else presence/absence
        #(coded as 1 or 0), for all new samples;
 # User must also supply a corresponding file of predictor data for those same samples;
 # These 2 files should have similar formats as the original taxa and predictor data sets;
 # Notes on file formats --
 #  A) The sample ID column in both files should be read into R as a row name (see Step 1 examples).
 #  B) Predictor data set -- Must include columns with the same names, units, etc.,
 #    as the model's predictor variables. All other columns will be ignored;
 #    Column order does not matter;
 #    Predictions and calculations of O/E will be made only for those samples that have;
 #    complete data for all model predictors.;
 #  C) Sample-by-taxa matrix. Can contain abundance or presence/absence (1 or 0).
 #                Missing or empty cells now allowed;
 #    Sample ID's (row names) must match those of predictor data.
 #    Any names for new taxa (column names) are acceptable, in any order;
 #    HOWEVER - Only those new-data taxa names that match the names in the
 #      calibration data can be used to calculate observed richness;
 #      All other taxa (columns) in the new-data bug matrix are ignored;
 #    To see a list of the calibration-taxa names, do:
    names(bugcal.pa)[colSums(bugcal.pa)>0];
```

- Define subset of data if desired
- Limit analysis to sites with complete data

```
# Example predictions: non-reference sites are labeled "test" (see Step 1);

pred.test<-predall; #predictor data - ALL sites;
bug.test.pa<-bugall.pa; #Bug presence/absence matrix, ALL sites;

#To limit to test sites only, use this code;
#pred.test<-predall[as.character(predall[,'RefCalVal'])=='test',];
#bug.test.pa<-bugall.pa[as.character(predall[,'RefCalVal'])=='test',];

#Drop all samples/sites that do not have complete data for the model predictors;
pred.test<-pred.test[complete.cases(pred.test[,preds.final]),];
bug.test.pa<-bug.test.pa[row.names(pred.test),];
```

- Calculate and display O/E, BC, and outlier status
- Results are not automatically saved and should be copied from the R console

Exhibit 34

- Looking at capture probabilities and predicted group occurrences is optional

```
#makes predictions for test data; *** Check PC at end of line, modify if needed
        #(may want to run BC at PC=1.e-14) **
OE.assess.test<-model.predict.v4.1(bugcal.pa,grps.final,preds.final,
grpmns,covpinv,prednew=pred.test,bugnew=bug.test.pa,Pc=0.5);

# Look at O/E and BC scores of test-data samples;
 OE.assess.test$OE.scores;
##### COPY these from the R console to a spreadsheet

# Look at predicted capture probabilties (1st 5 rows) for all calibration taxa, for test data;
 Head (OE.assess.test$Capture.Probs);
# Look at predicted group occurrence probabilties, for all test samples;
 OE.assess.test$Group.Occurrence.Probs;
```

- Calculate increaser/decreaser statistics
- Results are not automatically saved and should be copied from the R console
- For each of taxon, we list the 'Sensitivity Index'. The index is calculated from the average predicted probability of detection (assuming sites were under reference condition), the number of test sites at which taxa were predicted to occur, the number of test sites at which taxa were observed, and the ratio of observed sites to expected sites for each taxon (the 'Sensitivity Index'). We interpret it as a measure of sensitivity of a taxon to whatever stressors are influencing a taxon within the set of test sites submitted for assessment. A ratio > 1 indicates the taxon was found at more sites than expected and was thus an 'increaser' or tolerant taxon. A ratio < 1 indicates the taxon was found at fewer sites than expected and was thus a 'decreaser' or intolerant taxon.

```
# Increaser/Decreaser taxa
## use the output from this (in test sites) to find increasers and decreasers
## also called the sensitivity index
## Increaser values will be >1 (or >2 for certain increasers)
## Decreaser values will be <1 (or <0.5 for certain decreasers)

# limit above to test sites only
 taxa.pc<-OE.assess.test$Capture.Probs[as.character(predall[,'RefCalVal'])=='test',];
 bug.test.pa<-bugall.pa[as.character(predall[,'RefCalVal'])=='test',]; #Bug presence/absence matrix,
test sites;
# calculate observed occurences in all test sites over predicted occurences in all test sites
 Inc.dec.taxa<-apply(bug.test.pa,2,sum) / apply(taxa.pc,2,sum);
 Inc.dec.taxa
```

- Calculating O/E for an individual sample
- This gives more detailed results than the routine above, especially for individual taxa
- First identify the script and load the data
- Other lines are informative

Exhibit 34

```
## Assessing an individual sample or site;
        source("assess.one.sample.4.1.r")
        bug.test.pa<-bugall.pa
#This function assesses a single site or sample from a new (test) data set to which
# model.predict.v4.1() has already been applied.
# assess.one.sample() compares observed occurrences with the model-predicted
# probabilities of occurrence for all taxa;

# Input parameters are:
# case -- A selected sample ID, for which a prediction has already been made ;
        # The selected case must be among those assessed above;
# result.prd -- Output from O/E calculation above.
# bugnew -- Sample-by-taxa matrix of new samples.
# Pc -- Cutoff for capture probabilties for inclusion of taxa in O/E;
```

- Enter the name of the sample between quotes after *case=*

```
# The function produces a data frame with one row per taxon, and the following columns:
# observed presence(1) or absence(0);
# predicted capture probability;
# Big.diff = "Yes", if there is a big difference (>=0.5) between observed and predicted;
# In.OtoE = "Yes" if the taxon would be included in the O/E calculation for this sample,
        # given the stated value of Pc;

#By default, the function displays the results with its rows (taxa) sorted by
        # the magnitude of (observed-predicted),
        # as suggested in Van Sickle, J. (2008), JNABS 27:227-235;

site1.result<-assess.one.sample.4.1(case="11591_0",result.prd=OE.assess.test, bugnew=bug.test.pa,
Pc=0.5);

# See below for other sorting possibilities;
# Alternative display is to sort the taxa by their predicted occurrence probabilities;
 site1.result[order(site1.result$predicted,decreasing=TRUE),];
# Another alternative is to sort alphabetically by taxon name;
 site1.result[order(row.names(site1.result)),];
```

- End of script

Site Visit Form Instructions

Place a Site Visit Code label in the upper left corner (ONLY 1 SITE VISIT CODE PER FORM).
Place a Trip Label in the upper right corner. (Covering Project ID and Trip ID with label is alright.)

1. **Project ID**: If you do not have a Trip Label, enter the Project ID assigned by Data Management. If Project ID is not assigned, leave blank for Water Quality Database Manager.
2. **Trip ID:** If you do not have a Trip Label, enter the Trip ID assigned by Data Management. If Trip ID is not assigned, leave blank for Water Quality Database Manager.
3. **Date/Time**: Enter the date and time of the station visit.
4. **Personnel**: Enter the first and last name(s) of the personnel conducting field activities.
5. **Waterbody**: Enter the name of the waterbody such as "Missouri River".
6. **Location**: Description of sample location such as "upstream from bridge on Forest Service road 100". For confidentiality please DO NOT use proper names of people in the location field.
7. **Station ID**: If you have a Trip Label, enter the established ID. If there is no ID on the Trip Label, leave the field blank and Data Management will generate a Station ID when the Site Visit Form is submitted.
8. **Visit #**: Enter "1" if this is a new station. Leave blank if visit number is unknown.
9. **HUC**: If you do not have a Trip Label, enter the fourth code (8 digit) HUC the station falls within.
10. **County**: If you do not have a Trip Label, enter the county in which the station falls within.
11. **Lat/Long**: Latitude and Longitudes should be obtained in decimal degrees using a GPS unit reading **NAD83** whenever possible. If a lat/long is obtained by another method, the datum and method must be recorded in the Site Visit Comments.
12. **Lat/Long Verified**: Latitudes and Longitudes should be verified immediately upon return from the field. Verify by plotting on a paper map or using a mapping website. Once the lat/long has been verified check the Verified box and enter initials after "By". Do not make minor adjustments to measured values during verification; they are assumed to be correct within the limitations of the measurement system. Gross errors should be corrected as follows: 1) Draw a single line through the erroneous value(s) and initial. Do not erase the original reading. 2) Write the corrected value in the comment field along with the method and datum used to derive the corrected value.
13. **Elevation:** Record elevation collected by GPS and circle the GPS datum used. If elevation is obtained by another method, the datum and method must be recorded in the Site Visit Comments.
14. **Samples Collected**: Check the box next to each activity that is collected during the station visit.
15. **Sample ID**: Write the Sample ID (Site Visit Code-sample identifier) for all of the samples collected.
16. **Sample Collection Procedure**: Circle the appropriate Sample Collection Procedure ID.
    For each Chlorophyll-*a* transect, record the sample collection method in the first space provided and the sample location in the second space provided (example: A: T - R).
    For Phytoplankton, record the volume filtered for each sample collected.
17. **Analysis Requested**: Record the requested laboratory analysis for each chemistry sample and circle the preservative used.
18. **Field Measurements**: Record your field measurements in the spaces provided.
19. **Field Assessments**: Check the boxes next to each type of field assessment completed.
20. **Site Visit Comments**: Record general comments about the station visit, samples, and field measurements.
21. **Chemistry Lab Information**: If chemistry lab samples were taken, complete this section.
    Lab Samples Submitted to: Enter name of laboratory where samples will be sent.
    Account #: Enter account number at laboratory where samples will be sent.
    Date Submitted: Record date the samples were received by the laboratory.
    Sign and date the form each time the samples change possession.

Probable Hydrologic Consequences
Area F
Western Energy Rosebud Mine

1.0 INTRODUCTION

Western Energy has operated the Rosebud Mine located near Colstrip Montana in Rosebud and Treasure Counties since 1975 (See Figure O-1). The mine is operating under Montana Department of Environmental (DEQ) permits C1986003A, C1984003B, C1985003C, C1986003D, and C1981003E.

Western Energy submitted a permit application (C2011003F) for new Mine Area F in October 2011. The Rosebud Mine Site Map is shown as Figure O-2.

This report provides the identification and evaluation of probable hydrologic consequences (PHC) to support the Area F permit application in accordance with the requirements of ARM 17.24.314(3).

1.1 Background

There have been many previous investigations and evaluations conducted in the vicinity of and at the Rosebud Mine. Background reports considered in this PHC include:

- Area F Permit Application, Western Energy Company, October, 2011.
- Comprehensive Evaluation of Probable Hydrologic Consequences, Areas A, B and C, Western Energy Rosebud Mine, Nicklin Earth & Water, September 2013.
- Hydrology of Area 49, Northern Great Plains and Rocky Mountain Coal Provinces, Montana and Wyoming, Slagle et al, United States Geological Survey, January 1983.
- Hydrogeologic Conditions and Projections Related to Mining Near Colstrip, Southeastern Montana, Van Voast, Hedges, and McDermott, Montana Bureau of Mines and Geology, 1977.

- Hydrogeologic Responses: Twenty Years of Surface Coal Mining in Southeastern Montana, Van Voast and Reiten, Montana Bureau of Mines and Geology, 1988.

- Final Environmental Impact Statement, Western Energy Company's Rosebud Mine, Area C, Block 1, Montana Department of State Lands, US Office of Surface Mining, 1982.

Relevant Rosebud Mine monitoring reports include baseline and investigation reports, mining permit applications, and annual monitoring reports.

1.2 Approach

Baseline hydrologic data have been collected at Area F (Refer to Appendix B) and numerous previous investigations and hydrologic monitoring activities have been performed at the Rosebud Mine resulting in a very large amount of hydrologic data. Compilation, presentation, and evaluation of the available hydrologic data collected over the many years of operation of the Rosebud Mine allows for the identification and evaluation of probable hydrologic consequences beyond those developed based on baseline data. This information is provided in 17.24.304 and specifically in Appendix B of the permit application.

The key time-frames of interest include:

- Baseline (premine)

- Short-term (during mining and reclamation)

- Long-term (post mine and bond release)

1.3 Mining Progression

1.3.1 Past Mining

Mining has occurred at the Rosebud Mine since 1975 in Areas A, B, C, D and E. Figure O-3 shows the mining progression that has occurred at the mine over time and planned mining in the future.

1.3.2 Present Mining Situation

Active mining at Rosebud Mine is presently occurring in Areas A, B and C. Mining at Rosebud consists of a combination of topsoil removal, overburden removal, and coal removal. Topsoil is salvaged with appropriate mining equipment prior to overburden removal and stockpiled as necessary or hauled directly to regraded areas. Overburden is moved by the dragline and the coal is removed by means of a truck and shovel operation.

1.3.3 Future Mining

Figure O-4 depicts the planned mining progression at Area F. The present mine plan anticipates mining to occur from 2015 to 2034.

2.0 HYDROLOGIC SETTING SUMMARY

2.1 Climate

The climate of eastern Montana is classified as semiarid continental and is characterized by hot moderately dry summers, cool dry falls, cold dry winters and cool moist springs. Winter cold spells are often interrupted by periods of warmer weather. The passage of mid-latitude storm systems is typical of the climate of this area; day-to-day weather changes can be quite extreme because of the migrating systems.

At the mine, precipitation occurs predominantly as snow from about November to April. About one-third of the total annual precipitation is in the form of snow. Due to the prevailing westerly wind, the snow typically accumulates on the leeward slopes of drainage.

Refer to Appendix C for additional data and discussion of climate and weather at and in the vicinity of Area F.

2.1.1 Temperature

The average maximum and average minimum daily temperatures as measured at Colstrip are 88.1^{o} F in July and 9.6^{o} F in January respectively. The maximum and minimum temperatures ever recorded at Colstrip are 111° F (August 6, 1961) and -50° F (February 15, 1936).

2.1.2 Precipitation

The average annual precipitation at Colstrip is 15.1 inches. Monthly precipitation varies with higher average monthly precipitation in the spring (May and June). Snowfall and snow accumulation is usually highest in December and January. Total average snowfall is 41.6 inches.

2.1.3 Long-Term Precipitation

The long-term precipitation trends are discussed in Appendix C in terms of precipitation departure from average (DFA) plots. The DFA plot provides a graphical representation

of precipitation trends. Periods with negative values are indicative of lower than average precipitation (drought) and periods with positive values represent wetter than normal precipitation.

2.2 Water Availability

Generally, both surface water and groundwater are scarce at the Area F vicinity. The water supply is sufficient for domestic and livestock watering uses but not for irrigated agriculture. As typical of the semi-arid west, potential evapotranspiration exceeds average precipitation during the growing season.

2.3 Surface Water

The land surface at Rosebud Mine can be characterized by gentle slopes and subdued drainage divides. There are steeper slopes and narrow ridges present in the western portions of the area.

Ephemeral drainages at Area F include Trail, McClure, Robbie, Donley and Black Hank Creeks. McClure is tributary to Trail Creek which is tributary to the West Fork Armells Creek. Black Hank and Donley are tributary to Robbie Creek which is tributary to the West Fork Armells Creek. Armells Creek is tributary to the Yellowstone River.

Flow in these ephemeral drainages typically occurs only during periods of snowmelt and/or after periods of significant rainfall. When rainfall or snowmelt exceeds the infiltration rate of soils and vegetation evapotranspiration, water flows overland and then to drainage channels. Lesser amounts of runoff in drainage channels tend to be captured in stock ponds and/or infiltrate to the subsurface. Channelized runoff quantities tend to vary as they are dependent on precipitation patterns (e.g., wet versus dry climate periods), the nature (intensity and duration) of precipitation and snow accumulation and snow melt, soil conditions (dry, wet, frozen, etc.), vegetative cover, slopes and natural storage.

The proposed mine plan (Area F Permit Application Exhibit A) does not physically disturb the main Robbie, Donley and Black Hank Creek channels except where the haul road passes over these channels. Therefore, ephemeral discharges originating up-gradient of Area F pass through unimpeded.

As discussed in Appendix B (Hydrology), springs, ponds and wetlands are present within the main drainage channels found in and adjacent to Area F. Pond leakage and spring discharges have led to formation of wetlands down-gradient of the source of water. The function of springs, ponds and wetlands is also directly related to surface and groundwater hydrology.

2.3.1 Surface Water Quality

The surface water quality at Area F reflects runoff conditions and is variable. Baseline monitoring indicates that surface water has about two to three times higher specific conductivity when compared to the Rosebud Mine in general. Similarly, average TDS and major ion concentrations are higher in Area F surface water samples when compared to other Rosebud Mine drainages. Trace metals in Area F surface water are comparable to baseline data for Armells Creek and East Fork Armells Creek. One Area F surface water sample had lead concentration in excess of DEQ-7 numeric standards. There were no other exceedances of DEQ-7 standards in any other of the Area F surface water samples.

2.3.2 Surface Water Uses

Historically, the only known use of surface water at and in the vicinity of Area F is for wildlife and livestock watering direct from the source and from stock ponds. Wildlife and livestock also use water from springs. Stock ponds are constructed impoundments, typically in drainage bottoms, that store surface water flows resulting from precipitation events or snowmelt runoff. Some stockponds are sourced by springs. At areas adjacent to Area F, livestock water use will continue. During mining, surface water will be used for industrial purposes related to mining including road watering for dust control.

2.4 Groundwater

Groundwater at the Rosebud Mine occurs in shallow alluvial and colluvial deposits found in drainage bottoms and in Fort Union Formation consolidated deposits, including the Rosebud and McKay coal seams. At Area F, alluvial groundwater is limited and is hydraulically connected to the adjacent overburden in the upper portions of the Area F drainages. At these locations, the channel base of the alluvium is hydraulically isolated from the Rosebud coal. Progressing down-gradient along the drainages, the alluvium is

likely hydraulically connected to the Rosebud coal seam (see also Appendix I, Part A).

The overburden, Rosebud coal, interburden, McKay coal, and sub-McKay are all strata from the Tongue River Member of the Fort Union Formation. The Tongue River Member can be as thick as 540 feet. These units yield low quantities of water but at sufficient rates to provide domestic and stock watering supplies. Low yield springs also occur at outcrops from these deposits and they are frequently used for stockwater.

The groundwater flow direction in the coal seams is generally consistent with topography to the northeast.

Refer to Appendix I (Area F Groundwater Model Report) for a detailed characterization and discussion of groundwater and groundwater hydraulic properties at and in the vicinity of Area F.

2.4.1 Groundwater Quality

The groundwater quality at Area F varies significantly based on geologic stratum. The highest average TDS concentrations are observed in the overburden (average of 4,098 mg/L), followed by the alluvium (3,203 mg/L), Rosebud coal (2,101 mg/L), sub-McKay (1,961 mg/L) and McKay coal (1,819 mg/L). Generally, TDS concentrations are higher when compared to regional baseline data (Slagle et al, 1983). Sulfate is the dominant major ion with average concentrations of: 2,400 (overburden), 1,948 (alluvium), 1,065 (Rosebud), 1,052 (sub-McKay) and 979 (McKay) mg/L. DEQ-7 human health standards for one or more of the following analytes were exceeded in six groundwater samples: arsenic, fluoride, lead and selenium.

The overall groundwater quality at Area F is generally similar to the Rosebud Mine except that the overburden groundwater is characterized by higher concentrations of most major ions.

2.4.2 Groundwater Use

Premine groundwater use at and in the vicinity of Area F is mainly for livestock watering with a few domestic wells. The main source of water is wells developed in coal and sub-McKay deposits.

2.5 Springs, Ponds and Wetlands

2.5.1 Springs

Springs and seeps at Area F generally occur due to the surfacing of shallow, sometimes perched, groundwater that accumulates at the transition from more to less permeable strata. This tends to occur where erosional processes at drainages expose perched groundwater. Typically, the perched groundwater lies on low permeability mudstones. This groundwater may discharge as seeps or springs when these contacts are exposed to the surface. The flow from seeps and springs typically results in the presence of a down-gradient wetland. These surface expressions typically flow or “ooze” down the drainage for a limited stretch before being evapotranspired or absorbed into the soil. Of the springs monitored since 2011, only Spring 4 generally exhibits flows exceeding one gpm. Spring water quality is highly variable.

Springs and seeps are sources of water for wildlife and livestock in the vicinity of Area F. Springs are sometimes developed (e.g., excavated or impounded) to maximize the availability of water for livestock. These wet areas are often trampled by wildlife (e.g., elk) and livestock use and surrounding vegetation and water quality are impacted by this use. Monitored springs are characterized in detail in Attachment B-J of Appendix B (Hydrology).

2.5.2 Ponds

The ponds in the vicinity of Area F were constructed to store water for livestock use. Typically, a berm or dam is constructed across the channel to impound runoff flows. Some ponds are constructed down-gradient of a spring. Additionally, road and two track road construction can create ponding conditions. Detailed characterization of ponds at Area F is provided in Attachment B-L of Appendix B (Hydrology).

2.5.3 Wetlands

The identification, characterization and delineation of Area F wetlands are described in the report, “The Rosebud Mine Wetlands Delineation Report, Area F” (Cedar Creek Associates, 2013) (Appendix E). The Army Corps of Engineers determined that these

wetlands are isolated and not jurisdictional (See Appendix E). These wetlands are sourced by springs and seeps or seepage from pond embankments. The vegetative assemblies associated with wetlands are described in the wetland delineation report.

2.5.4 Aquatic Life

The aquatic life survey (ALS) (ERM, 2015)(See Appendix B) reports the results of the aquatic benthic community survey. Ten wetland areas within Area F were surveyed.

3.0 PROBABLE HYDROLOGIC CONSEQUENCES

3.1 Surface Water Probable Hydrologic Consequences

Due to mining operations, the surface water system will be impacted. Consequences to the surface water quantity, surface water quality, topography and erosional stability are discussed below.

Mining will alter the existing premine topography. For reclamation, the post mine topography (PMT) was designed to be as similar as possible to premine topography, given the constraints of earthmoving equipment, economics, contemporaneous reclamation, and stripping ratio. During reclamation, smooth transitions will be constructed between undisturbed and reclaimed land to re-establish surface drainage patterns.

During mining, the reclamation will be performed following the mining advance, causing temporary changes to the drainage system. As the post mine topography is developed, the drainage system will start to function similarly to the premine drainage system. The PMT was designed to meet the regulatory definition for approximate original contours. The final surface configuration resembles the premine configuration and blends into and complements the drainage pattern of the surrounding terrain. By developing a PMT that closely resembles the premine topography, Western Energy is ensuring that the post mine drainage system performs in a manner that meets the needs of the post mine land uses.

3.1.1 Surface Water Quantity – PHCs

3.1.1.1 Short Term Impacts – During Mining

Generally, surface water flows at Area F are ephemeral and dominated by short term/episodic precipitation and snowmelt runoff events. During mining, the surface water quantity will be impacted. Tributary drainages will be mined out and surface runoff from disturbed areas will be impounded in mine pits and/or sediment control structures in accordance with the mine's hydrologic control plan. The detention and controlled release of surface runoff will result in reduced peak flows to the Armells Creek drainage.

Generally, the nature of climate and weather at Area F dominates the water supply. Overall surface water supply is scarce and its use is opportunistic based on the capture of runoff from the infrequent flow events. Based on 20 years of discharge data collected by USGS at the Armells Creek gaging station (06294995), the average contribution to Armells Creek surface flows from Area F is 117 acre-feet per year. This represents the maximum impact if all of the runoff in the entire Area F were to be detained. However, surface flows will be augmented by discharges from sediment ponds (e.g., MPDES discharges). As the sediment ponds are designed to retain up to the volume of runoff produced by the theoretical 10-year 24-hour storm event, runoff from larger events will discharge to the main channels.

It is anticipated that the quantities of surface runoff, soil moisture storage, and infiltration to underlying groundwater will increase during mining due to the impacts of disturbed ground when compared to premine vegetated conditions. This increased runoff is then detained in mine pits and sediment ponds. Impounded water will be utilized (e.g., road dust control), evaporate, and infiltrate to the subsurface contributing to the recharge of underlying hydrostratigraphic units.

At times, impounded water will be discharged from sediment ponds to surface water drainages. Planned and unplanned discharges will occur in conformance with mine MPDES discharge permit requirements. Locations of all potential discharges to Trail Creek, McClure Creek, Robbie Creek, Donley Creek, and Black Hank Creek from disturbed lands which will be detained in sedimentation ponds are shown in Exhibit D of the permit application. Discharges from the permit area are described in more detail in Permit Sections 17.24.633, 17.24.639, and 17.24.313.

Based on the USGS flow data from Armells Creek, the average annual contribution to surface flows from runoff originating up-gradient of Area F is projected to be 149 acre-feet. As the main channels (Robbie, Donley and Blank Hank) are not mined out, up-gradient ephemeral discharges will flow through Area F unimpeded. Similarly, non-impacted runoff originating down-gradient of Area F will discharge to main channels, providing water supply to existing users.

Surface water (when present) is also connected to the underlying alluvium (where present). Smaller surface flows tend to rapidly infiltrate to the subsurface. If the alluvium becomes fully saturated, groundwater can surface to the channels. This has been observed at Robbie Creek in the vicinity of the county road, during the recent wet

climatic conditions. It also occurs downstream from Area F as discharges from groundwater cause intermittent and perennial flow conditions lower in the Armells Creek drainage. This water supply becomes available to downstream users.

Alternate water supplies (e.g., wells supplied by coal aquifers and sub-McKay sands) are available if adjacent surface water users are impacted by mining operations.

3.1.1.2 Long Term Impacts – After Mining

As reclamation proceeds, the drainage system will be restored. All disturbed drainages and stream channels will be constructed to approximate original drainage configurations. A tributary system will be designed and constructed to restore the premine system of incised drainages that collected runoff and sediment from the uplands and convey them to the main drainage channels. The post mine channels and floodplains are designed to mimic the premine channels' response to rainfall events. This is achieved by providing channel geometry (length, slope, longitudinal profile, cross-section, and bedform) that gives velocities, flow areas, and other hydraulic properties that are similar to premine properties for the same discharge events. As the mine area is reclaimed, long term effects on the drainage system are expected to be minimal.

Evaluation of available stream flow data collected at the Rosebud Mine confirms that flows are infrequent, ephemeral and occur in response to precipitation events and snowmelt. The key factor is precipitation. More specifically, the ephemeral flows reflect the nature of the snow accumulation and melt and higher intensity precipitation events. These factors are mostly independent of mining activities and post mine surface water flows should be essentially the same as premine upon completion of reclamation.

As surface flows are highly variable and event based, premine and post mine comparisons should be based on the evaluation of hydraulic function and quantifications from surface modeling of a set precipitation event such as a 10-year, 24-hour storm (e.g., SedCad™ modeling).

The evaluation of pre and post mine geomorphology, drainage basin characteristics and runoff presented in Tables J-1 through J-4 of Appendix J (Protection of the Hydrologic Balance) demonstrates that post mine surface water flows will be essentially the same when compared to premine as the reclamation will result in similar geomorphic and hydraulic characteristics.

Surface water losses (recharge) to the alluvial groundwater system should also return to premine conditions as natural surface water flows are reestablished and groundwater levels recover following mining.

3.1.2 Surface Water Quality - PHCs

As discussed above, tributary drainages will be mined out and runoff from disturbed areas will be contained. Sediment control structures will prevent the discharge of water with elevated suspended solids and sediment to receiving drainages for precipitation events up to the design event (10-year, 24-hour). The result is a net improvement of downstream water quality during mining.

For significant spring and summer-time runoff events (greater than 10-year, 24-hour), receiving drainages would likely have naturally occurring elevated suspended solids and sediment levels. The quality of receiving water during winter events would likely be variable, depending on the conditions. For example, melt water flowing over frozen land would likely be low in suspended solids, however significant flows in drainage channels would tend to transport suspended solids and sediment depending if the bottom of the channels are frozen.

As discussed above, the mine will at times discharge treated water in accordance with its MPDES permit. Under typical conditions, discharged water will infiltrate to the subsurface of the main undisturbed drainage channels. At times, when receiving drainages are flowing due to significant precipitation and/or snow melt events, the discharged water will likely be of similar quality to the receiving water.

The surface water quality at the mine is continually monitored to ensure that the surface water is protected. By continuing to monitor the surface water and enforcing and adapting the mine's hydrologic control plan (Exhibit D), current and future impacts to the surface water will be minimized.

Over the long term, implementation of the reclamation plan will establish topography, vegetation and drainage channels that approximate premine conditions. Tributary drainages will be restored during reclamation and flow patterns reestablished, including incised drainages that collect runoff and sediment from uplands and transport these to the primary drainages. Reclamation vegetation will mimic premine conditions and provide for similar surface runoff rates and volumes.

The comparison of premine to post mine geomorphology, drainage basins, and runoff provided in Appendix J (Tables J-1 through J-4) shows that the post mine hydrology is essentially the same as premine. When combined with reclamation vegetation, the post mine water quality will be similar to premine.

Generally, the quality of the surface water at the mine is highly variable, due to the nature of the flows. As such, statistically significant correlations of changes in surface water quality to mining have not been observed to-date. It should be noted that continued monitoring, data collection and evaluation may allow identification of trends should they occur.

Presently, the alluvial groundwater quality in East Fork Armells Creek is affected by a variety of factors. A relatively high proportion of the change is related to above average rainfall and recharge. The main transition that can be attributed to mining activity is the increase in chloride concentrations in eastern portions of this creek between Areas A and B. Otherwise, mining impacts to date are very limited primarily because presently groundwater in Area B spoils is not flowing toward the alluvium. Eventually, it is predicted there will be some increase (estimated at about 13 percent) in TDS concentrations in the alluvium as groundwater levels recover in Area B.

Similarly, post mine sediment yields should be comparable to premine. Generally, significant sediment transport and deposition are associated with high intensity, low frequency events (e.g., 10-year and greater). The impacts from these events overwhelm any minor differences in premine to post mine land cover, topography, and geomorphology.

Following reclamation regrading and approval of the Western Alkaline sediment control plan, sediment ponds will be removed and replaced by approved BMPs. The sediment control plan will demonstrate that modeled post mine sediment yields will be less than premine yields.

3.1.3 Surface Water Use - PHCs

At and adjacent to Area F, wildlife and livestock water use will continue. During mining at Area F, detained surface water will be used for industrial purposes related to mining including road watering for dust control. As noted previously, runoff from disturbed areas will be detained as required during mining. This reduces the quantity of water

available to down-stream wildlife and livestock use. Generally, stock water use at and immediately adjacent to Area F is opportunistic based on the storage of ephemeral flows in stock ponds as well as utilization of discharges from springs. Some stock ponds impound spring discharges.

On average, the net surface water availability will be slightly reduced during mining due to the detainment of runoff and potential impacts to springs from mine dewatering. This impact is the most pronounced immediately down-gradient of Area F and decreases with distance from the mine. Sufficient water supplies are expected during wet periods. Typically, the water supply from runoff is scarce during dry and average conditions.

Table O-1 presents an impact evaluation for all inventoried surface water rights in the vicinity of Area F (see Appendix B – Table B-18). Three types of surface water users are included in this table: springs, ponds and uses direct from source. A more detailed impact assessment of springs and ponds is presented in Sections 3.3.1 and 3.3.2, respectively. Table O-1 includes six surface water uses directly from the source. During mining, impacts to surface water users can be mitigated, most likely by the installation of water supply wells sourced by coal and/or sub-McKay aquifers.

Following mining, the water supply will be similar to premine conditions resulting from the restoration of premine hydrologic function. Western Energy will propose enhancements to the post mine topography (PMT) that will include features to capture surface water when available for livestock and wildlife watering.

3.2 Groundwater Probable Hydrologic Consequences

Mining will cause impacts to both the quantity and the quality of the groundwater in the mine area. Impacts result from the following mining activities as discussed below.

The subsurface is dewatered at active mine pits to about the level of the bottom of the Rosebud coal. This groundwater is typically routed to adjacent pits and/or sediment control ponds and used for road dust control.

Disturbance of the land surface alters the infiltration rate from the surface to groundwater. At premine conditions, the majority of precipitation evaporates, sublimates (from snow), or is lost as evapotranspiration by natural vegetation. If the quantity of precipitation is large enough, surface runoff occurs. A small portion of the remaining water infiltrates through the soil profile, some is held in the soil profile (field

capacity) and a small amount percolates to underlying groundwater. The amount of groundwater recharge from precipitation is relatively small. The groundwater model (Appendix I) utilizes general recharge rates of about 0.09 inches per year. Higher recharge rates (from 0.8 to 2.5 inches per year) are expected at clinker and alluvial deposits (drainage channels). During mining, higher than normal recharge is anticipated from water management structures such as sediment ponds.

Mining will remove the Rosebud coal and replace it with spoils. During mining, the dragline removes overburden material by pulling the bucket upward from near the base of the cut toward the top. This material is then "cast" into spoil ridges in the preceding cut. As the stripped overburden material is cast, it is spread over a relatively large area. During this process, the materials are thoroughly mixed, and blocks of geologic materials tumble down steep spoil pile slopes and form a "rubble layer" at the base of the replaced spoil. Moran et al. (1979) conclude that the rubble zone is probably thin but has a substantially higher permeability than the original materials. Backfilled spoils have a higher porosity than the original strata and these spoils probably have a higher vertical percolation rate since the materials when backfilled are more isotropic. Most sedimentary materials exhibit a strong preferential horizontal permeability.

Mining impacts of hydrological importance that can occur are the destruction of horizontal continuity in the overburden strata and the mixture of the overburden strata in the backfilled pits creating a more isotropic media. During this process, some geological materials that were previously saturated are intermixed with materials that were unsaturated. In addition, a variety of lithologies are mixed including siltstones, sandstones and shales. The mining process substantially increases the surface area of excavated materials exposed to air and water. During the mining process, soil structure is altered, vegetation is removed, and the replaced subsoil and topsoil probably has a slightly increased bulk density.

The Area F Groundwater Model (See Appendix I) has been developed to predict the quantity and duration of the impacts to groundwater associated with mining. Many years of groundwater quality data from the Rosebud Mine have been evaluated to assess potential impacts to groundwater quality from mining.

3.2.1 Groundwater Quantity - PHCs

Mining will remove the Rosebud coal aquifer and cause diminished water levels in this

aquifer in the mine vicinity for the duration of mining. Drawdown commonly extends laterally into unmined coal adjacent to mine pits. The degree of drawdown in unmined coal diminishes with distance from the mine pits, with the most extensive depression of the groundwater surface occurring down-gradient of the mine passes.

The Area F groundwater model report (Appendix I-B) simulates and predicts water level drawdowns over time during and after mining. Based on the results of the groundwater model, the drawdown (Rosebud and McKay coal) within a one mile radius of the Area F permit boundary is predicted to be less than five feet during the mine phase.

Following mining, backfill water levels are expected to return to premine coal-seam water levels. Post-mine model simulations were run to predict groundwater levels in the Rosebud Mine and its vicinity every five years after the cessation of mining at Area F, up to 50 years after mining. See discussion in Appendix I-B (Section 2.2) regarding the rationale behind the selection of the 50 year simulation horizon. The simulation results predict that following mining, water levels will gradually recover. However, the post mine model predicts that the five foot drawdown contour south of the eastern portion of Area F, in both the Rosebud coal and McKay coal will move further away from the permit boundary. The maximum distance between the permit boundary and the five foot drawdown contour is approximately 1.3 to 1.4 miles for both strata. The model predicts that 50 years after mining, the residual drawdown to the south and west of Area F will be less than 10 feet in the Rosebud coal and less than five feet in the McKay coal. Although it will take considerable time, it is expected that the regional groundwater flow gradient will eventually recover to near premine conditions because recharge and discharge areas for the principal aquifers will not be substantially altered by mining. The hydraulic characteristics of the spoils will facilitate storage and transmission of groundwater between the undisturbed up-gradient and down-gradient coal aquifer restoring the essential function of conveying groundwater from recharge to discharge areas. The key recharge areas at Area F which are associated with clinker and drainage channel bottoms are not excavated during mining. Upon the reestablishment of comparable topography, soils, and vegetation groundwater recharge rates in spoils areas will likely be slightly higher than in previously unmined terrain.

Mining near the alluvium may reduce the groundwater flow from bedrock units to the alluvium, which may result in lower alluvial groundwater levels. The ephemeral drainage channels dissect the overburden in areas south and west of the Rosebud coal

outcrop (see Figure O-5). In more southern portions of the mine permit area, there tends to be a dearth of alluvium or it is absent. The thickness and lateral extent of the alluvium tends to increase moving northward where it sequentially progressively truncates through the overburden, the Rosebud coal, the interburden, the McKay coal and then the sub-McKay.

Analysis of available groundwater level data (e.g., at alluvial well WA-223) in Appendix B shows that alluvium in the upstream (most southerly portions of the drainages) is likely unsaturated. Unsaturated alluvium up-gradient of the mine cannot be impacted by Area F mining.

The effects of mining to groundwater levels in the overburden are projected to be limited to the immediate vicinity of mining or mine passes. This is inferred from analysis set forth in Appendix I-A that demonstrated that overburden wells generally don't respond to mining unless that overburden is in close proximity to mine passes. For areas where the saturated or partially saturated overburden, and saturated or partially saturated Rosebud coal is mined out in the proximity of the alluvium, some limited reduction in flow to the alluvium from the overburden is anticipated. Figure O-5 shows areas where this is most likely to occur.

Table O-2 tabulates the simulated flow to the alluvium from bounding strata within the Area F boundary (see Appendix I-B). Within the Area F permit boundary, lateral contributions of flow from bedrock strata to the alluvium at the end of mining are simulated to be 32 percent lower than during premine conditions. Simulation results predict that it could take more than fifty years for flows from bedrock strata to alluvium to reach premine conditions. For instance, the results in Table O-2 show that within Area F the simulated flow from the bedrock strata to the alluvium fifty years post mining is about 10 percent lower than simulated premine flow. However, such an estimate is considered conservative as modeling does not take into account the effects of temporal increases of recharge to the alluvium that are likely to occur with MPDES discharges of stormwater runoff and/or pit water accumulations that may occur during mining in Area F. The detailed evaluation of the hydrologic response to mining of the East Fork Armells Creek (ABC PHC Addendum – Attachment 1, NE&W 2015) demonstrated, that MPDES discharges can lead to accelerated or rapid recovery of alluvial water levels.

Climatological factors (e.g. the amount of precipitation in any given year), are also highly influential in determining water levels in the alluvium. For example large amounts

of precipitation during a wet year may significantly accelerate the recovery of water levels in the alluvium. As the frequency and size of MPDES discharges as well as climatological factors cannot be predicted, it is not feasible to predict the time frame of recovery for water levels in the alluvium.

3.2.2 Groundwater Quality – PHCs

Groundwater quality within the permit area will be impacted. This has been the subject of considerable study throughout the Powder River Basin and elsewhere (Van Voast and others 1977 and 1988). TDS concentrations in spoils groundwater are generally higher when compared to the groundwater in the coal they replaced. Re-saturation of backfill, primarily by lateral groundwater flow from the undisturbed coal aquifers, can be expected to result in increases in TDS concentrations as a result of elevated levels of most soluble salts, (primarily sulfate and magnesium) leached from the overburden. According to Van Voast and Reiten (1988), average TDS concentrations of groundwater in mine spoils in southeastern Montana mines are 50 to 200 percent higher than the average concentrations in the undisturbed aquifers. Similar geochemical conditions have also been simulated in the laboratory with bench scale column-leach and paste-extract leaching techniques using overburden materials representative of those to be disturbed by mining at specific mines (Van Voast and Reiten, 1988).

Based upon the bench scale tests, it is projected that the total dissolved solids concentrations in the backfill water will reach a maximum during initial saturation and then decrease to an equilibrium level after one or more pore volumes of water pass through the backfill. As re-saturation of the backfill continues, salt concentrations are expected to be extremely variable and peak at concentrations potentially two to three times that of the baseline coal groundwater quality and then decline to some equilibrium value after being flushed by one or more pore volumes of groundwater.

Therefore, spoils groundwater near areas receiving relatively higher amounts of recharge (e.g. near clinker areas or alluvium) may establish geochemical equilibrium more quickly than in other areas. Similarly, spoils groundwater at the up-gradient edge of the spoils is expected to establish a relative equilibrium more quickly than at the down gradient edge.

The detailed evaluation (Appendix B [Hydrology]) of Rosebud Mine groundwater quality data indicates that the TDS concentrations in spoils will be higher than the

concentrations in premine overburden groundwater. In areas where spoils groundwater flows into adjoining strata, it can lead to increased TDS concentrations in those strata. TDS data from Areas A, B and C wells show that this has likely occurred at the Rosebud Mine. Furthermore, analysis of TDS concentrations in Areas A, B and C wells shows that the changes in water level associated with nearby dewatering activities may result in variable TDS concentrations in those wells.

Table O-3 presents a summary of water quality data in Areas A, B and C spoils and baseline overburden groundwater. The TDS concentration in spoils groundwater is highly variable with concentrations ranging from 860 to 8,750 mg/L. Appendix B Tables B-26A, B-26B, and B-26C present spoils and overburden groundwater quality data for Areas A, B and C, respectively. These tables show that the average TDS concentration in Area C overburden groundwater is higher than in Areas A and B. Likewise, the average TDS concentration in Area C spoils is higher than in Areas A and B. The maximum TDS concentration in spoils groundwater in Areas A, B and C is 6,710, 8,750 and 7,360 mg/L, respectively. These data indicate that higher average TDS concentrations in overburden may result in higher TDS concentrations in spoils groundwater.

Table O-3 shows that in Areas A, B and C the average spoils TDS concentration is 73 percent higher than the average overburden TDS concentration. This falls within the 50 to 200 percent range reported by Van Voast and Reiten (1988). Similarly, in Rosebud Mine Areas A, B and C, the average major ion concentrations in spoils groundwater are 34 percent to 167 percent higher than in overburden groundwater, whereas the average pH of spoils groundwater appears slightly lower than in overburden groundwater.

For comparison purposes, Table O-3 presents water quality statistics of the Area F overburden groundwater. It is characterized by higher concentrations of most major ions when comparing it to overburden groundwater in other mine areas. Therefore, it is reasonable to assume that the average TDS concentration in Area F spoils groundwater may be higher than observed in mine Areas A, B and C. If assuming that the average TDS concentration in Area F will increase proportionally to the overall increase observed in Areas A, B and C (73 percent), an average TDS concentration in Area F spoils of 7,089 mg/L can be projected. As stated earlier, data from Areas A, B and C show comparable maximum TDS concentrations in spoils groundwater, even though average baseline overburden TDS concentrations were variable. The maximum TDS concentration in spoils groundwater is governed by the complex geochemistry of

groundwater and geochemical equilibria limit the degree of mineralization of spoils groundwater.

The specific conductivity in groundwater at Area F ranges from 585 to 7,310 umhos/cm. The Area F groundwater classifications (ARM 17.30.1006) range from Class I (up to 1,000) and Class II (1,000 to 2,500) to Class III (2,500 to 15,000). The maximum classification for 24 out of 36 Area F monitoring wells is Class III. Alluvial groundwater is generally Class III, with only one out of 57 samples exhibiting Class II groundwater. Similarly, all Area F overburden groundwater samples were Class III. Based on the quality of groundwater samples from the Rosebud coal, McKay Coal and sub-McKay wells throughout Area F, it is clear that the only groundwater from these strata near the Rosebud coal outcrop produces Class I or II groundwater. This is primarily because of its near-surface proximity to recharge sources. In other portions of Area F, groundwater from these strata can generally be classified as Class III.

The maximum SC measured in spoils groundwater at Rosebud mine during the 1973 through 2013 period was 8,420 umhos/cm (see Table O-3). This value is well below the 15,000 umhos/cm cutoff for Class III groundwater. Based on these historical data, it is reasonable to assume that spoils groundwater at Area F will not exceed Class III in the future. As a result, the classification of alluvial and overburden groundwater in Area F is expected to remain the same. Similarly, the classification of Rosebud coal, McKay coal and sub-McKay groundwater in areas away from the Rosebud coal outcrop is expected to remain the same. However, a classification change of the Rosebud coal near the Rosebud coal outcrop is more likely. Note that if these changes do occur, they would be well within the permit since nearly all outcrops are well within the permit boundary. No transitions are likely to occur outside the permit boundary. The following factors are influential for assessing the potential for a classification change of the groundwater in this area:

- The stratum. The groundwater quality of the Rosebud coal adjacent to and downgradient of mine spoil is more likely to change since the Rosebud coal will either be replaced with spoils materials in areas that are mined out. The McKay coal is separated from the Rosebud coal or spoils by the interburden. The ABC PHC found that if the thickness of the interburden was less than 40 feet, there were more likely to be changes in water quality in the McKay coal and to a lesser degree the sub-McKay. According to geologic cross-sections provided in the permit (Appendix Q), the interburden is typically about 100 feet thick. Well logs

from four observation wells indicate thicknesses ranging from 41 to 64 feet. The preponderance of the data provided via a combination of the geologic exploration wells penetrating both the Rosebud and McKay coals, coupled with the observation wells indicate that thicknesses tend to be far over the 40 foot criterion seen in the cases discussed in the ABC PHC. Therefore, it is projected that any transitions in water quality for adjacent underlying strata would be limited to upper portions of the interburden. Changes in water quality for the McKay coal and subMcKay are considered unlikely because of the thickness of the interburden.

- Location with respect to mining. Groundwater in the strata below the immediate mining footprint is more likely to change classification simply because mine spoil will replace the Rosebud coal. Outside of the mining footprint, an increased down gradient distance from mining is expected to decrease the likelihood of a classification change. Hence, any transitions that do occur are projected to remain well within the permit boundary.

- Proximity to outcrop. In addition to the above, the Rosebud coal near its outcrop in some portions of Area F is bounded by clinker. Depending upon the proximity of the mining to that clinker, it is possible that quality of adjacent clinker (and immediately underlying interburden) would see an increase in TDS as a result of up-gradient mining. However, at the same time, clinker is known to receive much more recharge than the consolidated strata. Thus, it is anticipated that the impact of any lateral flux from mine spoil, through the residual/oxidized coal, and into the clinker will be diluted accordingly and progressively with distance from the mined areas. If significant transitions in water quality do occur, they are projected to remain very near the mine footprint because of the effects of recharge and dilution.

In summary, if transitions in classification do occur in the Area F permit, they are projected to be primarily beneath and just downgradient of the mining footprint.

3.2.3 Groundwater Use - PHCs

Several existing wells will be eliminated by mining. Several of these wells comprise the mine's groundwater monitoring network. Some of these wells were used in the past for stock watering purposes. Groundwater model simulations (Appendix I) indicate that

water levels in domestic, stock, and monitoring wells in the mine vicinity are likely to exhibit reduced water levels.

The potential hydrological impact from mining in Area F on the private wells and water supply wells within one mile surrounding and three miles down-gradient of the permit boundary is determined by the location of the well with respect to mining, the stratum in which it is completed, and the available water column in the well.

Groundwater level drawdowns at and adjacent to Area F are depicted in drawdown figures provided in the Area F Groundwater Model Report (Appendix I-B). A well would become impacted if the water column is reduced to the level limiting pump performance. The required minimum water column is well-specific. Wells that become impacted can be replaced with deeper or replacement wells as needed.

Figure O-6A shows the maximum simulated Rosebud coal groundwater drawdown contour and identified groundwater users (e.g., wells). Generally, the simulated affect is about five to twenty feet of drawdown or less in wells to the west and south of Area F. Wells located to the northeast of the mine permit boundary are not predicted to be impacted as the strata of interest (impacted strata) outcrop at the northern portion of Area F. Figure O-6B shows simulated Rosebud coal groundwater drawdown contours and identified groundwater users at 50 years following the completion of mining at Area F. At 50 years following mining, groundwater levels are predicted to have significantly recovered with limited potential impacts outside of the proposed Area F permit boundary.

Table O-4 presents an impact evaluation for the groundwater users listed in the inventory included in Appendix B (Hydrology), Table B-29. Note that the groundwater use inventory represents information from databases (GWIC, NHD, NRIS and Western Energy) that may be duplicative.

3.3 Springs, Ponds and Wetlands Probable Hydrologic Consequences

3.3.1 Springs - PHCs

A spring would be impacted by mining if it is physically disturbed (e.g., mined out) or if its water source or water quality is affected by mining drawdown. Springs located within, or near, the footprint of mining are more likely to be affected than the other springs. Figure O-7 shows the location of monitored springs.

Factors considered relevant for evaluating the potential significance of mining to springs include:

- Proximity to mining
- Strata or deposits sourcing the spring
- The observations to date for monitored springs in Rosebud Mine Areas A, B and C.

Evaluation of the spring water quality data from Rosebud mine Areas A, B and C does not identify changes in water quality associated with mining in those areas to date. Continued monitoring will allow ongoing evaluation of spring water quality.

Table O-5 presents an impact evaluation for the springs listed in the inventory included in Appendix B (Hydrology), Table B-31. Note that the spring use inventory represents information from databases (NHD, NRIS and Western Energy) that may be duplicative.

Springs 7, 10 and 11 are located at or near the edge of mine passes, and are likely sourced by overburden/Rosebud coal or Rosebud coal/clinker. There is significant potential for mining effects these springs as water bearing overburden and Rosebud coal near the springs will be mined.

Monitored Springs 3, 8 and 9 will potentially be affected by mining as they are located near mining passes within the disturbance boundary. The most likely water sources for these springs are either overburden sandstones or Rosebud coal and associated clinker (see Appendix B).

The remaining monitored springs are located outside of the Area F disturbance area and are unlikely to be affected by mining.

Springs 2 and 12 are located approximately 0.3 miles north of projected mine passes and about 0.2 miles north of the Rosebud coal outcrop. The source of these springs is unknown, however because of the distance from mining both laterally and vertically it is deemed unlikely that they would be impacted by mining.

Spring 13 is associated with Wetland D and is likely sourced by McKay coal. Spring 14 is a sub-McKay spring located approximately 0.9 miles east of projected mine passes. Given that the seepage in this spring is from strata beneath the Rosebud coal, the potential for impacts due to mining is limited, both from a water quantity and water quality perspective.

Monitored Springs 1, 4, 5 and 6 are overburden springs located 0.6 to 1 mile up-gradient from projected mine passes. These springs will not be impacted by mining as they are sourced from overburden strata well above the Rosebud coal. It is highly probable that they are sourced by perched groundwater in that overburden.

In addition to potential impacts to springs due to mining, some springs in Area F and its vicinity may be impacted by the relocation of the county road and the construction of the haul road. Figure O-8 shows the projected location of the roads with respect to the Area F springs and wetlands. From this figure it is apparent that Spring 11 is likely to be impacted by the haul road construction. Spring 8 and 13 are located less than 300 feet from the haul road. The haul road construction is projected to disturb the ground surface near Spring 8 and a spring mitigation plan is being developed by WECo. Similarly, Spring 13 could be impacted by haul road construction. Finally, Spring 2 and 12 are located 340 and 150 feet from the relocated county road. There is limited potential for the flow from these springs to be impacted by road construction, as the source of spring flow is not likely to be disturbed by construction. The water quality of springs in the vicinity of mining disturbance will be protected by implementation of the Area F Hydrologic Control Plan.

Mitigation plans will be developed and implemented for all springs that are impacted by mining related activities.

3.3.2 Ponds - PHCs

Area F ponds are shown on Figure O-7. No ponds will be mined out. The quantity of water and use of the down gradient ponds (Pond 4) will be impacted during mining due to reduced water supply resulting from the impoundment of tributary runoff. Table O-6 presents an impact evaluation for the ponds listed in the inventory included in Appendix B, Table B-40. Note that the pond inventory represents information from databases (NHD, NRIS and Western Energy) that may be duplicative.

Following mining, impacted ponds can be reestablished or mitigated as necessary to support wildlife and livestock use with the same function as premine.

3.3.3 Wetlands - PHCs

A wetland would be impacted by mining if it is mined out or if the water source to the wetland is affected by mine dewatering. All of the identified wetlands, except for Wetland B, are located along the main drainage channels, which are not mined out. Wetland B is located in the upper reach of Trail Creek, but is located away from planned mine passes.

Impacts to springs are discussed in Section 4.1.

Figure O-7 shows the locations of Area F wetlands with respect to projected mining and Figure O-8 shows the locations of wetlands with respect to Area F roads. Figure O-5 shows that impacts to the alluvium are limited to areas located adjacent to mine passes. Identified impacts to wetlands include:

- The upstream portion of Wetland C, which is associated with Spring 10, will be mined out. Depending upon if the water source of that wetland recovers following mining, it is possible that the downstream section of this wetland may be affected. In addition a portion of the wetland will be disturbed by haul road construction.

- Wetland D is associated with Spring 13. Both the spring and wetland may be impacted by the construction of the haul road.

- Wetland E and F-081 are associated with Springs 12 and 2, respectively. These springs may experience limited impacts as a result of adjacent road

construction and could potentially be impacted.

- Wetland B is associated with Spring 7 which has significant potential to exhibit altered flow as a result of mining.
- Wetland F028 is associated with Spring 11, which has potential to be impacted by reduced flow as a result of mining and haul road construction.
- Wetland F is associated with overburden Spring 9. Model simulations predicted that flows from the overburden toward the stream channel are likely to be reduced in this area.

Following mining, the source of water supply to wetlands from springs not physically disturbed may be reestablished as groundwater levels recover. The remaining wetlands in Area F are not likely to be impacted by mining activities.

3.3.4 Aquatic Life

As described in the Area F Aquatic Live Survey (ERM 2015)(See Appendix B), the aquatic organisms found at Area F wetlands are indicative of fairly poor to very poor water quality. This may be due to the heavy impact of cattle which was observed in most of the wetlands visited, but may also be influenced by the seasonal or intermittent conditions that are likely present at these locations. Such conditions are expected to result in the presence of species that are tolerant of variable water quality conditions. Therefore, limited changes in TDS concentrations in the spring water sourcing these wetlands are not expected to significantly change the presence and composition of aquatic life at these locations. As such, aquatic life is expected to reestablish in wet areas in the PMT similar to the emergence of aquatic life in the vicinity of the mine when previously dry areas become wet due to climate variations.

4.0 ALLUVIAL VALLEY FLOOR PROBABLE HYDROLOGIC CONSEQUENCES

PENDING DEQ DETERMINATION

5.0 MITIGATION OF MINE IMPACTS

Some mine-related hydrologic impacts can be mitigated. For example, a well that is adversely affected by mining can be replaced with a well that provides an equivalent amount of water of comparable quality. Both the Rosebud coal and sub-McKay sands yield sufficient water for livestock and domestic use.

Streamflow is generally a result of snowmelt runoff or intense thunderstorms, and the resulting discharge events typically have short durations. To mitigate the general lack of water, although this lack of water is not primarily a consequence of mining, the mine will propose enhancement features within the post mine topography to capture water when available and use it to enhance habitat for wildlife and livestock and to establish wetlands. These features will be in the form of small impoundments which will store water following runoff events, providing water sources and promoting establishment of wetland species which will diversify the post mine habitat types within the permit area. These small impoundments will also help to retain sediment within the permit area.

Western Energy is committed to the restoration of the hydrologic balance and the approved post mine land usage, which consists of wildlife habitat and grazing by both livestock and wildlife. The post mine landscape will be restored to the approximate original contour. The post mine channels will be designed to convey peak flows at velocities and depths similar to the premine channels for corresponding rainfall-runoff events to restore the hydrologic function of the premine drainage system. Impacted springs, ponds and wetlands will be reestablished or mitigated as part of reclamation.

Some of the hydrologic consequences of mining cannot be mitigated despite the best efforts of the mining company and regulatory performance standards. For example, the Rosebud coal aquifer will be removed by mining within much of the permit area.

The spoils which replace the mined coal will contain groundwater and should provide sufficient water to support a limited number of livestock wells. The post mine groundwater flow patterns, from west to east through the replaced backfill, will be similar to premine flow patterns. However, it may take some years for the post mine equilibrium to establish, and the interim groundwater quality and quantity within the permit area will be somewhat impaired when compared to premine conditions during the interim.

6.0 HYDROLOGIC MONITORING

Water resources at Area F will be monitored for quantity and quality at sites such as wells, surface water sites, springs and ponds. The proposed monitoring plan is provided in Appendix P. Monitoring data and interpretations are reported in Annual Hydrologic Reports (AHR). This on-going monitoring will provide information to adjust the mining and reclamations plans, if needed, to protect the hydrologic systems.

7.0 SUMMARY OF PROBABLE HYDROLOGIC CONNSEQUENCES

The key impacts to the hydrologic systems resulting from mining can be summarized as:

1) Interception of tributary surface flows during mining.
2) Diminished alluvial aquifer recharge from reduced surface flows during mining.
3) Groundwater level drawdowns resulting from mine dewatering during mining.
4) Changes in groundwater quality as the mined coal is backfilled with spoils.
5) Changes in groundwater quality in alluvial aquifers due to the migration of spoils impacted groundwater. The classification of alluvial groundwater within Area F and down gradient from Area F is not expected to change.

Following mining and reclamation, surface water flows and quality should return to premine conditions. Groundwater levels will recover over many years. It is anticipated that groundwater quality will reestablish geochemical equilibrium over time. Temporal changes in groundwater quality are not expected to negatively affect existing uses. There is potential for impacts to surface water use (livestock watering) and to private wells (livestock watering and domestic) located near the mine until groundwater levels recover. These impacts can be mitigated. Wells located at distance from the mine should not be impacted. Future monitoring should focus on spoils water quality and the potential for impacts to the alluvial aquifer.

WECo	PW-165	unknown			-	-	-	no		no	Well outside 5 foot drawdown contours and not an alluvial well.	
WECo	PW-29	Alluvium or Overburden			15	-	-	yes	10-20	no	Very shallow well half a mile up-gradient from mining. Rosebud coal is 100-150 feet deep at this location.	

Table O-4
Groundwater Users - Impact Assessment

Data Source (a)	ID (a)	Stratum (a)	Purpose (a)	Owner	Well Depth (ft)	Static Water Level (ft)	Water Column (ft)	Within Influence Boundary? (b)	Simulated Max. Drawdown (ft) (c)	Potentially Impacted ? (d)	Reasoning	Comments
WECo	WZ-025	unknown			-	-	-	yes	10-20	no	Unknown strata, unknown static water level. Well south of Area C west, not likely impacted by Area F mining.	Possibly same as GWIC 246645

Notes

(a) For more information refer to Appendix B - Hydrology.

(b) Is well located within the simulated maximum extent of the 5 foot Rosebud coal drawdown contour and is the well located south of Rosebud coal outcrop?

(d) This is simulated maximum drawdown as a result of both Area C and Area F mining.

(d) Only impact due to Area F mining was evaluated. Wells impacted by Area C mining, but not likely impacted by Area F mining were labeled not likely impacted.

Table O-5
Springs - Impact Assessment

Type	Source (a)	ID (a)	Purpose	Source Name	alternate IDs	Comments	Potentially Impacted?	Reasoning
Spring	NHD	00812928					no	Spring outside 5 foot drawdown contours, up-gradient from mining.
Spring	NHD	***139627490***					no	Spring sourced by stratum below Tongue River Member
Spring	NHD	***139627729***					no	Spring sourced by stratum below McKay coal, approximately one mile from mining.
Spring	NHD	***139628177***					no	Spring outside 5 foot drawdown contours, up-gradient from mining.
Spring	NRIS	42KJ 108264 00	stock	Spring, unnamed tributary of Black Hank Creek		livestock direct from source	yes	Spring within mining footprint. However, no evidence was found that it exists at this location.
Spring	NRIS, NHD, WECo	42KJ 108351 00	stock	Spring, unnamed tributary of unnamed tributary of West Fork Armells Creek		livestock direct from source	no	Spring sourced by stratum below Rosebud coal, close to Area C north, not likely to be influenced by Area F mining.
Spring	NRIS	42KJ 108365 00	stock	Spring, unnamed tributary of unnamed tributary of West Fork Armells Creek		livestock direct from source	no	Spring sourced by stratum below Rosebud coal, north of Area C north, not likely to be influenced by Area F mining.
Spring	NRIS	42KJ 108371 00	stock	Spring, unnamed tributary of Trail Creek		livestock direct from source	no	Spring outside 5 foot drawdown contours, > 1 mile and cross gradient from mining.
Spring	NRIS	42KJ 108383 00	stock	Spring, unnamed tributary of Black Hank Creek		livestock direct from source	no	Overburden spring up-gradient from mining.
Spring	NRIS	42KJ 108386 00	stock	Spring, unnamed tributary of Trail Creek		livestock direct from source	no	Spring outside 5 foot drawdown contours, > 1 mile and cross gradient from mining.
Spring	NRIS	42KJ 108387 00	stock	Spring, unnamed tributary of Trail Creek		livestock direct from source	no	Spring outside 5 foot drawdown contours, > 1 mile and cross gradient from mining.
Spring	NRIS	42KJ 108393 00	stock	Spring, unnamed tributary of Robbie Creek		livestock direct from source	yes	Spring within mining footprint. However, no evidence was found that it exists at this location.
Spring	NRIS	42KJ 108396 00	stock	Spring, unnamed tributary of McClure Creek		lievstock directly from source, possibly associated with Spring 11	yes	This water right may be associated with Spring 11. PHCs are discussed in Section 4.1.

Table O-5
Springs - Impact Assessment

Type	Source (a)	ID (a)	Purpose	Source Name	alternate IDs	Comments	Potentially Impacted?	Reasoning
Spring	NRIS	42KJ 108399 00	stock	Spring, unnamed tributary of unnamed tributary of West Fork Armells Creek		livestock direct from source	no	Spring sourced by stratum below Rosebud coal, north of Area C, not likely to be influenced by Area F mining.
Spring	NRIS	42KJ 108407 00	stock	Spring, unnamed tributary of unnamed tributary of West Fork Armells Creek		in mined out area C West, livestock directly from source	no	Spring located in Area C mining footprint. Not likely to be affected by Area F mining.
Spring	NRIS	42KJ 162812 00	stock	Spring, unnamed tributary of Donley Creek	WR 42KJ 162852 00	possibly same as SP-71, developed spring	yes	This may be a coal/clinker sourced spring, model predicts some drawdown at this location due to mining in Area C. No impacts to date from Area C mining have occurred. Hence impacts from Area F are unconsidered unlikely.
Spring	NRIS	42KJ 162860 00	stock	Spring, unnamed tributary of Donley Creek		developed spring	no	Overburden spring outside 5 foot drawdown contours, up-gradient from mining.
Spring	NRIS, NHD	42KJ 183221 00	stock	Spring, unnamed tributary of unnamed tributary of North Fork Trail Creek	***NHD 139628261***	livestock direct from source	no	Spring outside 5 foot drawdown contours, > 1 mile and cross gradient from mining.
Spring	NRIS	42KJ 183227 00	stock	Spring, unnamed tributary of Trail Creek		pit	no	Spring outside 5 foot drawdown contours and cross gradient from mining.
Spring	NRIS	42KJ 183228 00	stock	Spring, unnamed tributary of Trail Creek		pit	no	Spring outside 5 foot drawdown contours and cross gradient from mining.
Spring	NRIS	42KJ 183229 00	stock	Spring, unnamed tributary of Trail Creek		pit	no	Spring outside 5 foot drawdown contours, > 1 mile and cross gradient from mining.
Spring	NRIS	42KJ 183230 00	stock	Spring, unnamed tributary of Trail Creek		pit	no	Spring outside 5 foot drawdown contours, > 1 mile and cross gradient from mining.
Spring	NRIS, NHD	42KJ 183339 00	stock	Spring, unnamed tributary of McClure Creek	***NHD 139627830***	spring box	no	Spring outside 5 foot drawdown contours, sourced by stratum below the McKay coal.
Spring	NRIS	42KJ 183350 00	stock	Spring, unnamed tributary of Robbie Creek		likely same as Spring 3, spring box	yes	This water right may be associated with Spring 3. PHCs are discussed in Section 4.1.

Table O-5

ADDENDUM OVERVIEW
PROBABLE HYDROLOGIC CONSEQUENCES
AREAS A, B AND C
EAST FORK ARMELLS CREEK
WESTERN ENERGY ROSEBUD MINE

The Montana Department of Environmental Quality (DEQ) has requested additional information in order to anticipate and predict the long-term effects of mining on surface water flow and quality and alluvial groundwater flow and quality. This addendum focuses on the hydrologic response of East Fork Armells Creek. The PHC was developed based on data collected through water year 2011. This addendum includes the evaluation of additional data collected in 2012 and 2013. In addition, in Attachment 1, some data collected in 2014 were included in the evaluation as described in the narrative or tables. Therefore, the evaluations and conclusions presented in this document supplement the findings of the PHC. The information requested is summarized (or paraphrased) below:

- Provide a water budget that includes inputs to the stream from:
  - The release of pond and pit water.
  - Infiltration from sediment ponds adjacent to the stream.
  - Disposal of water from operations and domestic use at the Area A facilities.
- Indicate how the additional sources of water associated with mine activity have affected stream flow.
- Address the following:
  - What is the source of the increase and at what point is the concentration expected to reach equilibrium or begin to decrease in concentration?
  - How is the increased saturation of spoil adjacent to the stream likely to affect long term water quality in the stream and alluvium?
  - What is the TDS concentration expected to be at full saturation of the spoil?
  - What are the long-term implications for stream and alluvial water quality associated with inputs from the facilities, including fate and breakdown of lignin sulfonate?

    - How have increases in specific water quality parameters affected the uses (livestock, wildlife, and aquatic life) and how will those uses likely be affected with future predicted water quality change?
- Conduct a current aquatic survey.

Four attachments are enclosed which provide much of the information requested DEQ.

- Attachment 1: Detailed Evaluation – Hydrologic Response to Mining – East Fork Armells Creek (by Nicklin Earth & Water)
- Attachment 2: Assessment of East Fork Armells Creek – Vicinity of Areas A and B (by Nicklin Earth & Water)
- Attachment 3: Memorandum – Calcium Lignin Sulfonate vs Magnesium Chloride for Dust Suppression (by Schafer Limited, LLC).
- Attachment 4: Western Energy – Rosebud Aquatic Survey Assessment (by ARCADIS).

This overview discusses how each request is addressed in a given attachment as relevant.

Develop a Water Budget

Attachment 1 provides a detailed water budget which includes information addressing the following:

- The release of pond and pit water into the stream.
- Infiltration from sediment ponds adjacent to the stream.
- Disposal of water from operations and domestic use at the Area A facilities.

A series of scenarios to represent the water budget under baseline, two different phases during mining, and post-mine conditions are presented.

Information relevant to the release of pond and pit water is given in Section 3.2.3 and 4.2.3 of Attachment 1.

The respective conclusions for items described above are the following:

- The transition in water quality observed in the EFAC alluvium is not associated with MPDES discharges of pond and pit water. This is simply because the MPDES discharges possess lower TDS concentrations than the baseline alluvial groundwater as follows (based on MPDES data collected from 1999 to 2014):

    - Average MPDES TDS concentration of 1,589 mg/L.
    - Median MPDES TDS concentration of 1,210 mg/L.
    - The baseline (pre-mine) alluvial groundwater quality showed higher TDS averaging 2,299 mg/L. Attachment 1 provides more details on how this estimate was derived.

- The relative contributions directly from pond infiltration are very limited and too small to explain the changes in TDS concentrations observed in the EFAC alluvium. The rationale for this conclusion include the following:
    - In normal years many of the ponds are dry or contain little standing water.
    - In Area B, most of the groundwater between the alluvium and the spoils flows southward (as opposed to EFAC).
    - Some limited contribution from ponds in Area A may occur as water infiltrates into mine spoil and then flows toward EFAC. However, this flow or seepage rate is small. Furthermore, many of the wells indicating a transition in TDS concentration are up-gradient of most Area A ponds. Hence, the infiltration from ponds cannot be used to explain up-gradient transitions.

- The relative contributions from the facility water uses to TDS concentrations are considered inconsequential for the following reasons:
    - The quantity of imported Colstrip water is equivalent to 0.01 cfs (per communications with WECo staff) and its use and/or destination include the following:
        - Vehicle wash water which is pumped to two lined lagoons and then evaporates.
        - Office facilities domestic water is discharged to a septic system. The primary analyte of concern of a septic system is nitrate as opposed to TDS.

- Portions of the imported water are used for lawn irrigation.
- Cleaning of two transfer houses. A portion of the wash water subsequently runs towards sediment traps.

o Given the limited flow rate of 0.01 cfs, and given that substantial portions of this flow are lost to evaporation (lined ponds and irrigation), the facility and wash operations are not considered to be a viable explanation for the TDS concentration increases observed in the last few years in the alluvial wells.

What is the Source or Cause of the Recent Increase of TDS concentration?

The best explanation for the increase in TDS concentration is associated with temporal changes in groundwater level. See discussion in Section 4.2.3 of Attachment 1. Also, please refer to Figure 15 of that attachment. Both increases and decreases in TDS in EFAC alluvial wells tend to correlate with changes in groundwater levels both on and up-gradient of the mine. Precipitation and runoff has been above normal over the last several years leading to increased MPDES discharges and increased recharge to the alluvium. It is projected that when precipitation and runoff conditions are nearer normal for an extended period of time, TDS concentrations will gradually attenuate toward baseline conditions.

Point at which concentration is expected to reach equilibrium or begin to decrease in concentration

See prior paragraph. More discussion follows below in terms of long-term projections related to flow from spoil groundwater.

How is the increased saturation of spoil adjacent to the stream likely to affect long term water quality in the stream and alluvium?

Refer to Section 4.3 of Attachment 1. The best projection that can be made at this time is that, in the long term, the average TDS concentrations in the alluvium and stream would have a net increase of about 13 percent over baseline concentrations. The rate, or point in time, that this net increase is reached is impractical to predict. However, that time frame likely involves several decades after mining in Area A and B ceases.

What is the TDS concentration expected to be at full saturation of the spoil?

See Section 4.3 of Attachment 1. The baseline average concentration for TDS was defined as 2,299 mg/L. The projected average TDS equilibrium concentration of spoils is 4,360 mg/L. The projected average TDS in the alluvium and the EFAC at equilibrium after mining is 2,599 mg/L. Attachment 1 provides a detailed description on how these estimates were obtained.

What are the long-term implications for stream and alluvial water quality associated with inputs from the facilities , including fate and breakdown of lignin sulfonate?

Attachment 3 provides a letter report discussing the fate and breakdown of lignin sulfonate. The projected implication for use of lignin sulfonate in terms of effects on sulfate concentrations in groundwater is that there will be no measurable change in background sulfate concentration (page 2 of that Attachment 3).

The impact of magnesium chloride is discussed in Section 4.2.4, Attachment 1. It is projected that, in the long term, concentrations will decline. There is some indication of pending peaking concentrations of chloride at one, possibly two of the easternmost alluvial observation wells, P-03 and P-04. Once peak concentrations occur, the rate of attenuation will depend upon a number of factors including: infiltration rates, mass of magnesium chloride present in the unsaturated zone, variations in groundwater levels, etc. It is not practical to predict the rate of attenuation once peaking occurs.

How have increases in specific water quality parameters affected the uses (livestock, wildlife, and aquatic life) and how will those uses likely be affected with future predicted water quality change?

Note that the recent changes in TDS are likely related to the changing groundwater levels.

Overall, the water quality uses from a livestock and wildlife use perspective are anticipated to remain similar to what they were under baseline conditions. Some increase in TDS (compared to baseline), and specific conductance (compared to

baseline) is anticipated to occur gradually over time until groundwater levels in the mine spoils recover leading to more flow moving into the alluvium.

Presently, most of the alluvial groundwater under baseline conditions is classified as Class II or Class III. The classification of the alluvial groundwater will remain Class II or Class III.

With regard to the effects on aquatic life, please refer to Attachment 4.

Detailed Evaluation – Hydrologic Response to Mining East Fork Armells Creek

1.0 INTRODUCTION

This attachment to the PHC addendum to the Western Energy Rosebud Mine Areas A, B and C PHC (NE&W, January 2014) provides a supplemental evaluation of the hydrologic conditions for the East Fork Armells Creek (EFAC). The goal of this attachment is to present, to the degree feasible, a "water balance" quantification for a reach of EFAC extending from the eastern proximity of Area C to the eastern edges of Areas A and B. Figure 1 provides a general site map. Figure 2 provides details of relevant site features of interest in this evaluation.

2.0 BACKGROUND/OVERVIEW

2.1 Stream Classification

Prior to developing a water balance for EFAC, it is appropriate to determine or designate the type of stream present. The two classifications potentially relevant to EFAC are defined as follows (from ARM 17.24.301):

- "Ephemeral stream" means a stream or part of a stream which flows only in direct response to precipitation in the immediate watershed or in response to the melting of a cover of snow and ice and whose channel bottom is always above the local water table.
- "Intermittent stream" means a stream or reach of a stream that is below the local water table for at least some part of the year, and obtains its flow from both surface run-off and ground water discharge.

2.2 Definition of Classification for EFAC

It is clear that if a channel reach is ephemeral, then no direct hydraulic interaction between that reach and the alluvial groundwater exists. In this case, the analysis is greatly simplified. However, if the channel is intermittent, then some direct hydraulic interaction between the surface water and adjacent groundwater occurs. The ability to quantify the nature and or magnitude of that interaction may, or may not, be feasible depending upon just how complex that system is.

Van Voast, et al (1977) described the following condition for the EFAC upstream of Colstrip:

> *"Upstream from Colstrip, East Fork Armells Creek is generally dry except for water holes where its channel locally penetrates the water table."*

This statement indicates that Van Voast, et al (1977) did not observe flow in the EFAC upstream of Colstrip, as only "water holes" or localized expressions of "pooled" groundwater were present.

In 1982, Hydrometrics conducted the alluvial valley floor (AVF) study for WECo for the same portion of EFAC. The AVF study reported flow or standing water in short sections of the creek above Colstrip much of the year in the AVF evaluation. It should be noted that the flow and aquifer conditions in 1982 may have been influenced by above average runoff that year (see NE&W, 2014). In essence, the observations of each entity are not necessarily contradictory, but are likely explained by observations at different times under different precipitation/snowmelt runoff conditions.

Evaluations were conducted by NE&W (2014) in order to assist in defining the type of stream that is relevant for the EFAC in the vicinity of Areas B and C. Is it ephemeral or is it intermittent? Is there a transition point for stream type designation, etc.? The NE&W assessment included the following components:

- Evaluating alluvial well water level hydrographs.
- Collecting channel thalweg survey elevations located strategically near monitoring well locations possessing historic water levels that were

representative of pre-mine conditions.

- Reviewing aerial photographs from 2009, 2011 and 2013.

As a result of these analyses, the following observations/interpretations were drawn about the vicinity of EFAC adjacent to Areas A and B:

- Conditions at pre-Mine/baseline (before 1975): Portions of the EFAC reach between Areas A and B were likely intermittent before mining commenced (see Figure 2 of Attachment 2). The basis for this is that some adjacent alluvial monitoring wells exhibited water levels above nearby channel thalwegs.
- Conditions during mining ("earlier" mining – 1976 to mid 1990s): As mining commenced adjacent or near alluvial sections of the EFAC, substantial portions of that alluvium showed groundwater levels well below the channel thalweg. This was due to drawdown in areas being mined. This was readily apparent especially from the early to late 1980s and extending to the mid-1990s (see Figure 2 of Attachment 2). Hence, at least for the short-term, conditions of EFAC were akin to an ephemeral stream.
- Conditions as mining moved away from EFAC alluvium ("later" mining – mid 1990s to current). In more recent years, alluvial groundwater levels have recovered and, in some instances, exceed pre-mine water levels (see Figure 2 of Attachment 2, wells WA-101, WA-128, and P-04). One factor for this recovery is that mining moved away from the EFAC over time. Hence, there was less drawdown in the alluvium from mining. In some years, recovery was caused by greater recharge associated with above average precipitation and runoff. A key subset of this last factor is that in years of "excessive" precipitation and runoff, a significant amount of storage in sediment ponds and mine pits resulted. This necessitated a need to release flow into the EFAC channel in the form of MPDES discharge. Some of these discharges occurred over extended periods of time. This led to a substantial amount of

recharge into the EFAC alluvium and increases/recovery of alluvial water levels. In some instances, the water level recovery was profound (see Figure 2 of Attachment 2, WA-128, year 2000). The net effect is that water levels have increased substantially. Given that groundwater levels in eastern sections of the control volume are generally higher than measured prior to mining, the net effect is that surface water flow is more likely to occur at flume measuring station SW-55.

In summary, the nature of channel flow has varied over the last three decades at SW-55 as follows:

- Prior to mining, during extended periods of time when precipitation was at or below average, it is likely that base flow at SW-55 was non-existent, infrequent, or rates were nearly too low to be measured. Some temporary base flow of limited duration likely occurred following major precipitation/runoff events. However, given that the duration of these events was generally limited, the volume of recharge that occurred did not sustain base flow at SW-55 for the long-term.
- During “early” mining, it is likely that base flow at SW-55 was non-existent or the rates too low to be measured when mining was relatively near the alluvium as ground water levels declined in response to mine drawdown. This was mainly a factor when northern portions of Area B were mined near/adjacent to the EFAC alluvium. Some temporary flow exceptions existed in association with recharge from natural runoff events, and, also when MPDES discharges occurred.
- During “later” mining (recent), flow at SW-55 became more sustained as a result of groundwater levels exceeding pre-mine conditions. Again, most of this increase is in response to the extended MPDES discharges that were required for years of well above average precipitation, runoff, and subsequent pond and pit storage. This is especially so beginning in water year 2011.

The above conceptualization is validated by the flow observations summarized below for SW-55:

- Flow in the vicinity of SW-55 was infrequently observed prior to Area B mining (inferred from Van Voast et al, 1977).
- Flow events that did occur during most of the mining period are readily correlated to major precipitation and/or snowmelt runoff events. Following these events, the typical response has been for flows to be of short duration followed by a rapid attenuation to a "non-flowing or dry" condition. This is especially apparent up until water year 1994 (see Figure 9 – page 1).
- Periods of more extended base flow have been associated with water years of very high precipitation, such as water years 1994, 1995, 1997, 2000, and 2011 through 2013 (see Figure 9, pages 1 – 3).
- The most extended period of "base flow" over time has been observed during very recent mining activity, or since about 2011 (see Figure 9 – page 3). Such extended based flow is correlated to major precipitation/snowmelt runoff events coupled with significant MPDES releases to the EFAC which has led to greater local recharge (see Table 1 of Attachment 2).

Completing a water balance is indeed challenging because of the complex nature of the hydrogeologic system coupled with the highly transient stresses that are involved. Hence, any analysis that follows in this report is predicated upon a number of simplifications. Therefore, caution is clearly warranted in ascribing confidence to water balance calculations because of the confounding factors that exist and are inherent in any complex natural system.

3.0 WATER QUANTITY ASSESSMENT

3.1 Overview

This section presents the water balance evaluation, which considers the water quantity aspects of a selected control volume. This control volume is assigned to coincide with

the alluvium in the EFAC vicinity. The water balance parameters are used in the subsequent section to evaluate water quality aspects of the control volume.

Based upon the summary set forth in Section 2, the first step in the water balance evaluation is to establish the control volume and define those parameters that substantively affect the water balance of this control volume. The reach of the EFAC assigned for this analysis begins near WA-106 (up-gradient) and extends to the vicinity of the P-series wells (down gradient) (see Figure 2). The surface of this control volume coincides with the EFAC alluvium as mapped by Vuke, et al (2007) and as shown in Figure 3. The primary water balance variables assigned to this control volume are the following (See Figure 4):

- Alluvial groundwater inflow ($\mathbf{Q_{a\text{-}in}}$) and outflow ($\mathbf{Q_{a\text{-}out}}$).
- Recharge ($\mathbf{Q_r}$) into the control volume. This recharge includes surface recharge and infiltration within the EFAC channel itself.
- Lateral flow communication ($\mathbf{Q_{lat}}$) between bounding consolidating units (e.g., overburden, Rosebud coal, interburden and McKay coal). Under baseline conditions, this communication was dominated by inflow from the Rosebud coal.
- Vertical flow communication ($\mathbf{Q_v}$) may occur. However, given the extremely low vertical to horizontal hydraulic conductivity anisotropies that exist in the Tongue River member of the Fort Union, this vertical flow communication is assumed to be negligible and no further assessment of this variable is considered necessary for the water budget evaluation.
- Surface Water Outflow ($\mathbf{Q_{swo}}$). Note that EFAC at the up-gradient (west) edge of the control volume is ephemeral. Hence, no incoming base flow is assigned to the control volume. Flow at the downstream edge has been observed at times as measured at surface water gaging station SW-55. Most of these flows were historically related to runoff, or, attenuation from that runoff. At most other times, this station has exhibited either dry conditions or “base flow” rates that are very small or limited seepage. Since there have

been some "base flows" observed more recently at SW-55, $\mathbf{Q_{swo}}$ is retained for analysis purposes.

- No mine specific ponds are present within the control volume. Some wells are present. Only those stresses that are within the control volume are evaluated for the water balance. Those that are outside the control volume are factored into the other variables ($\mathbf{Q_{a\text{-}in}}$, $\mathbf{Q_{a\text{-}out}}$, $\mathbf{Q_{lat}}$).
- Alluvial aquifer storage (**S**).

Note that all these variables are transient over time. In effect, there are an infinite number of scenarios or possibilities that can be defined. As a result, simplifications must be made to establish a workable set of representative scenarios to assist in predicting the probable hydrologic consequences of mining as they pertain to EFAC alluvium.

3.2 Establishment of Flow Scenarios

The following four flow scenarios are established:

- Scenario 1: Baseline
- Scenario 2: "Early" mining (drawdown dominated phase)
- Scenario 3: "Recent" mining (water level recovery phase)
- Scenario 4: Post mining

Again, it is re-emphasized that these scenarios represent simplifications or idealizations of a very complex/transient system.

3.2.1 Scenario 1: Baseline

The variables applicable for Scenario 1 (and other scenarios) are defined in Figure 5. Information presented in Van Voast, et al (1977) provides some insights as to the magnitude of some of these variables. However, refinements to the Van Voast parameters were made based upon a more comprehensive alluvial well water level database that was collected subsequent to the Van Voast, et al effort.

Inflows

The inflows to the control volume for this scenario are simplified to incoming alluvial flow ($\mathbf{Q_{a\text{-}in}}$), areal recharge ($\mathbf{Q_r}$), and lateral inflow ($\mathbf{Q_{lat}}$) from bounding consolidated strata. The incoming flows were estimated as described below.

The estimate for $\mathbf{Q_{a\text{-}in}}$ was quantified using Darcy's law as 0.102 cubic feet per second (cfs) or 45.9 gallons per minute (gpm). Table 1 presents additional information on the derivation of this flow estimate.

Quantifying the magnitude of baseline recharge over the alluvial control volume is complicated by several variables. The most significant recharge component is likely seepage from the EFAC channel in association with episodic/short term surface water runoff that varies from year to year. Some other fractions are associated with infiltration from direct precipitation over the land surface. There is also ponding along stretches of this creek that potentially causes localized higher rates of recharge. It is noted that the actual recharge over the control volume is uncertain and cannot be directly quantified. For purposes of evaluation, it is assumed that the net baseline recharge ($\mathbf{Q_r}$) over the control volume is 5 % of the average annual precipitation. This equates to a flow rate of 0.033 cfs (14.8 gpm).

Van Voast, et al (1977) estimated a lateral flux ($\mathbf{Q_{lat}}$) through Areas A and B of about 1,050 cubic feet per day (cfd). Van Voast, et al assumed a transmissivity value of 10 ft^2/d for the Rosebud coal. A higher calibrated value of 19 ft^2/d was defined in the Rosebud Mine model (RMM). Applying the RMM transmissivity value of 19 ft^2/d leads to a higher estimated flow of 1,997 ft^3/d (or 10.4 gpm) which was subsequently assigned to $\mathbf{Q_{lat}}$ for flow from Areas A and B into the control volume.

Van Voast, et al describes flow through Areas A and B in the McKay coal as well. However, based upon NE&W evaluation of site well logs completed in the vicinity of the control volume, it is interpreted that the McKay coal is generally isolated from the alluvium over most of the footprint of this control volume. Hence, any flux into the alluvial control volume from the McKay coal was assumed to be negligible, or, it does not contribute to $\mathbf{Q_{lat}}$.

The sum of these inflow numbers ($\mathbf{Q_{a\text{-}in}}$, $\mathbf{Q_r}$, and $\mathbf{Q_{lat}}$) to the control volume is 0.158 cfs.

Outflows

Flow out of the control volume includes the alluvial groundwater outflow ($\mathbf{Q_{a\text{-}out}}$), surface water outflow ($\mathbf{Q_{swo}}$) and $\mathbf{Q_{wells}}$.

The alluvial groundwater outflow estimate ($\mathbf{Q_{a\text{-}out}}$) was quantified using Darcy's Law to be 0.139 cfs (62.3 gpm). Table 1 presents additional information on the derivation of this flow estimate.

$\mathbf{Q_{swo}}$ is unknown but assumed to be very small or negligible for the baseline condition based upon the available historic documentation and the conceptualization set forth previously.

There are four private wells documented within the control volume (See Figure 6). One well, GWIC 12003, was present before mining and used for domestic and stock watering purposes. No data are available for quantifying the amount of groundwater used at this well. However, the amount of groundwater used is deemed as likely inconsequential, at least compared to the other water budget flow parameters. Hence, for quantitative estimate purposes, private wells were not considered in this, or any of the remaining scenarios and $\mathbf{Q_{wells}}$ was assigned a discharge of 0 cfs.

Summary for Scenario 1

In summary, the difference between the inflows (0.158 cfs) and the alluvial groundwater outflows (0.139 cfs) equates to 0.019 cfs or (8.6 gpm) for $\mathbf{Q_{swo}}$. Based upon the background information set forth in Section 2.0, this flow rate seems to be a credible value to assign as a representative or "typical base flow" condition in the vicinity of SW-55 prior to mining.

The values defined above are deemed as representative, but again, it is warranted to reemphasize the inherent uncertainty associated with this complex natural system.

3.2.2 Scenario 2: "Early" Mining (drawdown scenario)

This scenario is considered the most complex of the four scenarios defined. During "early" mining, the system became highly transient. For instance, groundwater levels in the alluvium declined substantially in some portions of the control volume largely in

response to mining drawdown. These changes evolved over time with the progression of mining along the northern perimeter of Area B, and to some lesser degree because of mining at Areas A and C (east). These transient effects greatly complicate the water balance effort simply because of the changes in storage within the control volume. There are also resultant transient changes for the input and output variables of the control volume. Hence, it is deemed that developing a "representative" quantitative estimate for the control volume variables is infeasible for this "early" mining scenario. Nonetheless, this scenario is retained and discussed to illustrate the complexities during the alluvium "drawdown" phase as mining commenced.

Inflows

Again, the inflows to the control volume for this scenario include $\mathbf{Q_{a\text{-}in}}$, $\mathbf{Q_r}$, and $\mathbf{Q_{lat}}$. See Figure 7.

The incoming alluvial flow, $\mathbf{Q_{a\text{-}in}}$, is likely transient over time owing to the changes in hydraulic gradient that occurred near the up-gradient boundary of the control volume. It is projected that at first, there would be some increase in $\mathbf{Q_{a\text{-}in}}$ as the hydraulic gradient steepened. The lateral contributions from bounding strata, $\mathbf{Q_{lat}}$, in contact with the alluvial aquifer control volume changed over time as a result of transient changes in hydraulic gradient between these bounding units and the alluvium. As mining progressed, $\mathbf{Q_{lat}}$, likely became a net outflow since flow was being induced from the alluvial control volume by drawdown. This induction was likely most significant when Area B mining near the alluvium was being conducted. Yet, as mining progressed away from the alluvium, water levels were beginning to recover in the mine spoils so that this net outflow changed over time.

Another dominant transient factor involves the MPDES discharges delivered into the EFAC channel. This led to episodic/dramatic increases in recharge, $\mathbf{Q_r}$ for some years when compared to baseline conditions. Please refer to Attachment 2, Table 1 and Figure 2.

Outflows

Again, the outflows from this control volume total, in effect, the sum of alluvial groundwater outflow ($\mathbf{Q_{a\text{-}out}}$), surface water outflow ($\mathbf{Q_{swo}}$) and $\mathbf{Q_{wells}}$.

It is likely that the alluvial outflow estimate ($\mathbf{Q_{a\text{-}out}}$) is similar to, but slightly less than the calculated value of 0.139 cfs defined for the baseline scenario. Because of the drawdown that occurred during mining, it is more likely that $\mathbf{Q_{swo}}$, as measured at SW-55, showed dry channel conditions for this scenario. Again, flows associated with the pumping wells are assumed to be negligible when compared to the magnitude of the other flow factors involved.

Summary for Scenario 2

It is concluded that because of the unduly transient nature of the inflow/outflow variables involving the control volume, a representative water balance cannot be meaningfully computed for Scenario 2. Nonetheless, this scenario assists in understanding how the system has behaved over time since mining began in Areas A and Area B.

3.2.3 Scenario 3: Current Condition

The variables defined in Figure 8 are estimated in part based upon information defined in Van Voast, et al (1977). In some aspects, this scenario is reasonably similar to the baseline scenario since alluvial groundwater levels have recovered. The primary difference is that many of the alluvial wells show groundwater levels above baseline water level observations.

Inflows

Again, the inflows to the control volume for this scenario include $\mathbf{Q_{a\text{-}in}}$, $\mathbf{Q_r}$, and $\mathbf{Q_{lat}}$. The incoming flows were estimated as described below.

The estimate for $\mathbf{Q_{a\text{-}in}}$ (incoming alluvial flow) is quantified in Table 1 to be 0.061 cfs (27.3 gpm). Note that this is lower than the pre-mine $\mathbf{Q_{a\text{-}in}}$ from Scenario 1, because of a reduction in the hydraulic gradient near this area, which in turn is associated with decreased up-gradient alluvial water levels in response to mining. Note that groundwater levels in the alluvium in this portion of the mine are still in the recovery phase.

The estimate for areal recharge component of $\mathbf{Q_r}$ over the control volume was assumed to be 5 % of the annual precipitation over that control volume land surface or 0.033 cfs

(14.8 gpm).

It is noted that there have been recent (temporal) MPDES recharge contributions to the control volume as well. In a majority of years, this discharge has been small or negligible. However, in some years this element of recharge is very substantial as shown below:

Water Year 2000 (167 million gallons year [mgy]) [0.71 cfs].
Water Years 2001 – 2006 (no discharge)
Water Year 2007 (28 mgy) [0.12 cfs].
Water Years 2008-2010 (no discharge)
Water Year 2011 (61 mgy) [0.26 cfs].
Water Year 2012 (109 mgy) [0.46 cfs]
Water Year 2013 (172 mgy) [0.73 cfs].

The MPDES discharge to EFAC decreased substantially in water year 2014 down to 16 mgy (0.07 cfs). For water balance purposes, it is assumed that most of the MPDES discharge above went to recovery of storage (water levels) that had decreased during early mining phases.

Under Scenario 3, the net water year 2013 recharge (total $\mathbf{Q_r}$) is computed as 0.763 cfs.

The lateral contribution, $\mathbf{Q_{lat}}$, is presently much smaller when compared to baseline conditions. It is deemed that the proportion of contributions from Area A are similar to, or less than, what existed pre-mine. For purposes of water balance quantification, the pre-mine flux contribution from Area A used for Scenario 1 was assumed, or 0.01 cfs (4.4 gpm) was applied.

The contribution from Area B to $\mathbf{Q_{lat}}$ is likely inconsequential since the general flow at the southern edge of the control volume is toward mine spoils. It is possible that there is presently some limited flow from the spoils to the alluvium near the very down-stream end of the control volume. This would be limited to the monitoring period starting in 2011 since, prior to that time, groundwater levels in the mine spoils were below groundwater levels in the alluvium. However, if any flow is directed from the spoil into the alluvium, it is deemed at this stage to be inconsequential.

Thus, the total $\mathbf{Q_{lat}}$ is assigned to be 0.01 cfs. All this flux is from Area A for Scenario 3.

The sum of these inflow numbers ($\mathbf{Q_{a\text{-}in}}$, $\mathbf{Q_r}$, and $\mathbf{Q_{lat}}$) is 0.834 cfs.

Outflows

The outflows from this control volume total, in effect, the sum of alluvial groundwater outflow ($\mathbf{Q_{a\text{-}out}}$), surface water outflow ($\mathbf{Q_{swo}}$) and $\mathbf{Q_{wells}}$ and includes any flow from the alluvium into the Area B spoils.

The net outflow from the alluvium to Area B spoils is assumed to relatively small compared to the other outflow variables. Also, the well usage within the control volume is considered negligible when compared to the other water balance factors.

The alluvial outflow estimate ($\mathbf{Q_{a\text{-}out}}$) was quantified using Darcy's Law to be 0.140 cfs.

Groundwater wells within the control volume are shown in Figure 6 with details provided in Table 2. One of these wells is relatively deep. Three of these wells show stock water rights with one showing domestic use as well. Given the location of these wells, actual water pumpage is likely to be very limited for stock water use. Domestic uses, from a water budget perspective for the EFAC are considered inconsequential. Hence, for water budgeting purposes $\mathbf{Q_{wells}}$ was assigned a discharge of 0 cfs.

The flow $\mathbf{Q_{swo}}$ at SW-55 ranged from 0 to 10.36 cfs, with a median value of 0.043 cfs (19.3 gpm). The median flow was used as an indicator of the "base flow" (from the alluvial control volume). It should be noted that the "base flow" is likely elevated well above natural conditions because of the effect of the MPDES discharges that have occurred from 2011 through 2013.

Assuming a median flow of 0.043 cfs, then the total computable outflow ($\mathbf{Q_{a\text{-}out}}$ and $\mathbf{Q_{swo}}$) from the control volume was assigned to be 0.183 cfs.

In summary, the instantaneous difference between the inflows (0.834 cfs) and the total computable outflows (0.183 cfs) equates to 0.651 cfs or (292 gpm) over the course of the 2013 Water Year. This difference is best explained as a combination of change in storage in the control volume (net increased groundwater levels) and likely includes some outflow into Area B spoils.

3.2.4 Scenario 4: Post Mining

Once mining is completed, it is assumed that over time, the post-mining scenario will be very similar to the pre-mining scenario. This will ensue in large part once the dominant hydrologic/hydraulic feature, the EFAC alluvium, fully recovers to pre-mine conditions, and the lateral flux from the bounding strata recovers in response to groundwater level recovery. The latter will occur when groundwater levels of the mine spoils approximate pre-mine water level conditions of the Rosebud coal. Hence, for water budget purposes (and for post mine water quality assessment), the net overall water budget applied to Scenario 4 is assumed to be the same as it was under baseline or pre-mine conditions (Scenario 1).

It is anticipated that there will likely be some difference in flow contribution from mine spoil as compared to the Rosebud coal. That contribution may be higher or lower depending upon the resultant transmissivity of those spoils.

4.0 WATER QUALITY ASSESSMENT

The objectives of this section of the report are the following:

- To utilize the water balance evaluations conducted in Section 3.2 to assist in quantifying the potential impact of mine spoils and other mine operations on water quality in the EFAC control volume.
- To define other potentially relevant factors contributing to the water quality transitions that are observed.

Note that the assessment is applied only to Scenarios 1, 3 and 4 since no meaningful water balance quantification could be applied to the highly transient Scenario 2.

4.1 Scenario 1: Baseline

4.1.1 Alluvial Water Quality

All available baseline total dissolved solids (TDS) concentrations and specific conductance (SC) values for the alluvial groundwater in the water balance area are

listed in Table 3. Pre-mine TDS concentrations in the water balance area range from 1,240 mg/L to 4,320 mg/L. Using the average pre-mine TDS concentration in each well, an overall average pre-mine TDS concentration of 2,299 mg/L was calculated for the alluvial groundwater in the water balance area. Based on the SC values, about half of these pre-mine alluvial groundwater samples are considered Class II (1,000 - 2,500 umhos/cm), whereas the other half can be classified as Class III groundwater (2,500 - 15,000 umhos/cm). The classification of the baseline alluvial groundwater at the P-series wells at the down gradient boundary of the water balance area is:

- P-01: Class II-III
- P-02: Class III
- P-03: Class III
- P-04: Class III
- P-05: Class II

Note that more discussion about EFAC alluvial water quality is given Section 4.2.4.2 of the ABC PHC (NE&W, January 2014).

4.1.2 Surface Water Quality

Due to the ephemeral nature of stream flow in the vicinity of the mine, the surface water quality is highly variable. The flow variability is demonstrated using measurements collected at surface water station SW-55 since 1982 and presented in Figure 9 (Pages 1 through 3). The average baseline EFAC TDS concentration is 1,421 mg/L, with concentrations ranging from 2 to 5,180 mg/L. Van Voast et al. list pre-mine TDS concentrations near SW-55 of 1,840 mg/L, 2,010 mg/L and 2,400 mg/L. Note that these latter values are reasonably consistent with the water quality of the alluvium, indicating that the surface water samples obtained by Van Voast may have been related to base flow or surface expressions of alluvial groundwater.

More surface water quality details for EFAC are discussed in Section 3.2.3.2 of the ABC PHC (NE&W, January 2014). It is noted that the surface water quality is highly variable as would be expected in a stream whose flows are largely dependent upon runoff from precipitation and snowmelt. Figure 10 illustrates the variability of the TDS concentration at SW-55 over time.

4.2 Scenario 3 – Current Mine Conditions

4.2.1 Alluvial Water Quality

The total dissolved solids concentration is a measure of the degree of mineralization of the water. It is generally proportional to the combined concentration of common ions in the water. At Rosebud Mine the common ions present at the highest concentrations in the alluvial and spoils groundwater are sulfate, bicarbonate, calcium and magnesium. For estimating impacts of spoils influenced groundwater on the alluvial water quality, it is reasonable to assume that the concentrations of these constituents will change proportionately to changes in TDS concentrations.

In order to evaluate transitions in water quality over time, TDS time series graphs for active alluvial wells within and upgradient of the EFAC control volume were developed (see Figure 11). Under pre-mine conditions, alluvial groundwater quality was generally Class II or III (see Table 3).

Increases in TDS concentrations are apparent in several of the alluvial wells, including wells up-gradient of mined areas. The pre-mine alluvial well TDS average was defined as 2,299 mg/L. The average of the most recent TDS concentrations available for alluvial wells in the EFAC control volume is 3,309 mg/L. As is the case for pre-mine conditions, the alluvial groundwater is currently Class II or Class III.

Also, chloride levels have increased substantially as well, particularly in the eastern portions of the EFAC control volume vicinity.

Several potential factors were evaluated to assess the transitions in water quality which are observed in EFAC alluvial wells including the following:

- The hydraulic/transport relationship between mine spoils and EFAC alluvium.
- Mine operations, including operation facilities and mine haul roads. With regard to the latter, dust control agents that have been used include magnesium chloride (used historically) and lignin sulfonate (used presently).
- Natural factors.

4.2.2 Evaluation of Mine Spoils versus TDS

Assessment of Figure 11 indicates that TDS concentrations have increased significantly for several of the alluvial wells within the EFAC drainage. The following provides a general conceptual summary of the observations of TDS concentrations in alluvial wells that have a sampling period extending from early 1980 to present.

Downgradient wells (within/near the control volume)

- WA-101 (present TDS concentrations comparable to early 1980s concentrations but possible slight increase). Mining commenced in the vicinity of the well about two years following the first observations.
- WA-126 and WA-128 (exhibiting about 50 percent net increase in TDS concentrations compared to very first observations). Mining commenced in the vicinity of these wells about one year after first observation.
- WA-131 (exhibiting about a 50 percent increase in TDS concentrations compared to very first observations). Mining in the vicinity of this well preceded first observations.
- WA-124 (showing about a 50 percent net increase in TDS concentrations based upon very first observations). Mining began near this well about one year after first observation.

Upgradient (within control volume)

- WA-114 (exhibited increase in concentrations until about 1990. Some increase was observed in 2013).
- WA-104 (showed increases in TDS concentration from prior to 1979 to about 1984, then stabilized concentrations were observed until early 1990s. Mining commenced in the vicinity of this well in southeastern portion of Area C in about 1990. At about the same time, TDS began to decline until about year 2000. Since 2000, TDS concentrations have been relatively stable.

Up-gradient (west, outside of control volume)

- WA-214 and WA-171 (both showed dramatic increases in TDS concentration in the latest sampling event). These wells are sampled once every three years. Note that these wells are up-gradient of any mining activity.
- Well WA-215 (showed stable concentrations in TDS concentration for the period of record). This well is up-gradient of any mining activity.
- WA-118 (showed an increase in TDS concentration of about 50 percent in the latest observation event). This well is up-gradient of any mining activity.

In summary, wells retained for further assessment of the potential significance of mine spoils impacts are: WA-101, WA-104, WA-114, WA-124, WA-126, WA-128 and WA-131; which are adjacent Area A, B and C mining activity.

Generally, groundwater in the alluvium is considered to flow parallel to the primary axis of the EFAC stream alignment (Van Voast, et al, 1977). Hence, a practical means of assessing the potential for spoils water to enter the alluvium is to compare groundwater levels in mine spoils to alluvial groundwater levels. In effect, if spoils groundwater levels are lower than alluvial groundwater levels, groundwater is interpreted to flow from the alluvium into mine spoils deposits. If spoils water levels are higher than the alluvial water levels, then flow may be moving from the spoils into the alluvium. Figure 12 examines this condition for Area B by comparing spoils water levels to alluvial water levels for three sets of wells. Based upon the hydrograph plots, groundwater has tended to flow from the alluvium (southeastward) toward the spoils for most of the period of record.

In order to refine the analysis further, local interpretative water level contour plots were developed and are presented in Figure 13 for the following years: 1995, 2005 and 2013. Those plots demonstrate that during these years, flow from the Area B spoils toward the EFAC alluvium is unlikely. On the other hand, it is interpreted that any groundwater from Area A spoils flows toward the alluvial aquifer for the years evaluated.

Hence, assessment of potential impacts of mine spoils is limited to groundwater flow emanating from Area A spoils.

In order to project the significance of Area A spoils impacted groundwater on the alluvial groundwater under Scenario 3, an idealized representation would be to mix the alluvial groundwater directly with spoils impacted groundwater from Area A. Therefore, a simplified mass balance calculation was used to estimate the approximate percentage increase in TDS concentration at the downstream edge of the control volume assuming spoils influenced groundwater contributions were entering the control volume from Area A.

The average Area A spoils TDS concentration during water years 2011 through 2013 was 3,538 mg/L. TDS concentrations from the following Area A spoils wells were available and used to obtain this average: WS-100, WS-106, WS-107, WS-113, WS-114 and WS-115. The parameters used for this simplified mass balance calculation are as follows:

- Outgoing surface water flow, $\mathbf{Q_{swo}}$ = 0.04 cfs
- Outgoing alluvial groundwater flow, $\mathbf{Q_{a\text{-}out}}$ = 0.14 cfs
- Lateral groundwater contribution from Rosebud Coal/Mine Spoils – Area A= 0.01 cfs with a TDS concentration of 3,538 mg/L.
- The TDS concentration of incoming alluvial groundwater: 2,299 mg/L

For convenience, the recharge contribution was ignored. Again, the primary aim was to see if there is the potential that Area A spoils groundwater explains the transition in water quality observed in the alluvium.

Based on the limiting assumptions made in the above calculation, the percent increase in TDS concentrations in the water exiting the control volume would be approximately three percent assuming that thorough mixing of spoils groundwater with alluvial groundwater had occurred. Given that average alluvial TDS concentrations within the control volume have increased about 34 %, it is interpreted that the influence of Area A spoils groundwater on the observed transition in water quality in the alluvium is very limited.

Exhibit 32

4.2.3 Assessment of Other Potential Factors - TDS

Other facility features and ponds were assessed to determine their potential for impacting groundwater TDS concentrations (see Figure 14).

Facility Features near EFAC

WECo uses Colstrip water for the following purposes:

- Vehicle washing.
- Office and facilities buildings (domestic use and lawn irrigation).
- Cleaning of two transfer houses in Area A.

The combined water use for all these purposes equates to 0.01 cfs from September 2012 to August 2013. The use is not differentiated between these purposes.

The water used for vehicle washing is pumped to two lined lagoons where it evaporates and does not contribute to the groundwater. Hence, these lined ponds are not considered a factor for the water budget or for influencing the water quality of the alluvium.

There is also a drain field serving the Area A offices. The primary effluent parameter associated with drain fields is nitrate nitrogen. The most recent nitrate nitrogen concentrations for active alluvial wells in the area do not indicate any substantial increases. Also, many of wells showing transitions in TDS are located up-gradient of the drain field.

Most irrigation water applied to lawns is consumptively used via evapotranspiration.

Finally, the water used for cleaning the transfer houses in Area A runs to nearby sediment traps.

It is concluded, given the low rates of water use, the fact that portions of this water go to evaporation ponds, lawn irrigation is consumptively transferred to the atmosphere, and domestic water primarily ends up as waste-water directed to an effluent drain field; that the none of the aforementioned features are considered to be a measurable factor in

explaining the transitions in TDS concentrations being observed.

Ponds near EFAC

Figure 14 shows the presence of standing water in ponds adjacent to the EFAC alluvium in 2013. Some recharge from these ponds is anticipated. However, the following are noted:

- In most years, many of these ponds have been dry or contain much less standing water than was observed in 2013.
- Any leakage that occurs from these ponds is limited by the extremely low vertical hydraulic conductivity of the underlying interburden strata.
- Given the interpretations presented in Figure 13, most of the recharge from the Area B ponds will likely flow southward as the spoils are recharged. In this case, little, if any flow, would reach the EFAC alluvium.

Any infiltration from ponds containing water in Area A could reach the alluvium via flux through mine spoils. The ponds in Area A have a limited surface area. Again, many of the observations or transitions in water quality are being observed in the alluvium up-gradient of these ponds. Hence, recharge from the Area A ponds is interpreted as an insignificant factor affecting TDS concentrations in the EFAC alluvial wells aside from prior interpretations set forth in Section 4.2.2.

Finally, standing water in the pits in Area B is not a factor since water from those pits does not flow toward EFAC. Pit water in Area A likely adds recharge water to Area A spoils. Area A spoils groundwater flux toward the EFAC was discussed in Section 4.2.2 (last paragraph).

In summary, it is interpreted that contributions from ponds to the TDS concentrations in the alluvium are very limited, and cannot be used to explain the changes in TDS concentrations being observed in EFAC.

MPDES Discharge Water Quality

MPDES discharge water quality was examined as a potential factor for transitions in TDS concentrations. Water quality data from MPDES discharges within the control volume from 1999 to 2014 exhibited the following TDS characteristics:

Statistic for TDS Concentration (mg/L)	All discharges	Planned Discharges	Unplanned Discharges
Average	1,589	1,724	1,036
Median	1,210	1,780	793
Range	394 – 3,840	700 – 3,840	394 - 3,360
Standard Deviation	798	746	792

As described in Section 3.2.3.2 of the PHC the majority of MPDES discharges at Rosebud Mine are planned. Unplanned discharges typically occur as a result of precipitation events in excess of the 10 year 24 hour design storm. Using flow data obtained from the 2011 through 2014 Rosebud Mine Annual Hydrology Reports it can be estimated that about 25 percent of the total volume of MPDES discharge during this period was unplanned. Given that three of the ten wettest years on record occurred during this period (Colstrip weather station data, 1948 - 2014), it is reasonable to assume that the proportion of unplanned discharges is usually lower than 25 percent. However, even if all discharges were planned, the average and median TDS concentration in MPDES discharges in the water balance area (1,724 and 1,780 mg/L) is still well below the average baseline alluvial TDS concentration of 2,299 mg/L. Hence, there is no basis to conclude that TDS in MPDES discharges is responsible for the increases being observed in the EFAC control volume.

Increases in Alluvial Groundwater Levels

Another potential factor that must be considered for the increases in TDS concentrations includes temporal increases in water levels, especially if those water levels are anomalously high compared to baseline conditions. TDS concentration increases have been observed in relatively shallow observation wells throughout Montana, including the Powder River Basin, since 2011 as a result of well above average precipitation, runoff and recharge According to Mr. John Wheaton of the Montana Bureau of Mines and Geology (MBMG): "The concept is well known and often discussed" [email correspondence 2/24/15 between NE&W and the MBMG].

More specifically, as it relates to the EFAC, TDS concentrations are responsive to water level changes in the alluvium. Figure 15 provides a compelling presentation of the influence of water levels in the EFAC alluvium versus TDS concentrations. When water levels increase, TDS concentrations tend to increase. When water levels decline, TDS concentrations tend to decrease. This relative rate of response is variable but a pattern is clearly present as set forth in this figure. Some examples and other interesting observations include the following:

- WA-118: TDS concentrations rose and fell in concert with the changes in water levels. This well is located more than one mile up-gradient of any mining activity. Mining is not a factor influencing TDS concentrations in this alluvial well.
- WA-104: TDS concentrations rose and fell in concert with the changes in water levels. Some of the earlier transitions pre-date any mining in its vicinity.
- WA-128: This well showed a similar pattern as others. A notable anomaly in this pattern was observed in about water year 2000. This temporal decline in TDS is deemed to be associated with MPDES discharges which consisted of water of relatively low TDS.

It is apparent that increasing water levels are the best explanation, and the dominant factor, for the recent higher TDS concentrations observed in the EFAC alluvium. The increases in the eastern portion of the EFAC control volume are due to recharge that

consists of natural recharge combined with recharge from MPDES discharges that occur over an extended period of time. Note that precipitation and runoff, and MPDES discharges have been anomalously above average since 2011. In other cases, substantial water level increases began well before 2011 (see Figure 15).

4.2.4 Chloride Concentration Observations

Section 4.2.4.2 of the PHC discusses disproportionate increases in chloride concentrations observed in selected alluvial wells near the Area A facilities. According to the PHC, a potential source of chloride is magnesium chloride which was used as a mine dust control agent until recently. Also, the same compound was used as a dust control agent by the county on the gravel roads in the area.

The highest concentrations of chloride observed in the alluvial groundwater are primarily found at the P-series wells (see Figure 16). Note that time series in Figure 16 were updated with data through the end of water year 2014. It is likely that runoff from roads, and collection of runoff water in sediment ponds, followed by infiltration led to magnesium chloride being transported into the underlying alluvium. This is likely the primary factor leading to the increases in chloride concentration that have been observed.

Recently, the mine has ceased using magnesium chloride as a dust control agent and replaced it with lignin sulfonate (see Attachment 3).

The time series plots provided in Figure 16 indicate that one alluvial well, P-04, and possibly well P-03, has/have shown indications of pending peaking in chloride concentrations. More monitoring over the long-term is required before this can conclusively ascertained.

Once peaking occurs, and there are some indications this is pending in the near future, chloride concentrations will gradually attenuate with time. Such attenuation will depend upon a number of factors including: infiltration rates, mass of magnesium chloride present in the unsaturated zone, variations in groundwater levels, etc. It is not practical to predict the rate of attenuation once peaking occurs.

4.3 Scenario 4 – Future Conditions

Projections for alluvial water quality for the future are predicated on the following assumptions:

- Assumption 1: The overall water budget for the EFAC alluvium will be similar to pre-mine conditions. In other words, it is assumed that the groundwater flux from the mine spoils to the EFAC alluvium will be similar to estimated historical contributions from the Rosebud coal. Some justification for this assumption is provided by Van Voast et al. (1977). They found that in general the ranges of hydraulic conductivity values in the Rosebud coal and spoils are similar. If the water levels in the spoils eventually recover to pre-mine levels, as is generally assumed, the magnitude of the incoming flow of groundwater into the alluvium from bounding strata is projected to be comparable to pre-mine estimates.
- Assumption 2: The average spoils TDS concentration will be similar to the one associated with equilibrium concentrations defined at existing spoils wells. PHC section 4.2.4.2 presents a discussion of spoils groundwater quality for data collected from 1979 to 2011. The available data were collected at spoils wells throughout the mine (PHC Figures 29A and 29B). Given the number of spoils wells and the areal distribution of these wells throughout the mine, it is reasonable to assume that the data collected to date are a good indicator of future water quality transitions. Though it is apparent that spoils groundwater quality is highly variable, it is reasonable to assume that average TDS equilibrium concentration observed at present will be similar to average TDS equilibrium concentration in the future.

Based upon Assumption 1, the water budget scenario for Scenario 1 (Figure 5) was employed for projecting future water quality in the EFAC alluvium.

In order to address Assumption 2, groundwater quality data collected from spoils wells

in Areas A, B, and C was evaluated. If a spoils monitoring well showed less than a 10 % change in TDS concentration in the last 10 years, it was assumed to exhibit equilibrium concentrations. The average equilibrium concentration was determined to be 4,360 mg/L. Table 4 provides more detailed information on how this estimate was obtained. To further investigate the validity of Assumption 2, an average spoils TDS equilibrium concentration was calculated including data from Area D and E wells using the same method (data not shown). This concentration was found to be nearly identical to the estimate obtained from the data in Table 4.

The incoming and outgoing groundwater quantity and quality (TDS) were assigned as follows:

- $\mathbf{Q_{lat\text{-}in}} * C_{l\text{-}in}$ = 0.023 cfs * $C_{l\text{-}in}$ (with $C_{l\text{-}in}$ = 4,360 mg/L)
- $(\mathbf{Q_{a\text{-}out}} + \mathbf{Q_{swo}}) * C_{a\text{-}s}$ = 0.158 cfs * $C_{a\text{-}s}$ (with $C_{a\text{-}s}$ unknown)
- $(\mathbf{Q_{a\text{-}in}} + \mathbf{Q_r}) * C_{a\text{-}r}$ = 0.135 cfs * $C_{a\text{-}r}$ (with $C_{a\text{-}r}$ = 2,299 mg/L)

Refer to Figure 5 for the baseline flows. Note that baseline surface water outflow, $\mathbf{Q_{swo}}$, and alluvial groundwater outflow, $\mathbf{Q_{a\text{-}out}}$, are assumed to possess the same TDS concentration, $C_{a\text{-}s}$ (unknown). Similarly, the incoming alluvial groundwater, $\mathbf{Q_{a\text{-}in}}$, and the areal recharge water, $\mathbf{Q_r}$, are assumed to possess the same concentration, $C_{a\text{-}r}$. The TDS concentration for the spoils, $C_{lat\text{-}in}$, is applied to the projected flow of spoil groundwater (from Areas A and B).

- Solving for $C_{a\text{-}s}$ yields a TDS concentration of 2,599 mg/L which represents a thirteen percent increase in TDS concentration. Again, it is reemphasized that this is a prediction of post-mine conditions based upon the reestablishment of equilibrium flow. The rate, or point in time, that this net increase is reached is impractical to predict. However, that time frame likely involves several decades after mining in Area A and B ceases.
- Again, it is reiterated that similar increases should be anticipated for the other parameters such as sulfate, bicarbonate, calcium and magnesium which are the most common ions that define TDS concentrations.

Presently, most of the alluvial groundwater under baseline conditions is classified as Class II or Class III. Based upon water quality projections set forth above, the classification of the alluvial groundwater in EFAC will remain Class II or Class III.

5.0 SUMMARY AND CONCLUSIONS

A water balance evaluation was conducted for the following purposes:

- Provide a quantitative understanding of the hydrologic factors that explain flow conditions in the reach of EFAC between Areas A, B, and C.
- Provide an assessment of factors that are currently affecting the water quality of the groundwater in the EFAC alluvium. Transitions in TDS and chloride levels are apparent in several alluvial wells in the EFAC.
- Assess future or probable hydrologic consequences that are anticipated to occur in the vicinity of EFAC.

Based upon the above evaluation, the following are the conclusions that are drawn:

- Groundwater levels or alluvial aquifer storage under pre-mine conditions were primarily dependent upon a recharge associated with major precipitation/snowmelt runoff events.
- Generally, flow in the EFAC between Area A and B was very limited under normal climatic conditions. Surface water base flow was typically of short duration except following recharge events associated with precipitation/snowmelt runoff.
- Mining has affected water levels in the alluvium in two ways. One way is that groundwater was drawn from the alluvium during mining in close proximity to the alluvial aquifer system. The second way is that when well above average precipitation and significant runoff occurs, surface water is detained/retained in mine pits and ponds to control sediment and runoff in accordance with MPDES permitting requirements. When water ponds and pits discharges to the EFAC channel over extended periods of time, increased rates of recharge occur. These increases have led to higher groundwater levels in EFAC alluvium. In some cases, these increases result in groundwater levels that exceed pre-mine levels.

- The present water quality transitions as measured by TDS in the EFAC alluvium are dominated by changes in alluvial water levels. These transitions occur in the EFAC alluvium in the EFAC control volume reach between Areas A, B, and C and in EFAC areas up-gradient and out of the influence of the Rosebud Mine.
- Other much less significant factors for TDS transitions include groundwater flow from mine spoils, pits, ponds and facility features.
- The transport of groundwater containing higher TDS concentrations will increase with time as groundwater levels in spoils recover toward pre-mine conditions in both Areas A and B. Once those water levels fully recover, it is estimated that the increase in TDS in the alluvium will be about 13 percent when compared to baseline conditions.
- Changes in chloride concentrations, especially those observed in the eastern section of the EFAC control volume are probably explained by the use of magnesium chloride as a dust control agent at the mine. The historic use of magnesium chloride as a dust control agent for the county road may be a factor as well. Recently, the mine has ceased using magnesium chloride and presently uses lignin sulfonate as a dust control agent.

Finally, as a point of emphasis, it is noted this is a highly complex natural system. Hence, the water budget and water quality calculations applied to pre-mine, current and post-mine conditions are predicated on a series of assumptions.

Notes
(a) Quantified on the basis of information from Van Voast, et al (1977).
(b) The hydraulic gradient was calculated based on water levels both upstream (WA-100) and downstream (P-11) from the water balance boundary. Note that well P-11 was used in the original calculations by Van Voast, et al (1977).
(c) The hydraulic gradient was calculated based on availabe alluvial water levels upgradient (WA-122) and downgradient (P-03) from the water balance boundary. The hydraulic conductivity of the gravel was assumed to be the same as at the downgradient location.
(d) The hydraulic gradient was calculated based on available water levels in WA-100 (upgradient) and P-03. WA-100 is closest to historical well WA-114 (see (b)). No close downgradient alluvial water levels were available.
(e) The hydraulic gradient was calculated based on available water levels at WA-104 and WA-114 (downgradient). No close upgradient alluvial water levels were available.
(f) Note that water bearing zone remains constant at the downstream end because of a shallow confining clay layer being present.

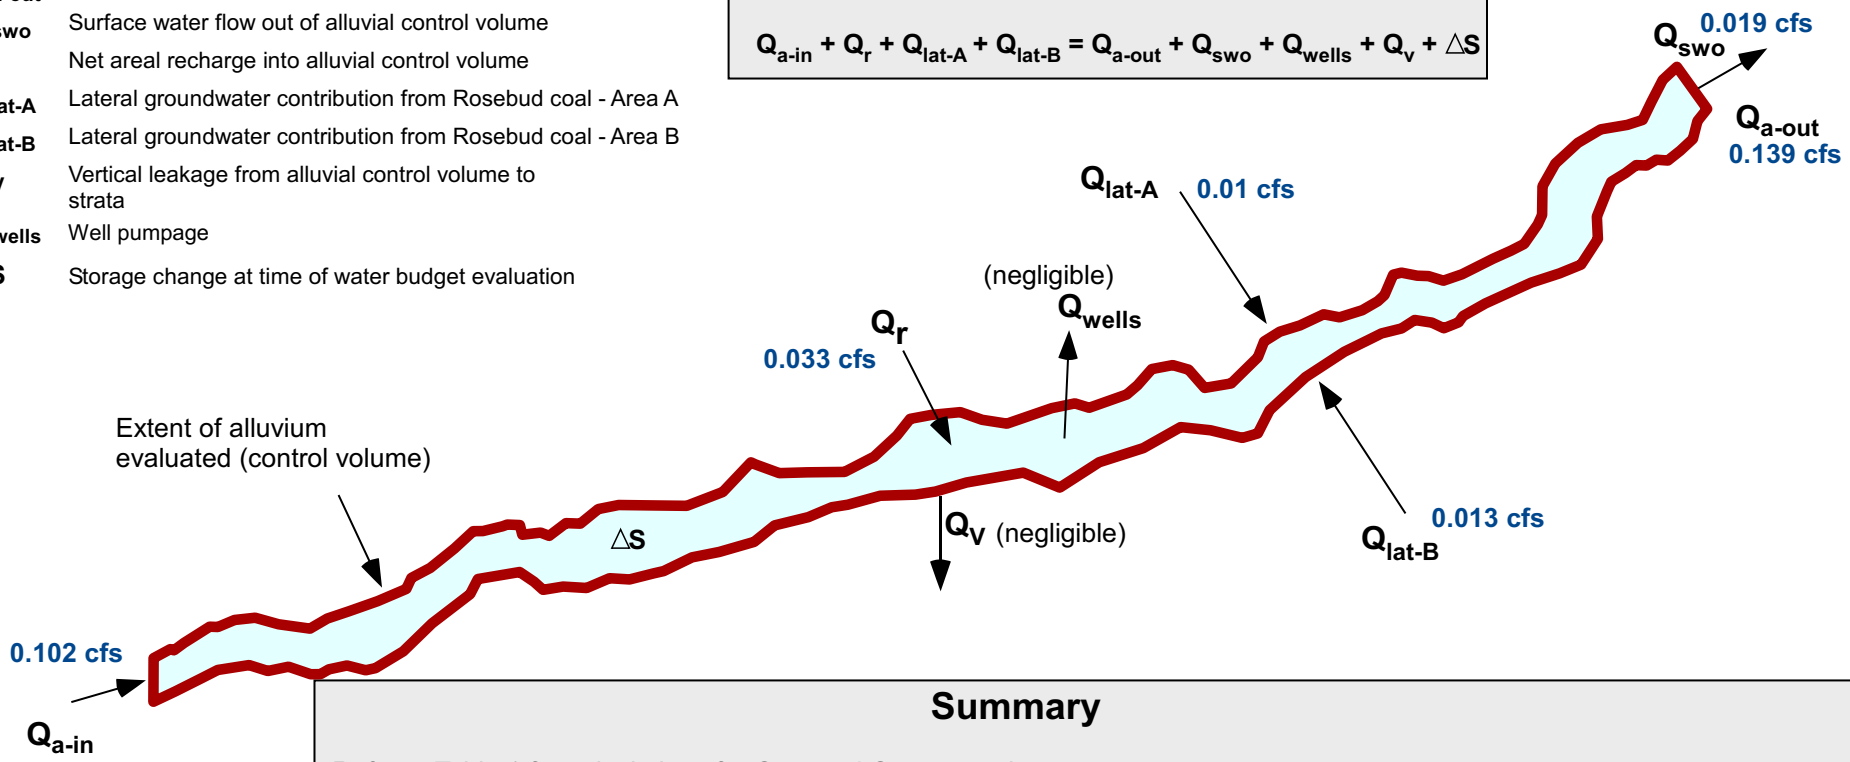
Water budget Equation

$$Q_{in} = Q_{out} + \triangle S \text{ or}$$

$$Q_{a\text{-}in} + Q_r + Q_{lat\text{-}A} + Q_{lat\text{-}B} = Q_{a\text{-}out} + Q_{swo} + Q_{wells} + Q_v + \triangle S$$



Summary

Refer to Table 1 for calculations for $Q_{a\text{-}in}$ and $Q_{a\text{-}out}$ premine.

(1) The net recharge, Q_r, is assigned by assuming 5 % of average annual precipitation over the area of the control volume infiltrates into the underlying alluvial aquifer.

(2) The lateral flow contributions, $Q_{lat\text{-}A}$ and $Q_{lat\text{-}B}$ are defined based upon estimates provided in Van Voast, et al which were updated using a higher transmissivity for the Rosebud coal as calibrated in the Rosebud Mine groundwater model.

(3) Little groundwater use was documented in the control volume (see Figure 6 for details). Hence, extractions by wells, Q_{wells} were assumed to be negligible.

(4) The Tongue River member strata possesses very low vertical hydraulic conductivities. Hence, vertical flow out of the control volume, Q_v, was considered negligible.

(5) The surface flow out, Q_{swo}, was calculated using the above equation under the assumption that no transient changes in water levels or changes in storage were occurring for the baseline period represented.

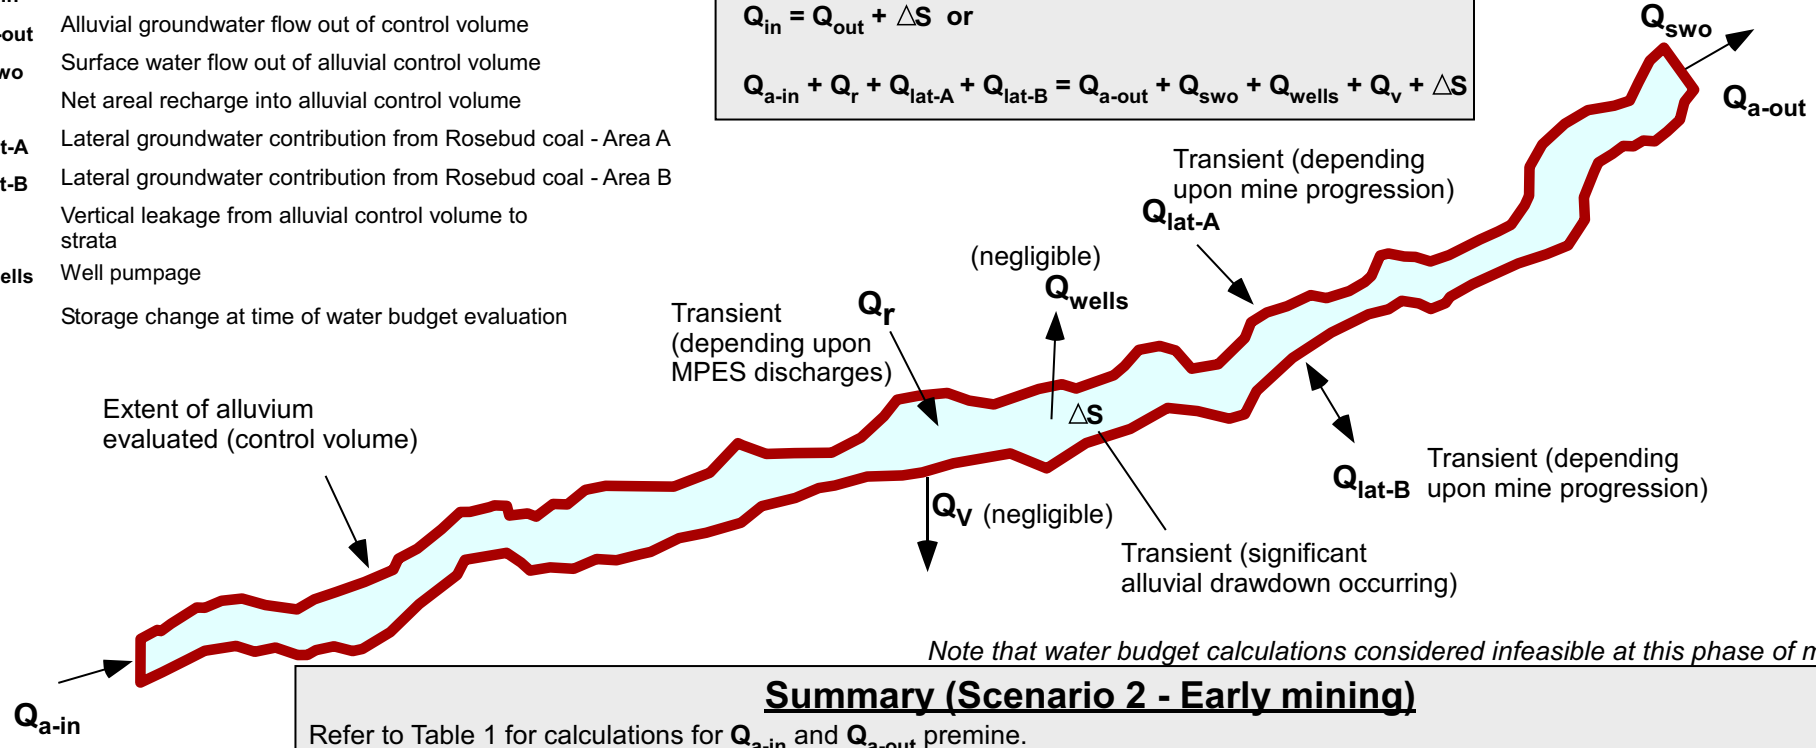
Water budget Equation

$$Q_{in} = Q_{out} + \triangle S \text{ or}$$

$$Q_{a\text{-}in} + Q_r + Q_{lat\text{-}A} + Q_{lat\text{-}B} = Q_{a\text{-}out} + Q_{swo} + Q_{wells} + Q_v + \triangle S$$



Note that water budget calculations considered infeasible at this phase of mining.

Summary (Scenario 2 - Early mining)

Refer to Table 1 for calculations for $Q_{a\text{-}in}$ and $Q_{a\text{-}out}$ premine.

(1) The net background recharge, Q_r, is assumed as the same at `the baseline contribution. In addition, there are likely MDPES dis charges that occurred during this scenario which acted as a source of recharge. Thus, recharge would be highly dependent upon this source of recharge when it occurred.

(2) The lateral flow contributions, $Q_{lat\text{-}A}$ and $Q_{lat\text{-}B}$ would vary as mining progressed, especially when mining was conducted near/adjacent to the alluvium. It is likely that in the case of $Q_{lat\text{-}B}$ that substantial net flow was induced out of the southern boundary of the control volume. The mining sequencing, or its proximity to mining has varied over time. Hence, these vari ables have been highly transient.

(3) Little groundwater use is documented in the control volume (see Figure 6 for details). Hence, extractions by wells, Q_{wells} were assumed to be negligible.

(4) The Tongue River member strata possesses very low vertical hydraulic conductivities. Hence, vertical flow out of the control volume, Q_v, was considered negligible.

(5) Q_{swo} during the early mine phase was likely less than baseline under normal climate conditions because of overall alluvial aquifer drawdown.

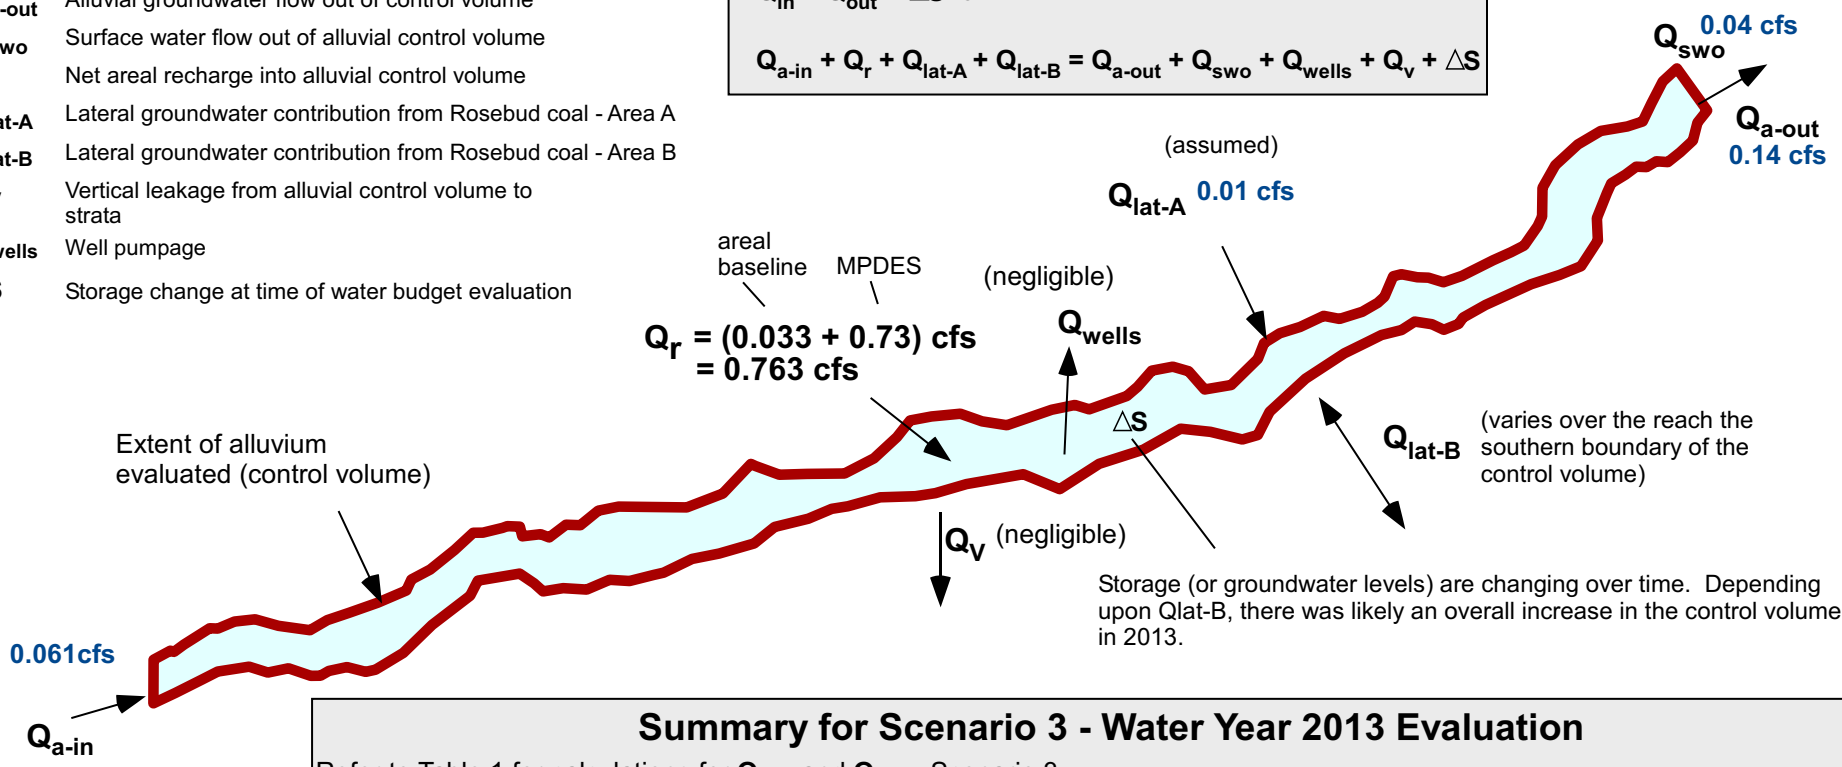
Water budget Equation

$$Q_{in} = Q_{out} + \triangle S \text{ or}$$

$$Q_{a\text{-}in} + Q_r + Q_{lat\text{-}A} + Q_{lat\text{-}B} = Q_{a\text{-}out} + Q_{swo} + Q_{wells} + Q_v + \triangle S$$



Summary for Scenario 3 - Water Year 2013 Evaluation

Refer to Table 1 for calculations for $Q_{a\text{-}in}$ and $Q_{a\text{-}out}$ Scenario 3.

(1) The net recharge, Q_r, is assigned by assuming 5 % of average annual precipitation over the area of the control volume infiltrates into the underlying alluvial aquifer. A net addition to this recharge was added to account for recharge from MPDES discharges.

(2) The lateral flow contributions, $Q_{lat\text{-}A}$ was assigned for Area A spoils to be similar to the Rosebud coal contribution (pre-mine). The 2013 flow for Qlat-B is considered to be variable an not quantifiable owing to range of mining activity in Area B and B-Extension. In some areas there is flow out of the control volume and in other areas of prior mining, flow interchange is very limited.

(3) Little groundwater use was documented in the control volume (see Figure 6 for details). Hence, extractions by wells, Q_{wells} were assumed to be negligible.

(4) The Tongue River member strata possesses very low vertical hydraulic conductivities. Hence, vertical flow out of the control volume, Q_v, was considered negligible.

(5) The surface flow out, Q_{swo}, was defined using the median flow measurement value defined at SW-55 for the 2013 water year.

Water levels in well alluvium as represented by well WA-101 have always been above the water levels in the mine spoil as represented by WS-184. Hence, flow is interpreted to be from the alluvium into the mine spoils in this vicinity of the mine. Thus, any transitions in water quality in the vicinity of WA-101 are not related to flow from Area B spoils.

Water levels in well alluvium as represented by well WA-126 have always been above the water levels in the mine spoil as represented by WS-157. Hence, flow is interpreted to be from the alluvium into the mine spoils in this vicinity of the mine. Thus, any transitions in water quality in the vicinity of WA-126 are not related to flow from Area B spoils

Water levels in well alluvium as represented by well WA-124 were above the water levels in the mine spoil as represented by WS-158 until the mid-1990s. Thereafter, spoil water levels at WS-158 were similar to slightly above water levels in the alluvium. See Figure 13 for further discussion.

Report
Assessment of East Fork Armells Creek
Vicinity of Areas A and B
by
Michael E. Nicklin, PhD, PE

1.0 BACKGROUND

The purpose of this report is to provide a synopsis of the nature of the relationship between the groundwater and the East Fork Armells Creek (EFAC) in the portion of the Western Energy Company's Rosebud Mine between permitted Areas A and B. The focus of this investigation was to assess if it is likely or not that this portion, or portions, of this creek should be considered as ephemeral or intermittent.

The following activities were performed in this assessment:

- Reviewed prior reports completed by others.
- Assessed alluvial well hydrographs in the vicinity of Areas A and B.
- Collected supplemental survey elevations of the EFAC channel thalweg at locations near selected alluvial wells. The evaluation focused on locations where pre-mining water level data were available.
- Evaluated the significance of other influences, such as mining, Montana Pollutant Discharge Elimination System (MPDES) discharges, etc. to alluvial aquifer conditions and potentially to surface water flows between Areas A and B.

2.0 PREVIOUS INVESTIGATIONS

One of the more relevant prior investigations which addressed the hydrologic conditions of the EFAC between Areas A and B was conducted by Van Voast, et al (1977). Pre-mine data up to 1976 were considered in the Van Voast investigation. The following are selected/relevant excerpts from the Van Voast, et al report:

> *"Most streams flow only during periods of snow-melt and after infrequent events of high-intensity rainfall. Rosebud Creek and East Fork Armells Creek downstream from Colstrip have perennial flow generated by continuous ground-water discharge. . . ."*
>
> Pertinent to Areas A and B:

> *"Flow of ground water in alluvium along East Fork Armells Creek is almost parallel to the water course. The alluvium is recharged vertically from precipitation and streamflow, and laterally from subcrops of bedrock aquifers. Most water in the alluvium is transmitted within the basal gravel beds. . .".*
>
> *"Upstream from Colstrip, East Fork Armells Creek is generally dry except for water holes where its channel locally penetrates the water table."*

Hence, it seems that Van Voast, et al characterizes this section to be a losing reach, i.e., water infiltrates from the stream into the alluvial aquifer. Thus, if EFAC flows were present, they were not dependent upon base flow from groundwater.

Another study was the alluvial valley floor (AVF) evaluation conducted for WECo by Hydrometrics (1982). That report described groundwater flow nearly parallel to the watercourse, similar to the interpretations defined in Van Voast et al (1977). That same report also described flow or standing water in short sections of the creek above Colstrip much of the year in the AVF evaluation.

A significant factor described in both studies that will affect the hydraulic communication between a stream and an adjacent alluvial aquifer is the nature of the geologic substrate between the stream channel and that underlying aquifer. Both the Van Voast, et al and AVF studies described a significant thickness of silt and clay between the base of the EFAC channel and the underlying alluvial aquifer. Such a condition will limit to some degree, any potential surface water and groundwater interaction.

The Environmental Impact Statement (EIS) for Area C (MDSL, 1982) states that the East Fork Armells Creek is intermittent in the vicinity of Area C.

Hence, it is clear that differences of opinion exist regarding the nature EFAC in the reach of interest. Therefore, the focus of this evaluation is to provide better resolution of the nature of the channel in the EFAC vicinity near Areas A and B.

3.0 OTHER FACTORS AND RECENT OBSERVATIONS

There are two primary human factors that affect EFAC flow in the Colstrip area and they are:

- Importation of Yellowstone River water to Colstrip, and
- Mining of coal at the Rosebud Mine.

Other human factors which can be locally influential include the presence of local stock ponds and roadway culverts, etc.

3.1 Importation of Yellowstone River Water to Colstrip

The overall water balance of the hydrogeologic regime in the Colstrip area has been altered via the importation of Yellowstone River water for use at the power plant. This imported water is stored in the surge pond (Castle Rock Lake). This imported water also serves to provide water supplies to Colstrip. Some portions of this imported water contribute recharge from pond leakage. For instance, leakage results from the surge pond and it is discussed in Van Voast et al. Another example is discharge of municipal waste water which leads to recharge and increased flow in EFAC within and downstream of Colstrip.

All these factors have resulted to increases in the EFAC alluvial water levels in the Colstrip area. Given that the EFAC alluvial aquifer is hydraulically continuous throughout the Colstrip area, some increase in the alluvial aquifer water levels is anticipated to have occurred in eastern portions of EFAC between Areas A and B as a consequence. The relative degree of this effect is not simple to quantify and is not evaluated in this report.

3.2 Influence of Mining Activity

Mining activity also influences the relative relationship between surface water conditions of EFAC and the underlying alluvial aquifer system. The following counterbalancing effects have been observed during mining:

- Dewatering of the Rosebud coal during mining reduces groundwater flows in the alluvium near EFAC. When water is taken from a coal seam during mining, water flows out of the alluvial aquifer and groundwater levels decline. The amount of this flow induction (and water level decline) is dependent upon the degree of hydraulic connectivity between the coal seams mined and the EFAC alluvium. The degree of connectivity, in large part, depends upon the proximity of mine passes to the alluvium. Between Areas A and B, the Rosebud coal is in contact with the EFAC alluvium. The EFAC alluvial deposits are much nearer mine passes in Area B when compared to mining in Areas A and E. Hence, mining in northern portions of Area B affects the aquifer most. The degree of the mining impacts from a water quantity perspective diminishes as Area B mine passes move away (generally south) from the EFAC alluvium, and as spoils are placed between the alluvium and the active mining passes.

- Recovery of alluvial water levels is dependent upon recharge from a combination of following sources:

- Runoff can be a major source of groundwater recharge along the main stem of EFAC. In some years, significant runoff occurs in association with either snowmelt and/or precipitation.
- Local recharge to nearby land surfaces also occurs but this recharge is much less significant compared to recharge from EFAC channel runoff.
- Recharge during mining results from MPDES discharges to the EFAC channel. This factor has been particularly dominant in years when precipitation and runoff is above average. The net result of above normal precipitation is that much greater volumes of water are retained/detained in ponds and mine pits. This stored water is then discharged to the EFAC channel over an extended period of time. Hence, a large volume of recharge occurs. Table 1 provides a summary of documented MPDES flow volumes into the EFAC drainage. Substantial discharges were observed in water years 2000, 2011, 2012 and 2013.

  Based upon observations of WECo mine staff, the MPDES discharges directed to EFAC infiltrate from the channel base, thus recharging the underlying alluvial aquifer. Such recharge has led to rapid recovery of water levels and even increases in alluvial groundwater levels exceeding pre-mine water level conditions. Thus, the key effect of MPDES discharges is to act a major recharge source to the EFAC alluvium between Areas A and B.

It is instructive to compare the significance of mining activity and the effects of MPDES discharges using observation well WA-101 (see Figure 1). The surveyed EFAC channel elevation (as interpolated) near this well is 3291.04 feet (see Figure 2). This elevation is compared to water level elevations of alluvial well WA-101. The following is an interpretative summary of the groundwater levels in this well over time:

- Water levels in this alluvial well prior to mining in the area showed a seasonal response likely related to early season runoff and the consequent increase in recharge to the alluvium from this runoff. Water levels tend to oscillate above and below the projected channel thalweg. The levels are more likely to be above the thalweg during runoff season and more likely to be below the thalweg during the drier portion of the year.
- Mining in Area B and Area C commenced near this well in 1983. As a result, water levels in the alluvium were drawn down slightly and were more likely to be below the channel base. After 1988 the groundwater levels remained persistently below the channel until about 1993.
- When mining in Areas B and C moved away from the EFAC alluvium near WA-101, water levels began to recover gradually over time until they were at,

or above, pre-mine levels by about 1994. The water levels continued to increase over time to reach levels exceeding pre-mine conditions. This increase is likely due to a combination of distance to mining passes, natural recharge, and discharge from mine pits/ponds into the EFAC drainage above or near this well.

- Beginning in 2011, water levels at WA-101 increased well above pre-mine conditions. This latter response is associated with the substantial MPDES discharges into EFAC since that year (Refer to Table 1). It was also likely affected to a lesser degree by natural recharge primarily related to runoff contributed from more up-gradient portions of the drainage during these years.

4.0 OTHER HYDROGRAPH EVALUATIONS

In addition to WA-101, other observation wells in the EFAC alluvium were compared to nearby surveyed channel thalweg elevations. Each of these is discussed below. Refer to Figure 2 for location and hydrographs for each respective well discussed.

Before proceeding with well specific discussions, it is noted that direction of alluvial groundwater flow will tend to follow the primary axis of the alluvial valley floor as opposed to following the sinuous alignment of the channel thalweg. This is especially true if there is little or no hydraulic connection between the stream channel and the alluvium. Channel thalweg elevations were collected as near to each specific alluvial well as feasible, and, along an equivalent projected potentiometric head elevation. The purpose was to provide a comparison of pre-mine alluvial groundwater levels to channel bases in the vicinity. In three instances, interpolated elevations from the survey data were employed.

WA-114 versus thalweg elevation - 3321.27 feet

See Figure 2 for the location of channel thalweg survey point and the hydrograph for alluvial well WA-114.

Early water levels (prior to 1982) for alluvial well water WA-114 indicate groundwater levels were interpreted to be about two feet below the base of East Fork Armells Creek at the surveyed thalweg location. In 1982, water levels increased abruptly during late winter and early spring at this well potentially indicating that channel recharge had occurred in association with a snow-melt and/or precipitation runoff event. The well water levels had risen above the surveyed channel thalweg elevation. Thereafter, water levels were observed to decline to below the surveyed channel thalweg elevation. The seasonal increase in groundwater levels in 1982 was likely affected significantly by the runoff water captured in a nearby stock pond embankment. When this stock pond

captures EFAC surface water flow, it tends to infiltrate (recharge) the underlying alluvium. Hence, it is difficult to quantify what "normal" water level conditions would be at WA-114 had it not been for the pond.

Additional evaluations are presented in Section 5.0 discussing the potential for historical/current existence of ephemeral or intermittent conditions for EFAC in the vicinity of WA-114.

Mining commenced in the vicinity of WA-114 in late 1983 resulting in substantial drawdown beginning in early 1984. Since 1984, water levels had persistently remained well below pre-mine levels until about 2011. At that time, water levels had recovered to near, if not slightly above, pre-mine levels. This recovery is interpreted to be from the far above average precipitation/runoff/recharge beginning in 2011. A substantial fraction of this recharge is a result of the increased MPDES discharges into the EFAC channel which subsequently infiltrated into the underlying alluvium. Again, the pond embankment also causes significantly increased recharge in this area. Even with the increased recharge from the MPDES discharges and the pond embankment, groundwater levels at this well have remained below the surveyed thalweg elevation.

EX-40 versus thalweg elevation (interpolated) – 3313.66 feet

See Figure 2 for location of channel thalweg survey point and hydrograph for alluvial well EX-40.

Alluvial well EX-40 (abandoned) has a limited water level data set extending from June 1980 to July 1983. All data were collected at this well prior to mining in its vicinity which commenced in the latter part of 1983. The water levels in this well are interpreted to have varied from below to slightly above the channel thalweg. It is likely that the higher water levels are associated with early year runoff. For instance, as in the case of WA-114, the water levels increased beginning early 1982, probably as a result of increased recharge associated with a significant snowmelt/precipitation runoff event(s) that occurred that year. As in the case for WA-114, the local groundwater elevations at this location may have been affected to some degree by nearby stock pond(s) [see Figure 2]. This includes the pond described in the vicinity of WA-114. There was also a stock pond very near EX-40. As a result, it is difficult to project what "normal" water level conditions at EX-40 would have been without the ponds being present.

Additional evaluations are presented in Section 5.0 discussing the potential existence of ephemeral or intermittent conditions for EFAC in the vicinity of EX-40.

WA-101 versus thalweg elevation (interpolated) – 3291.04 feet

See prior discussion for this well in Section 3.0.

EX-27 versus thalweg elevation (interpolated) – 3282.30 feet

See Figure 2 for locations of channel thalweg survey point (interpolated) and hydrograph for alluvial well EX-27.

Alluvial well EX-27 (abandoned) has a limited water level data set extending from June 1980 to May of 1987. Mining commenced in the vicinity of this well location in the latter part of 1983. The water levels in this well are interpreted as being substantially below the channel thalweg for the entirety of its observation history.

WA-128 versus thalweg elevation – 3271.51 feet

See Figure 2 for location of channel thalweg survey point and hydrograph for alluvial well WA-128.

This alluvial well has a water level measurement history from late 1980 to present. Based upon the data set one water level measurement of 3269.1 feet was taken prior to mining commencing in this vicinity of Area B in early 1981. That measurement is about 2.4 feet below the surveyed channel thalweg elevation of 3271.51 feet.

As in the case of WA-101 and WA-114, water levels in WA-128 show a historic response to the effects of drawdown from mining, and in turn, the recovery of water levels over time, particularly in response to MPDES discharges. Notable responses in this well's hydrograph correspond to MPDES release that occurred in year 2000, 2007 and 2011 (refer to Table 1 for MPDES discharges by year).

Recent water levels have been persistently about three feet above the pre-mine water level measurement collected in December 1980. Water levels since 2011 have also been observed to be persistently above the surveyed channel thalweg demonstrating the significance of the MPDES discharges into EFAC.

WA-126 versus thalweg elevation – 3265.97 feet

See Figure 2 for locations of channel thalweg survey point and hydrograph for alluvial well WA-126.

This alluvial well has a water level measurement history from late 1980 to present. One water level measurement of 3265.1 feet was taken prior to mining commencing in this vicinity of Area B in early 1981. That measurement is about 0.9 feet below the surveyed channel thalweg elevation of 3265.97 feet.

The water levels in this well exhibited a historic response to nearby mining activity. Water levels since 2011 have been above the thalweg elevation, due primarily to the effects of MPDES discharges to EFAC.

WA-124 versus thalweg elevation – 3258.91 feet

See Figure 2 for locations of channel thalweg survey point and hydrograph for alluvial well WA-124.

This alluvial well has a water level measurement history from late 1980 to present. Based upon the data set one water level measurement of 3254.7 feet was taken prior to mining commencing in this vicinity of Area B in early 1981. That measurement is about 4 feet below the surveyed channel thalweg elevation of 3258.91 feet.

Note that water levels did show increases from about 1982 to 1983 as mining in Area B had been on-going. A logical explanation for this increase is that groundwater collected during mining was being discharged into EFAC near, or just upgradient of, this alluvial well. Water levels were ultimately drawn down to about 9 feet below the thalweg in the late 1980s to mid-1990s. Presently, water levels in this well are very near the surveyed channel thalweg elevation.

P-04 versus thalweg elevation – 3245.96 feet

See Figure 2 for locations of channel thalweg survey point and hydrograph for alluvial well P-04.

This alluvial well has a water level measurement history from late 1974 to present.

Water levels in this well are likely affected by a down-gradient ponded area. The embankment causing this impoundment is possibly a relic embankment associated with a road alignment shown on United States Geological Survey topographic mapping.

The historic water levels prior to mining in Area B exhibited relatively regular seasonal variation centered about the surveyed thalweg elevation. This seasonal variation may, at least in part, be a result of seasonal runoff and pond storage.

The water levels in this well declined to below the thalweg when Area B mining commenced. In about 1990, water levels recovered to levels similar to those that were observed prior to Area B mining. Area B mining had gradually moved away from the alluvial channel vicinity by this time.

Since approximately 1993, water levels in P-04 have been well above the channel thalweg. Presently, the water levels at this location have been at their highest in year 2000 and since 2011. These high water levels are associated with the elevated MPDES discharges as defined in Table 1.

5.0 INTERPRETATIVE DEFINITION OF STREAM DESIGNATION

The information and interpretations provided previously, coupled with evaluation of recent aerial photography, allows for better resolution of the "point" along EFAC where it transitions from ephemeral to intermittent conditions. Figure 3 presents aerial photography for the following dates:

- August 11, 2009
- July 16, 2011
- July 21, 2013

An evaluation of the EFAC channel condition between observation wells WA-114 (upgradient) and WA-101 (downgradient) was conducted. Note that prior evaluations had indicated the existence of intermittent channel conditions near WA-101. The conditions near up-gradient (west) wells WA-114 and EX-40 (see Figure 2) were less conclusive because of the existence of pre-mine stock ponds.

Figure 3 also includes water level hydrographs for alluvial wells WA-114 and WA-101. The following are noted on Figure 3:

- Water levels at WA-101 were observed to be above pre-mine observations for 2009, 2011 and 2013.
- Water levels at WA-114 were observed to be near pre-mine observations for 2009, 2011 and 2013.

Hence, the channel conditions near/between these wells for the above aerial photographs should provide information regarding the following:

- Was the channel ephemeral or intermittent historically (pre-mine)?
- What is the current condition as consequence of mining activity and other factors?

The aerial photographs were each evaluated to determine if channel (standing/flowing) water was present. Note that channel water may be associated with either direct surface runoff and/or groundwater. This analysis makes no attempt to distinguish between standing water versus flowing water from the aerial photographs.

On the August 11, 2009 aerial photograph the first channel water was interpreted to begin at the point designated as A1 (upper left on Figure 3). No significant precipitation/runoff events were documented near this date. Hence, the presence of channel water at A1 is interpreted to be from groundwater. In summary, the channel was dry up-gradient (west) of A1. Based upon the 2009 aerial photograph, the EFAC between from the vicinity of WA-114 to A1 is ephemeral. The channel below A1 is intermittent.

On the July 16, 2011 aerial photograph some localized surface water (SW) were interpreted to be present up-gradient (west) of A1. It is noteworthy that a major precipitation event occurred on July 15, 2011. Hence, there is a significant likelihood that the localized surface water observed in the channel is from direct runoff event as opposed to being an expression of groundwater.

On the July 21, 2013 aerial photograph the first channel water was interpreted to begin at the point designated as B1 (lower left on Figure 3). No significant precipitation/runoff events could be discerned near this date. Hence, the presence of channel water at B1 is interpreted to be from groundwater. In summary, the channel was interpreted to be dry upgradient (west) of B1. Based upon the 2013 aerial photograph, the EFAC between from the vicinity of WA-114 to B1 is ephemeral. The channel below B1 is intermittent.

Given that groundwater levels at WA-101 are elevated (increased) relative to historical conditions, it is likely that the "transition point" between an ephemeral to an intermittent condition has migrated up-gradient slightly from what it was historically. Again, the increased water levels are largely attributable to an increase in recharge from the MPDES discharges necessitated from the far above average precipitation that has been observed in recent years (see Table 1).

Finally, even with elevated groundwater levels, there is no evidence of channel water near WA-114. Hence, the channel near WA-114 is deemed to have been ephemeral historically as well as currently.

6.0 SUMMARY AND CONCLUSIONS

ARM 17.30.602 defines an ephemeral stream as a stream or part of a stream which flows only in direct response to precipitation in the immediate watershed or in response to the melting of snow and ice whose channel bottom is always above the local water table.

Based upon the opinions expressed by Van Voast, et al, and based upon the evaluation conducted herein, I conclude the following:

- Based upon the aforementioned ARM definition, the transition point where the EFAC is interpreted to become ephemeral under current conditions is located up-gradient (west) from observation well WA-101 (point B1 in Figure 3). For historic conditions it is more likely that the ephemeral conditions began nearer vicinity of point A1 (Figure 3).
- Imported water for use at the power plant and for municipal purposes has affected groundwater levels in the vicinity of Colstrip.

- Mining has had a dual impact on the relationship between the EFAC between areas A and B and the alluvial aquifer as follows:
    - When mining was nearer the EFAC alluvium, groundwater level declines resulted.
    - MPDES discharges increased the groundwater levels. When significant discharges occurred, those discharges ultimately led to groundwater level conditions well above base-line conditions.
- The recent groundwater level conditions, and the current persistent flows observed in the EFAC, are not indicative of the natural condition for this portion of the creek. The water levels have been affected by far above average precipitation and the resultant increase in MPDES discharges that have occurred since 2011. Other human caused changes, such as stock ponds, have affected water levels and flows in EFAC as well.
- It is projected that when precipitation/runoff conditions return nearer to normal the following will transpire:
    - Alluvial groundwater levels will decline; and
    - Flows in EFAC will return nearer to pre-mine baseline conditions
- Finally, there are other factors and limitations to the evaluation that was conducted including the following:
    - In some areas, such as the very eastern portion of Area B, there is only one pre-mine groundwater elevation. Therefore, it is difficult to project with scientific certainty normal groundwater levels.
    - There are other factors affecting the degree of communication, or lack thereof, between a stream and an aquifer. One of these factors is existence of silt and clay between the EFAC channel thalweg and the underlying aquifer. This natural barrier reduces the degree of any potential surface water and groundwater interaction. Apparently though, the observations of mine staff are that MPDES discharges do infiltrate into the alluvium. Given that well hydrographs do respond (rise) accordingly, there is some degree of hydraulic connection between the EFAC channel and the underlying alluvial aquifer.

Exhibit 32

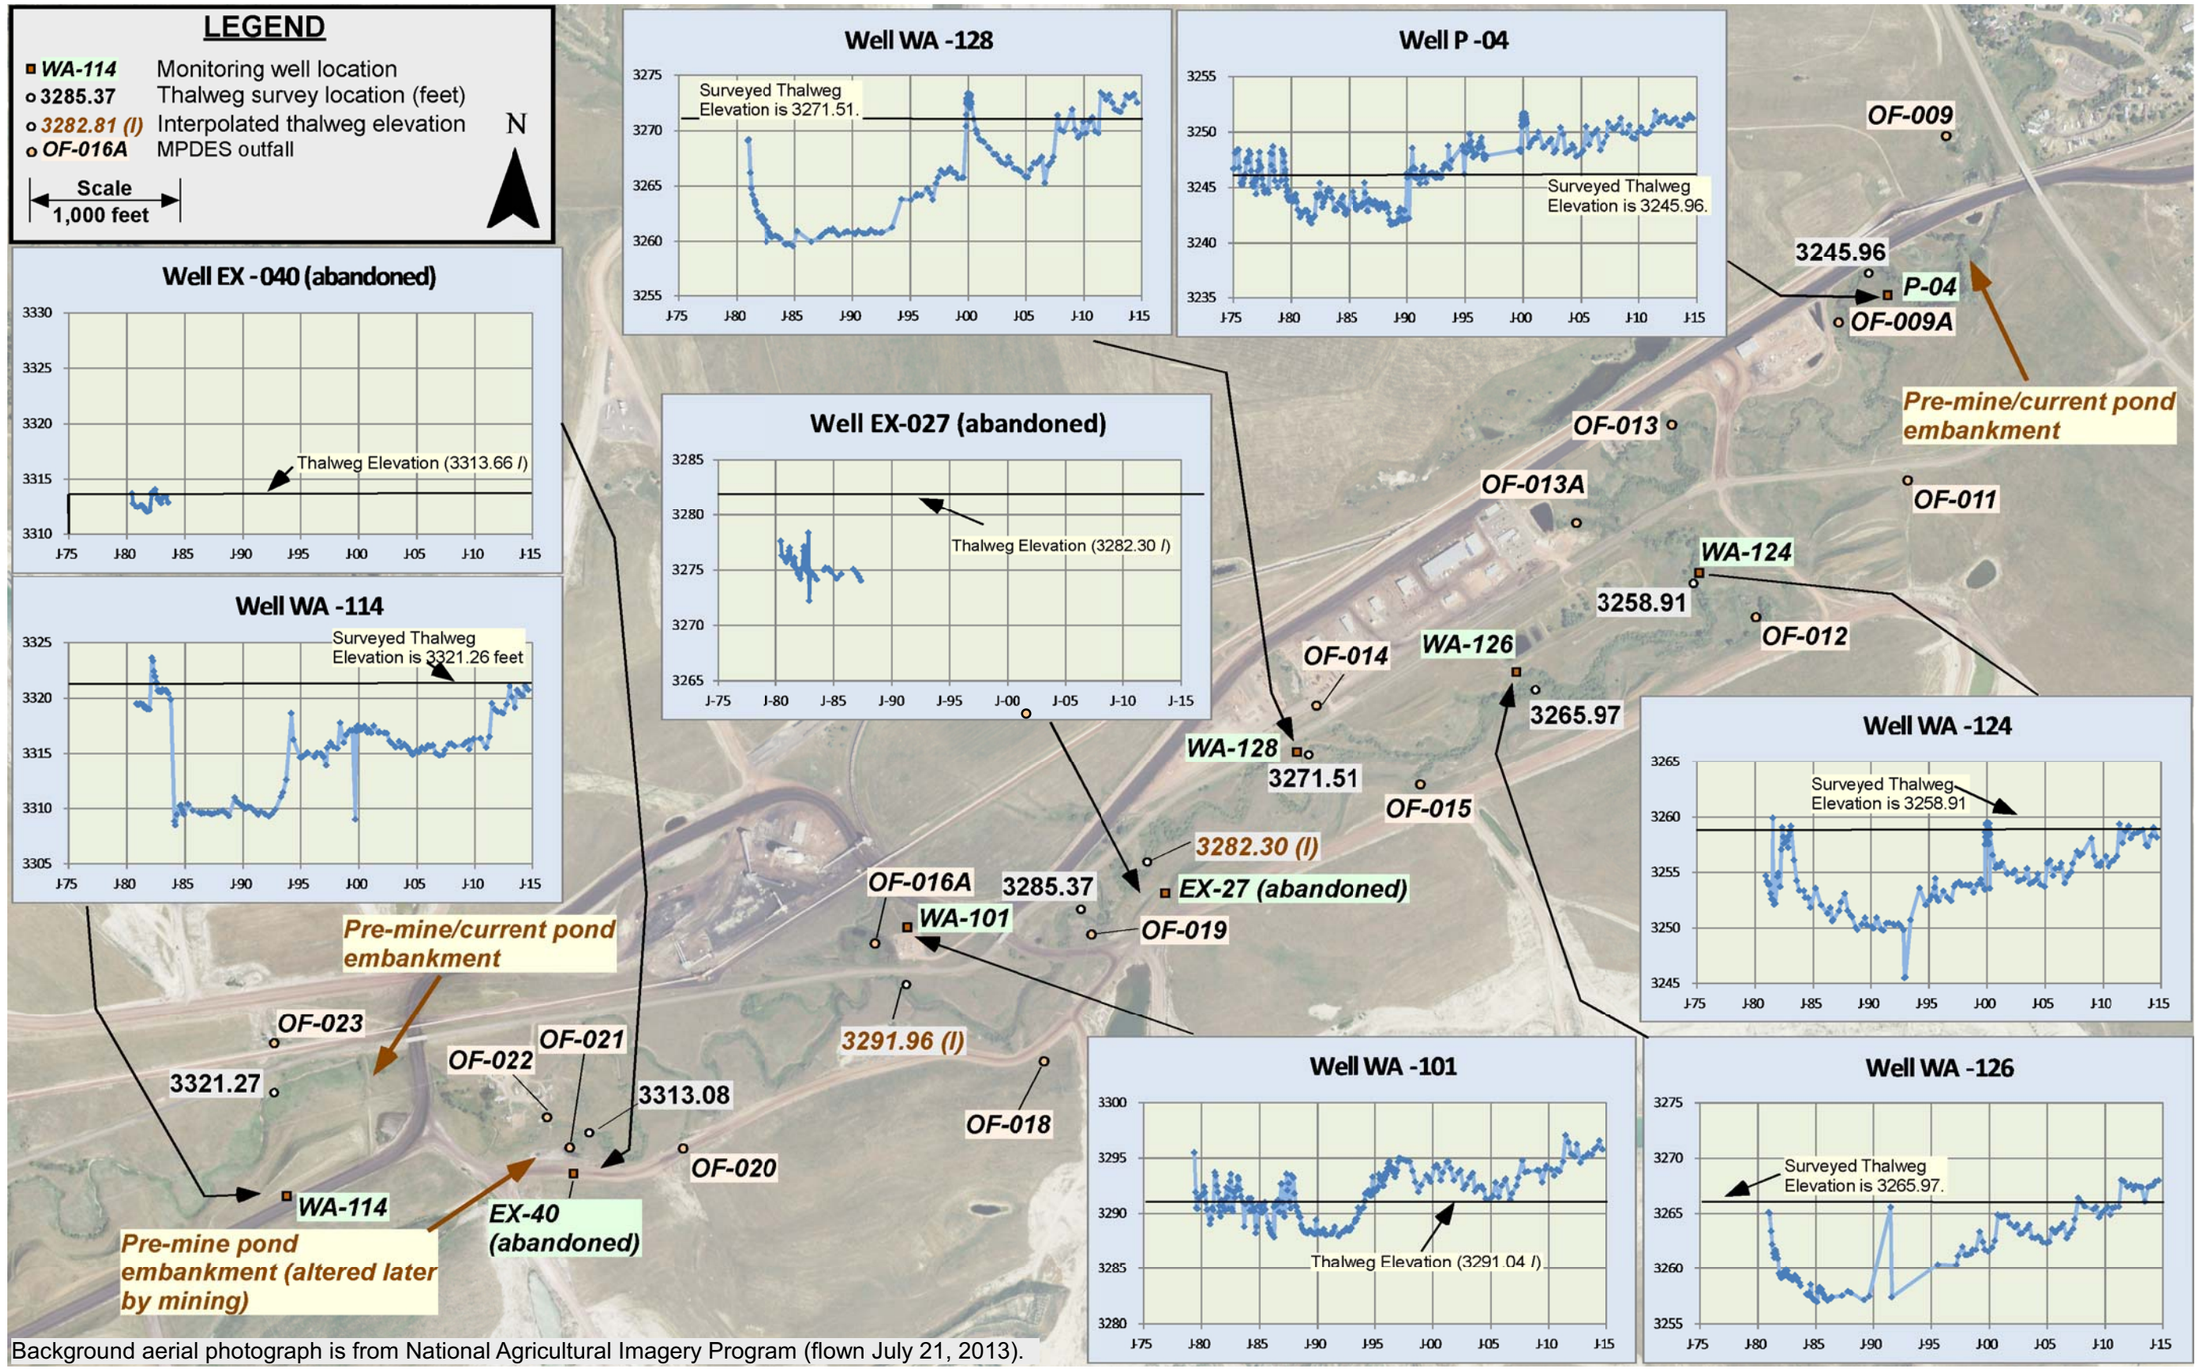

Figure 2. Comparison of East Fork Armells Creek alluvial well hydrographs to nearby surveyed channel thalweg elevations (feet).

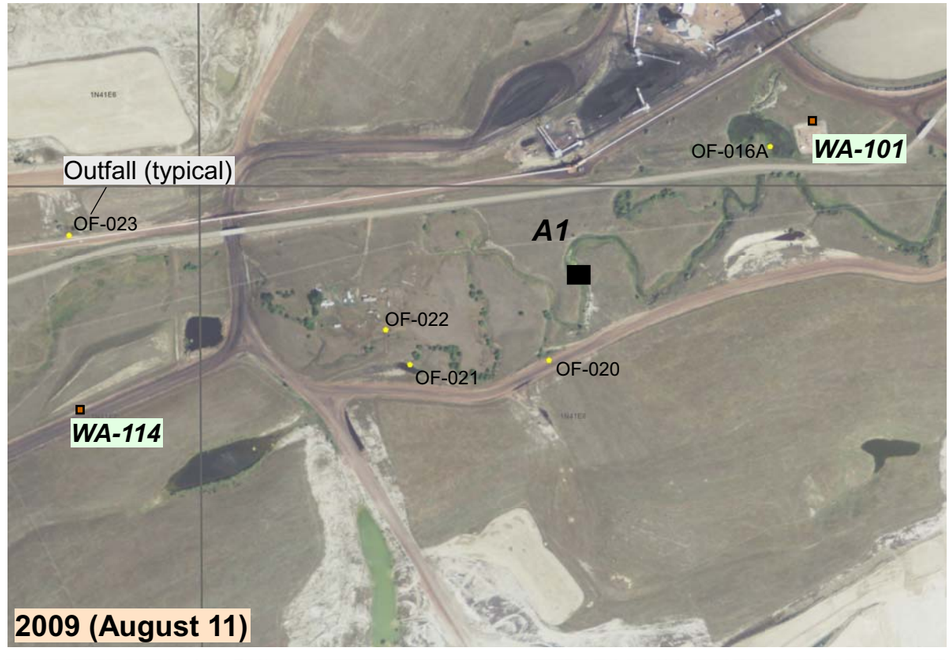

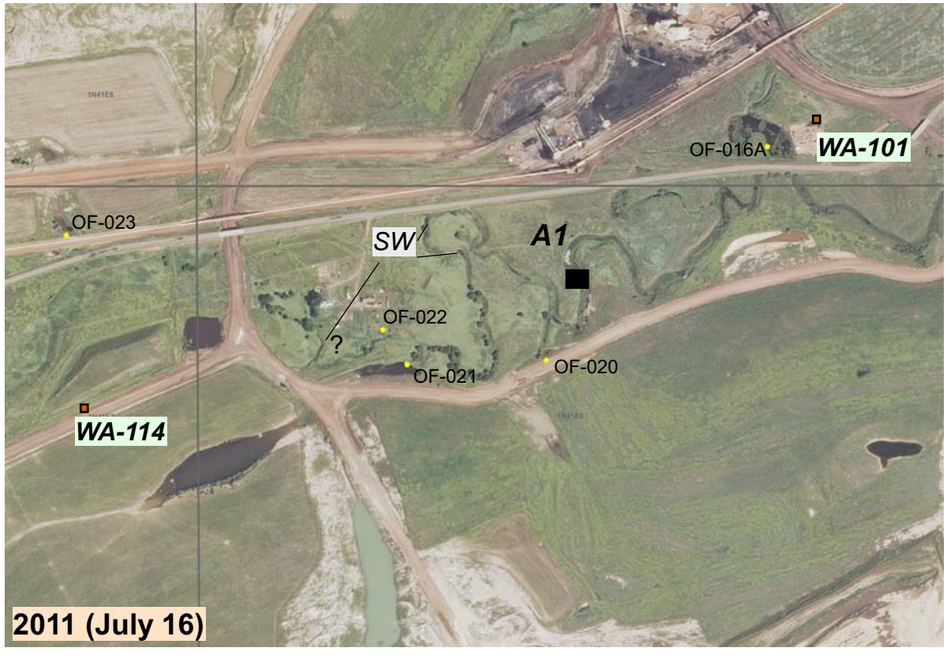

N

Scale not indicated

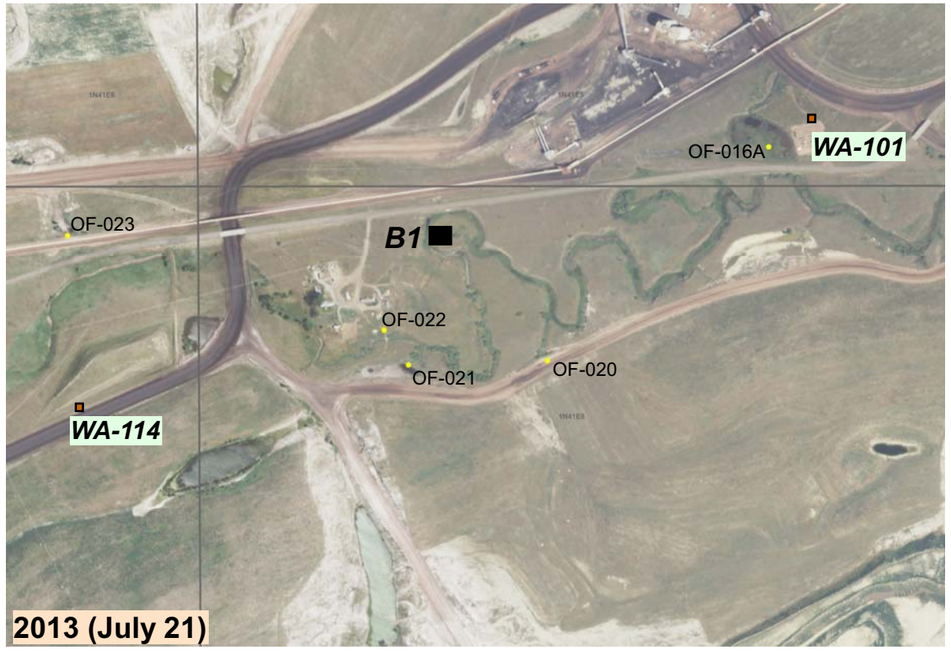

Figure 3. Evaluation of transition from ephemeral to intermittent channel.

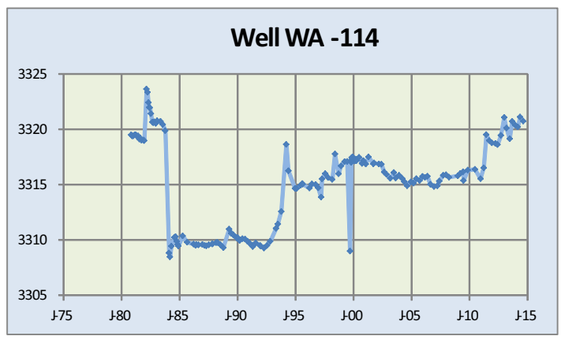

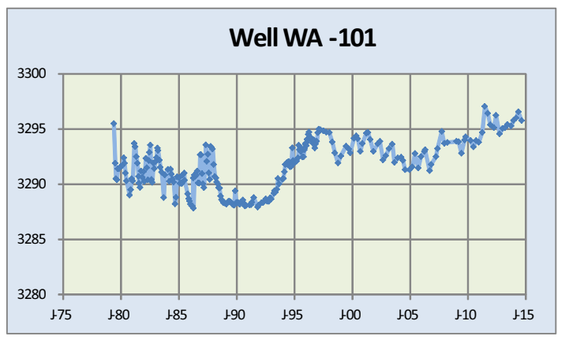

2009 summary .

1. Channel condition dry above point A1. Channel water observed downgradient of point A1.
2. Hydrograph at WA-114 shows water levels below pre-mine conditions.
3. Hydrograph at WA-101 shows water levels above pre-mine conditions.

2011 summary (a major precipitation/runoff event occurred on July 15, 2011).

1. Some limited zones of standing water (SW) observed upgradient (west) of point A1. Given the near coincidence of runoff event to aerial photography, the source of the standing water observed is inter preted to be from direct runoff (as opposed to groundwater).
2. Hydrograph at WA-114 shows water levels have recovered to pre-mine conditions.
3. Hydrograph at WA-101 shows water levels well above pre-mine levels.

2013 summary

1. Some standing water (SW) interpreted to be present at point B1 with some limited pooling downgradient.
2. Hydrograph at WA-114 shows water levels at or above pre-mine conditions. Yet, no standing water near this well. Hence, the channel near WA-114 is deemed ephemeral.
3. Hydrograph at WA-101 shows water levels above pre-mine levels.

Re: Calcium Lignin Sulfonate vs. Magnesium Chloride for Dust Suppression

---

Background

Magnesium chloride has been historically used on haul roads at Westmoreland's Rosebud Mine for dust suppression. Westmoreland is evaluating the potential effects of changing to Calcium Lignin Sulfonate (CaLS) for use as a dust suppressant. The primary issue evaluated in this memorandum is the potential for application of CaLS to increase sulfate in area surface water.

The approach used to assess potential sulfate loading from CaLS was to compare the application rate of CaLS to that of magnesium chloride. The potential sulfate loading (from CaLS) was estimated based on observed chloride trends in surface water (from magnesium chloride). Comparison of magnesium and chloride concentration in various samples collected in the East Fork Armells basins (Figure 1) shows that median background chloride in surface water is only about 14 mg/L, and the ratio of magnesium to chloride is typically around 10:1. Some samples, however, show higher chloride concentrations (rarely over 200 mg/L) and have elevated chloride relative to magnesium. In these samples, the ratio of Mg/Cl is closer to that found in magnesium chloride ($MgCl_2$ - 0.22:1), suggesting that dissolution of applied magnesium chloride from haul roads may be a source of chloride.

Sulfate release from CaLS, while possible, would be less pronounced than for chloride release from magnesium chloride for several reasons.

1. The sulfur in CaLS is combined in the organic molecular structure as shown in Figure 2. The lignin molecules have high molecular weight (500 to 100,000) and therefore have very low solubility. In order for the sulfur to be released, the lignin molecule would need to biodegrade. Degradation of lignin occurs very slowly.

2. The amount of sulfur contained in CaLS is lower than the chloride in magnesium chloride. Even using the lowest formula weight for CaLS (calcium 3-(2-hydroxy-3-methoxyphenyl)-2-[2-methoxy-4-(3-sulfonatopropyl) phenoxy] propane-1-sulfonate - $C_{20}H_{24}CaO_{10}S_2$) yields a sulfur content of 12.12 % (which is equivalent to 36.4% as sulfate), compared to the chloride in magnesium chloride of 74.2 %. Based on typical application rates for magnesium chloride and CaLS (Table 1), the amount of sulfate added per unit area of haul road surface is less than half the amount for chloride. Manufacturers literature on CaLS suggests an even lower sulfur content of 3.1 % (total

S of 31,100 ppm)

3. Finally, the background (median) levels of chloride (14 mg/L) and sulfate (783 mg/L) in the East Fork Armells basin samples differ by about 50 times. Even if the chemical mobility of sulfate was as great as that of chloride (which it is not), the effect of CaLS on background sulfate levels should be less than 1 % of the relative contribution of chloride from magnesium chloride.

Given the low mobility of sulfur in CaLS, the lower application rate of sulfur versus chloride, and the higher natural abundance of sulfate, the potential overall sulfate loading from CaLS will be low. Application of CaLS is not expected to cause a measurable change in background sulfate.

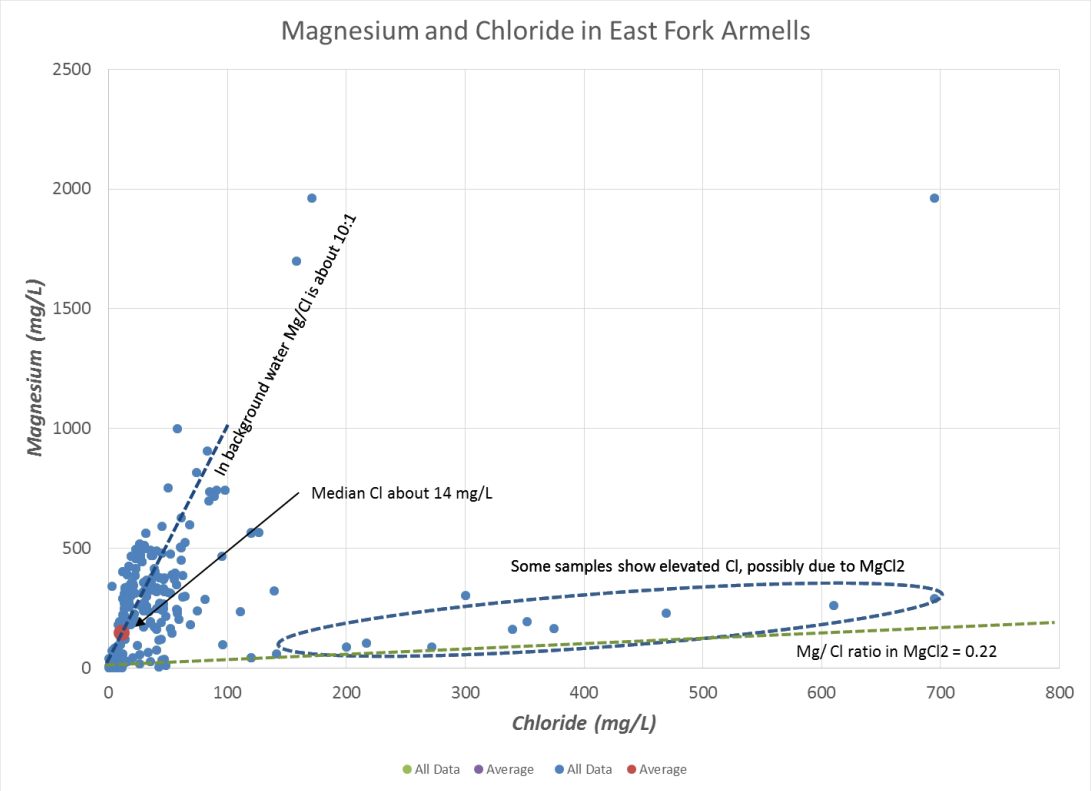

Figure 1. Magnesium and chloride in East Fork Armells Creek samples.

Aquatic Survey Assessment

---

1. INTRODUCTION

The following letter report describes the results of the aquatic habitat assessment and benthic community survey work performed by ARCADIS on October 9, 2014 within the East Fork Armells Creek (EFAC).

2. SAMPLE LOCATIONS

Aquatic surveys within EFAC were conducted to support existing permitting efforts for surface water discharges, per recent comments received by Montana Department of Environmental Quality (MDEQ). These recent comments included a June 3rd, 2014 MDEQ letter to Western Energy Company (WEC) stating that their application for Permit ID C1984003B Amendment AM4 was deficient and that WEC needed to "confirm, based on current and future anticipated concentrations in the stream, that uses have not or will not be impaired (MDEQ 2014)." In addition, MDEQ requested that WEC "conduct a current aquatic survey along stretches of East Fork Armells Creek (EFAC) adjacent to the Rosebud Mine permit areas (Areas A, B, and C) to identify assemblages of aquatic life using the stream habitat." MDEQ states the data collected from the aquatic survey will be used for future permit revisions in Area A and Area C.

Prior to conducting the aquatic survey, two ARCADIS scientists performed a reconnaissance along the stretch of EFAC adjacent to the Rosebud Mine permit areas (Areas A, B, and C) on October 9, 2014. The reconnaissance was performed to confirm existing drainage conditions (i.e., wetted extents and potential

Exhibit 32

habitat types) that would be representative of the current EFAC aquatic community. Based on the largely homogeneous aquatic habitat observed, consisting of primarily low-gradient drainage with minimal flow, heavy siltation, and riparian and emergent wetlands, two representative locations were selected to survey the current benthic community. The attached Figure 1 indicates the locations of EFAC1 and EFAC2. Location EFAC1 is positioned lower in the EFAC drainage. Compared to more upstream stretches, EFAC1was less impounded, had more visible flow sections and a higher degree of meander and sinuosity patterns in the drainage. This location had an established riparian zone with herbaceous, shrub, and tree vegetation layers, and some in-channel woody debris. Location EFAC2 is found in the middle portion of the EFAC drainage and near the upper extent of the wetted conditions observed during the reconnaissance. EFAC2 represents a low-gradient drainage. Compared to EFAC1, this location had a minimally developed flowing channel, relatively wider and more impounded wetted channel, and less meander and sinuosity. The riparian zone contained emergent vegetation.

3. SURVEY METHODS

Benthic macroinvertebrates were surveyed on October 9, 2014. Survey protocols and taxonomic identification of the benthic community organisms followed both MDEQ's sampling and analysis protocols *Sample Collection, Sorting, Taxonomic Identification, and Analysis of Benthic Macroinvertebrate Communities Standard Operating Procedure* (MDEQ SOP) (MDEQ 2012) and USEPA's *Rapid Bioassessment Protocols for Use in Streams and Wadeable Rivers* (RBP) (Barbour et al. 1999). The MDEQ SOP details a semi-quantitative reach wide sampling technique to collect samples from a known area, which allows the estimation of population density, in addition to diversity and abundance. This sampling technique includes the use of a d-frame net at a total of 11 transects within a sampling reach to be collected as kick samples working downstream to upstream. Barbour et al. (1999) recommends either 40 times the wetted stream width or a representative 100 meter reach (as a minimum for smaller-sized streams) for sampling. Based on drainage conditions, an approximate 100 meter reach was established at each benthic community survey location. Following RBP methodologies, general aquatic habitat conditions were detailed to include measurements of water quality parameters and physical characterization of riparian vegetation, instream features, presence of aquatic vegetation and large woody debris, and sediment and substrate components.

Based on existing habitat observed, the number of transects to provide a representative benthic community sample was reduced down from 11 to 8. Based on professional judgment, the MDEQ SOP methodology and its applicability to these low gradient survey reaches was compromised by the lack of riffles, exposed inorganic substrate, and the largely homogeneous habitat observed within each of the survey reaches. The individual area (1 ft^2 – 0.093 m^2) sampled within each survey reach was increased slightly (1.3 ft^2 – 0.12 m^2) to account for the difference and to obtain a representative 1 m^2 area sampled for the reach. Benthic organism abundance was noted throughout the collection process and available habitats were sampled to provide the representation of the existing community. For EFAC1, this included kick net samples, sweeps of emergent vegetation, and hand-picking and rinsing of functional large woody

debris. For EFAC2, the primary habitat was emergent vegetation and exposed root mats of emergent vegetation within a limited free-flowing narrow channel, which was sampled primarily by sweeping emergent vegetation and kicking substrate and root mat and detritus into kick net.

A representative area (approximately a 1.3 ft^2 quadrat) was selected along each transect to collect each of the kick samples. In an area of flow, the kick sample was collected within the representative area, by using hands with a hand trowel or by feet to disturb the area and wash and large rocks, sticks, or debris into the net for a period of 30 seconds. For slackwater habitats with emergent vegetation, the kick net was swept through the vegetation for 30 seconds within the representative area. All individual kick net samples were composited into a 5 gallon bucket and then elutriated to remove large debris. Contents were sieved using a standard #35 (500 micron) mesh size and then transferred to a wide-mouthed plastic sample jar. Samples were preserved with 90% isopropyl alcohol, and sent to Normandeau Environmental Consultants (Normandeau) in Stowe, Pennsylvania, for taxonomic identification. Normandeau taxonomic identification and community sample processing followed by MDEQ protocols to subsample an approximate 500 ± 10% organisms.

Water quality parameters were collected using a YSI 556 multimeter and a Hach 2100P turbidity meter at representative locations within EFAC1 and EFAC2.

4. RESULTS

The aquatic conditions of EFAC are indicative of low-gradient streams, with influences from a mixture of water origins (seasonal runoff, groundwater), and supportive of a tolerant benthic community. Existing habitat is characterized by heavy siltation, low flow, and high amount of organic substrates, with prevalent emergent vegetation along riparian zones.

Table 1 provides a summary of the temperature, specific conductance, dissolved oxygen, pH and turbidity measured at each location. Table 2 summarizes the main physical characteristics and substrate observations for both EFAC1 and EFAC2. Attachment 1 includes observations included during the RBP assessment of aquatic habitat and a set of photographs detailing the habitats surveyed at EFAC1 and EFAC2.

Table 3 provides the results of the taxonomic identification for the EFAC1 and EFAC2 benthic community samples. Community diversity and abundance was similar between the two locations, with a total of 25 and 26 taxa identified at EFAC1 and EFAC2, respectively. Communities were represented by eight orders of aquatic organisms, including aquatic worms, snails, amphipods, mayflies, damselflies, caddisflies, beetles, midges, and fly larvae. Within EFAC1, the side swimmer amphipod within the genus of *Hyalella* was the most dominant benthic organism observed. Within EFAC2, the non-biting midge within the genus of *Paramerina* was the most dominant benthic organism observed. For both locations, mainly tolerant Dipteran taxa comprised over 50% of the community, with *Hyalella* following closely at nearly 25% and

above within the community. Based on the MDEQ protocols, a community indicator metric (Hilsenhoff Biotic Index [HBI]) was calculated using Montana-specific tolerance values for identified taxa. The HBI metric represents the relative sensitivity of the sample to nutrient perturbation. The HBI, based on 2005 operable Taxonomic Units (taxonomic endpoints) found in Appendix A of the MDEQ SOP, was calculated for both locations (6.98, 7.90), and indicates “fairly poor” to “poor” conditions (Hilsenhoff 1987).

In summary, the aquatic habitat assessment and benthic community survey was conducted in general accordance with RBPs and MDEQ SOP protocols to satisfy the current deficiency letter and to support the potential for future permitting within existing areas A, B, C within the EFAC.

PART II. MINERAL FUELS

THE FORSYTH COAL FIELD, ROSEBUD, TREASURE, AND BIG HORN COUNTIES, MONTANA

By C. E. DOBBIN

INTRODUCTION

Location and relations of the field.—The Forsyth coal field embraces an area of about 800 square miles in southern Montana, south of Yellowstone River and east of the 107th meridian, and includes parts of Rosebud, Treasure, and Big Horn Counties. (See pl. 1.) The Forsyth field is only a fractional part of the great coal field which extends from the Big Horn and Musselshell Rivers eastward into the Dakotas and southward into the Powder River Basin, Wyo. The coal of this broad region ranges in grade from lignite, which occurs in the Dakotas and the extreme eastern part of Montana, to subbituminous coal in the Forsyth, Tullock Creek, Sheridan, and Bull Mountain fields.

Interest in the Forsyth field has been stimulated recently by the construction of a branch line of the Northern Pacific Railway 30 miles long up Armells Creek and the East Fork of Armells Creek to one of the thick Fort Union coal beds long known to occur in the region. The field is of present importance because it contains a large tonnage of coal that can be recovered by strip mining.

Field work and acknowledgments.—The Forsyth field was examined to collect data upon which to classify the public land included in it with regard to its value as coal land. The geologic mapping was done with the plane table and telescopic alidade, and all locations were tied to land corners. Altitudes are based on the United States Coast and Geodetic Survey bench mark at Finch railroad station and upon precise levels established by the engineers of the

Exhibit 31

Northern Pacific Railway and the Northwestern Improvement Co. The field work was done in the summer of 1923, and the writer was assisted by Prof. C. R. Fettke, C. M. Clark, and D. S. Mossom. The examination was made under the supervision of W. T. Thom, jr., and the writer feels indebted to him for suggestions both in the office and in the field. Acknowledgments are due to Mr. S. P. Sawyer, resident engineer of the Northwestern Improvement Co., and his associates for their unfailing courtesy and kindness in furnishing altitudes and other data necessary to properly carry on the work. Thanks are also due to the residents in the field for the many favors they showed. Finally, the writer takes this means of publicly thanking his assistants for their efficient work during the field examination.

Land surveys.—The earliest land surveys in the Forsyth field were made in the Yellowstone Valley in the years 1878 and 1879 and embraced T. 6 N., Rs. 38–41 E. In 1885 land surveys were made along Armells Creek in Tps. 2 and 3 N., Rs. 40 and 41 E., T. 4 N., R. 40 E., and T. 5 N., R. 39 E. In 1886 T. 1 S., R. 41 E., was surveyed. Except T. 5 N., R. 38 E., and T. 1 S., R. 40 E., surveyed in 1903 and 1908, respectively, all other townships in the field were surveyed in the period 1909–1916.

Many land-corner marks in Yellowstone Valley and along Rosebud and Armells Creeks are missing. In the upland areas practically all corner marks searched for were found, and to them all geologic mapping was tied. The corners of all townships surveyed before 1911 were marked by stones many of which have been so much weathered that all identification marks have been obliterated.

Previous work.—The general geology along the Yellowstone Valley has been described by Campbell[1] and that north of the Forsyth field and beyond the Yellowstone River by Bowen.[2] In 1920 C. E. Dobbin and W. T. Thom, jr., made a reconnaissance study of the principal geologic features of the coal-bearing area of southeastern Montana, the results of which were released in a press notice.[3] The Tullock Creek coal field, which adjoins the Forsyth field on the west, has been described by Rogers and Lee.[4] The location of other coal fields in the region surrounding the Forsyth field that have been

GEOGRAPHY

Land forms.—The Forsyth field lies in the Great Plains province and is a much dissected plateau across which the Yellowstone River and its tributaries have cut their valleys. To a large extent the topography of the field is determined by the nature of the underlying rocks. Where the surface strata are soft and incoherent clay and shale the upland areas have a subdued, rolling, and barren appearance, becoming rougher and minutely dissected in parts subject to stream erosion. These types of topography are characteristic of areas where the Bearpaw shale and the Lebo shale member of the Fort Union formation crop out. (See pl. 4, *B*.) In those areas where the rocks of the Lance formation are the surface strata the land is rough; the divides are long and narrow and the intermittent streams flow in narrow and deep valleys and invariably have their sources in narrow ravines trenching the edge of an escarpment several hundred feet high which is capped by a resistant sandstone. (See pl. 2, *B*.) Such an escarpment is a prominent topographic feature on the east side of Armells Creek. Although some rather broad and nearly flat lying areas have been developed in parts of the field where the Tongue River member of the Fort Union formation crops out, these parts are generally characterized by isolated buttes, mesalike hills, and long, narrow divides. These eminences usually have a cap rock of slag or clinker formed by the burning of one of the several thick coal beds of the member. The rocks between successive beds of clinker, except certain massive sandstones to be described later,

Exhibit 31

are much less resistant than the clinker and weather into steep and bare light-colored slopes.

The divide between Armells and Sarpy Creeks in T. 1 N., R. 39 E., and adjoining townships rises rather abruptly several hundred feet above the surrounding country. (See pl. 4, *A*.) This divide is less than a quarter of a mile wide and is capped with a coal clinker 50 feet or more thick. The top of the ridge is about 4,780 feet above sea level and is the highest point in the Forsyth field. The point of lowest altitude is 2,511 feet above sea level and is on the Northern Pacific Railway at the east line of T. 6 N., R. 41 E. The range of relief in the field is thus about 2,269 feet.

East of Armells Creek the flood plain of the Yellowstone River has a maximum width of slightly less than 1 mile at Forsyth, and in some places it has been obliterated by the river undercutting its banks. West of Armells Creek the flood plain attains a maximum width of about 2 miles near Howard and is extensively cultivated. South of the flood plain are rolling areas of Bearpaw shale and terrace gravel, which extend southward 8 miles from the river in Tps. 5 and 6 N., R. 38 E.

On the divide between Sarpy and Armells Creeks, in Tps. 3 and 4 N., Rs. 38 and 39 E., is a fairly extensive deposit of terrace gravel capping an escarpment at an altitude of 3,650 feet, or a little more than 1,000 feet above the level of the Yellowstone River, which corresponds to the highest gravel terrace of the Tullock Creek field.[6] Several hills and ridges in the northern part of T. 4 N., R. 41 E., capped by the same gravel are prominent landmarks. The most extensive gravel terrace is that which occurs in T. 6 N., R. 41 E., east of Forsyth, at a height of 200 feet above the Yellowstone River.

The flood plain of Rosebud Creek is about a quarter of a mile wide and is bordered on both sides by steep bare bluffs several hundred feet high capped by clinker. Viewed from any high point the tributaries of Rosebud Creek in this field appear to run in U-shaped valleys cut in a plateau of clinker, remnants of which make the cap rock on prominent and persistent escarpments rimming the valleys. The valley bottoms are broad and fairly level. Toward the headwaters of these streams the land becomes increasingly rough and, save for a few poor trails, is accessible by saddle horse only.

Drainage and water supply.—The northern part of the field is skirted by the Yellowstone River, which receives all the drainage of the field either directly or by its tributaries, the largest of which are Sarpy, Armells, and Rosebud Creeks. West of Armells Creek the Yellowstone meanders along the north side of its flood plain and

[6] Rogers, G. S., and Lee, Wallace, op. cit., pp. 44–47, 1928.

Exhibit 31

has a border of alluvium averaging 1½ miles wide. Hay and Reservation Creeks cross its flood plain and enter the river near Finch and Howard post offices, respectively. Reservation Creek is about 16 miles long and contains little water during the dry months. East of Armells Creek the Yellowstone flows near the south side of its flood plain, and has undercut its banks and obliterated nearly all of its flood plain along that side except a tract nearly a mile wide on which the town of Forsyth stands. Armells Creek is about 12 miles long and forks in sec. 21, T. 4 N., R. 40 E. Its West Fork extends southwestward about 18 miles and its East Fork southeastward about 16 miles and thence westward about 14 miles. The main creek and both forks contain flowing water the year round. Several short dry streams are tributary to Armells Creek; the largest is Cottonwood Creek, which drains eastward along the south line of T. 5 N., R. 39 E. In T. 2 N., R. 39 E., the larger tributaries of West Fork of Armells Creek are Trail and Donley Creeks, each about 7 miles long and having a north and a south fork. Sheep, Sevenmile, Corral, and Stocker Creeks are the larger tributaries of the East Fork of Armells Creek and except the flow from a few springs in their bottoms contain no water during the dry season. The western border of the field is drained by tributaries of Sarpy Creek. The East Fork of Sarpy Creek in this field is about 7 miles long and is a perennial stream. East Bear, East Beaver, and Horse Creeks, tributaries to Sarpy Creek in order from north to south, are not over 5 miles long and are usually dry. Rosebud Creek, which drains the southern part of the field, is a perennial stream. Its flood plain ranges in width from a few hundred feet to half a mile and locally is irrigated. The larger tributaries of Rosebud Creek from the west are, in order from north to south, Miller Coulee, Lee Coulee, Richard Coulee, Slough Grass Creek, Little Cottonwood Creek, Big Cottonwood Creek, and Lynch Coulee. Rye Grass Creek is the only notable stream which enters it from the east. Practically all these streams have shallow pools of water here and there along their courses in the dry season, and for short distances there may be a slight surface flow of water.

Many springs occur in the field, but water for domestic use and for stock is obtained chiefly from dug or drilled wells. Fair water in small amounts can be obtained from seepages in the terrace gravel along the Yellowstone River. No springs were observed in that part of the field where the Bearpaw shale is the surface formation. Good water issues from the sandstones near the base and at the top of the Lance formation in several places. The spring most used and most easily accessible is on the Yellowstone trail between Forsyth and

Exhibit 31

Armells Creek. This spring is protected by a concrete cover and furnishes a steady supply of drinking water. Another spring which yields satisfactory drinking water is on Sevenmile Creek near the southeast corner of sec. 1, T. 3 N., R. 40 E. The water issues from the base of the massive sandstone at the top of the Lance formation and is the supply used by stockmen and sheep herders for miles around. Springs can also be found in most of the deep and narrow coulees in the middle of the Lance formation, but the water in some of them is highly mineralized. No springs were observed in the Lebo shale anywhere in the field, and sandstones, which might yield water, are usually absent from the Lebo or if present are extremely lenticular and discontinuous.

Springs issue from nearly all the coal beds in the upper part of the Fort Union. This is especially true of the Rosebud bed where it crops out in bottoms of streams. The quantity of water supplied by such springs differs greatly. In some places there may be only enough water to make small pools in the bed of the stream; in others, as along the outcrop of the Rosebud bed in T. 2 N., R. 39 E., and in Miller Coulee, T. 1 N., R. 41 E., a number of springs may contribute enough water to make a small but steady flow even during the summer. Several drilled wells have obtained an abundant supply of water from the sandstones overlying the Rosebud coal bed. One of the best of these wells is at the Hafer place in sec. 12, T. 1 N., R. 41 E. The ground-water resources in the part of this field in Rosebud County have been discussed by Renick,[7] and the ground-water conditions in Treasure and Big Horn Counties were studied by Hall.[8]

Railroads, settlements, and roads.—The Northern Pacific Railway follows the south bank of the Yellowstone River across the northern edge of the field, and a branch line 30 miles long has been constructed up Armells Creek and its East Fork to Colstrip, a coal-mining camp of about 100 people in sec. 34, T. 2 N., R. 41 E. The Chicago, Milwaukee, St. Paul & Pacific Railway follows the north bank of the Yellowstone as far west as Forsyth where it swings northwestward and crosses over into the basin of Musselshell River. The projected North & South Railway will follow the valley of Tongue River east of this field and will connect with the Northern Pacific and Chicago,

[7] Renick, B. C., Base exchange in ground water by silicates as illustrated in Montana: U. S. Geol. Survey Water-Supply Paper 520, pp. 53–72, 1924; Some geochemical relations of ground water and associated natural gas in the Lance formation: Jour. Geology, vol. 32, pp. 668–684, 1924. Renick, B. Exhibit 31

Milwaukee, St. Paul & Pacific railways at Miles City, and with the Chicago, Burlington & Quincy Railroad at Sheridan, Wyo.

Forsyth, the county seat of Rosebud County, with a population of about 1,850, is the largest town in the field and is the chief shipping and trading center. The small stations, Howard and Finch, west of Forsyth on the Northern Pacific Railway, serve as shipping points for cattle and farm products.

The Yellowstone Trail crosses the central part of T. 6 N., R. 41 E., on the gravel bench and descends to the flood plain of the Yellowstone River at Forsyth. West of Forsyth it roughly parallels the Northern Pacific Railway to the western limit of the field. The Electric Trail, which follows approximately the Chicago, Milwaukee, St. Paul & Pacific Railway, starts at Forsyth and leads northwestward to Vananda, Ingomar, Sumatra, Roundup, and other towns in the Musselshell Valley. A graded county road follows Armells Creek and its West Fork to the northwest corner of T. 1 N., R. 40 E., where it connects with ungraded roads traversing the central part of the field. A graded road follows the East Fork of Armells Creek to Colstrip and leads thence to the Hafer ranch in sec. 12, T. 1 N., R. 41 E., from which two graded roads lead to Rosebud Creek. The graded road between Forsyth and points along Rosebud Creek and the Tongue River leaves the Yellowstone Trail 4½ miles east of Forsyth and runs southeastward into the valley of Rosebud Creek.

The road following Rosebud Creek in this field leads southwestward to Lame Deer, Busby, and Sheridan. On the geologic map are shown practically all the roads in the field. (See pl. 7.) These roads can be traversed by automobiles, though driving may be difficult in places where the roads cross the drainage lines at right angles.

Sarpy post office, in sec. 36, T. 1 N., R. 38 E., receives mail twice a week from Hysham on the Northern Pacific Railway about 12 miles west of this field. All other post offices in the Forsyth field not on the railroad receive their mail by stage from Forsyth.

GEOLOGY

The Forsyth field contains exposed rocks of Upper Cretaceous, Tertiary, and Quaternary ages, comprising the Judith River formation, Bearpaw shale, Lance and Fort Union formations, Oligocene or Miocene (?) terrace gravel, terrace gravel of Pleistocene age, and Recent alluvium. Exposures of the rocks are good throughout the field, and it was possible to obtain many detailed stratigraphic sections, some of which are given in the following pages. The pub-

Exhibit 31

lished sections were selected with the purpose of showing in detail the character of all the rocks in the field above the Bearpaw shale.

Geological section in the Forsyth coal field

System and series	Group and formation	Character	Thickness (feet)
Quaternary.		Recent alluvium and Pleistocene terrace gravel.	0-50
Tertiary (Oligocene or Miocene series).		Terrace gravel cemented into a conglomerate; largely made up of andesitic porphyry. Crops out 1,000 to 1,100 feet above Yellowstone River.	60
Tertiary (Eocene series).	Fort Union formation.	Tongue River member. Prevailingly light-colored sandstone and sandy shale; several of the sandstones thick and massive and weathered into many varied shapes; contains several thick coal beds which have burned along their outcrops and have fused the overlying rock into a slag or clinker.	1,686
		Lebo shale member. Soft incoherent dark gray to black shale, clay, and sandy shale with abundant ferruginous concretions; weathers into gentle treeless slopes and diminutive badlands. Big Dirty coal bed at base.	105-170
Tertiary (Eocene ? series).	Lance formation.	Tullock member. Light-yellow calcareous sandstone and sandy shale closely resembling the strata of the Tongue River member of the Fort Union; sandstones well stratified and rarely massive; usually crops out in a prominent escarpment; contains many thin coal beds, few of which are burned.	240-270
		Hell Creek member. Massive, thick sandstones in the lower part grading upward into greenish-gray and grayish-yellow sandy shale and clay; contains no workable coal in the Forsyth field. Basal sandstone may correspond to the Colgate sandstone member of the Fox Hills sandstone of eastern Montana.	660-675
Cretaceous (Upper Cretaceous series).	Montana group. Bearpaw shale.	Dark-gray fissile marine shale with abundant fossiliferous calcareous concretions. Transition zone, 40 to 60 feet thick, at top may correspond to lower part of Fox Hills sandstone of eastern Montana.	1,000±
	Montana group. Judith River formation.	Upper member composed of grayish-white massive sandstone succeeded below by brown marine shale. Not all of formation exposed in this field.	95+

CRETACEOUS SYSTEM

MONTANA GROUP

Judith River formation.—The rocks of the Judith River formation are the oldest rocks exposed in the Forsyth field and were brought to the surface by the Porcupine uplift. They crop out in the bluffs about a quarter of a mile south of the Northern Pacific Railway between Reservation Creek and the western limit of the field. The

Exhibit 31

top of the formation consists of a very hard, heavily bedded, grayish-white sandstone about 20 feet thick, which makes a prominent bench protruding through terrace gravel. (See pl. 2, *A*.) Its marine origin is shown by the fairly abundant but rather fragmentary remains of *Baculites* and other marine invertebrates. Beneath this sandstone there is 75 feet of brown sandy shale exposed at irregular intervals in the gravel-covered slopes above the level of the alluvium. No fossils were found in the shaly part of the formation.

Bearpaw shale.—Here as elsewhere throughout its outcrop in eastern Montana the Bearpaw is made up almost entirely of dark-gray fissile marine shale containing an abundance of light-brown calcareous concretions. These concretions are rounded and of various sizes, and some contain numerous marine invertebrate fossils of many kinds. At the top of the Bearpaw is a transition zone of thin-bedded sandstone and sandy shale, 40 to 60 feet thick, below the massive sandstones of the overlying Lance formation. This sandy zone represents the final stage of the last marine invasion in Montana and may be of the same age as the lower part of the marine Fox Hills sandstone of the Dakotas.

The Bearpaw, like the Judith River, has been brought to the surface in the northwestern part of the field by the Porcupine uplift and dips about 3° S. It crops out in low rounded hills covered by a mantle of terrace gravel, so that good exposures of the shale occur only in the stream valleys. No direct measurements of its thickness can be made in this field. Measurements made by the writer in the steep bluffs of the Musselshell River in western Garfield County showed that its average thickness for this general region is about 950 feet.

TERTIARY (?) SYSTEM

LANCE FORMATION

In the Forsyth field the lithologic difference between the upper and lower parts of the Lance formation warrants the separation of the formation as mapped into the Hell Creek[9] and Tullock[10] members.

In the opinion of the writer it is probable that more refined study of the lower part of the Hell Creek member would demonstrate the equivalence of its massive basal sandstone as here mapped with the upper or Colgate sandstone member of the Fox Hills sandstone of eastern Montana[9] and would lead to its combination with the sandy

[9] Thom, W. T., jr., and Dobbin, C. E., Stratigraphy of the Cretaceous-Eocene transition beds in eastern Montana: Geol. Soc. America Bull., vol. 35, pp. 481–506, 1924.

[10] Rogers, G. S., and Lee, Wallace, Geology of the Tullock Creek coal field, Rosebud and Big Horn Counties, Mont.: U. S. Geol. Survey Bull. 749, 1923.

Exhibit 31

strata which are here provisionally included in the upper part of the Bearpaw, but which, it is thought, correspond to the lower part of the Fox Hills. The most striking differences between the Hell Creek and Tullock members of the Lance in this field are the contrast in their topographic expression and the absence of coal in the Hell Creek member. Further details regarding their lithologic differences are given below.

HELL CREEK MEMBER

The Hell Creek member of the Lance formation as here mapped rests conformably on the sandy transition zone at the top of the Bearpaw shale, and no hard and fast line can be drawn between them. The basal part of the member is made up of grayish-brown cross-bedded sandstone, probably corresponding to the Colgate sandstone member of the Fox Hills sandstone of eastern Montana, and crops out west of Armells Creek in a pine-clad escarpment south of the rolling, treeless areas of Bearpaw shale. Sandstones slightly higher in the member crop out along the Yellowstone Trail between Armells Creek and Forsyth, and some are more than 50 feet thick.

Although the Hell Creek member in this field does not contain very great thicknesses of somber-colored clay and shale, such as are characteristic of the member at its type locality on Hell Creek, northern Garfield County, yet by far the greater part of the shale has a greenish-yellow tint that is decidedly different from the more yellow sandy shale of the Tullock member. The top of the member was consistently drawn at the base of the Wright coal bed, which is a persistent bed, though in many places it may be less than a foot thick or may consist entirely of carbonaceous shale.

The areas where the Hell Creek member crops out are, unless modified by terrace gravel, very rough and in many places almost inaccessible even to saddle horses. Badlands in the Hell Creek member occur on Armells Creek up to its forks and on Smith and Reservation Creeks. Throughout the field the lower 450 feet of the member is made up chiefly of gray and brown sandstone with alternating beds of very light gray and greenish-yellow shale. The sandstones are commonly as much as 50 feet thick, and many of them are cross-bedded and full of clay balls. One sandstone contained clay balls as much as 9 inches in diameter. Most of the thick beds have a brown sandstone cap rock which is much harder than the lower part of the bed and projects as a shelf. The action of the wind on the softer material beneath the cap rock has produced many fantastic erosion forms. The presence of cross-bedded conglomerate layers, some of which contain pebbles an inch or more in diameter, and the lack of distinctive bedding planes in the lower part of the member suggest that the rocks are of fluviatile origin and were deposited in stronger currents

Exhibit 31

than those flowing when the upper part of the member was laid down. The lenticularity of the massive sandstones in the lower part of the Hell Creek is very striking here as elsewhere in Montana where the member crops out. A sandstone may persist for several miles as a rather prominent ledge and be replaced by sandy shale within a few hundred feet.

The upper 175 feet of the Hell Creek member is made up almost invariably of light-colored sandy shale containing lenses of gray and brown ledge-making concretionary sandstone. Locally on Armells Creek the upper part of the Hell Creek member is made up of typical "somber beds" containing ferruginous concretionary layers and soft, incoherent cross-bedded sandstone. In these places the contrast in color and composition between the Hell Creek and Tullock members is very striking. In most places, however, the one grades insensibly into the other, and were the Wright coal bed absent there would be no definite horizon to mark their limits.

In the railroad cut at the mouth of Armells Creek the basal sandstone of the Hell Creek member contains thin partings of plant-bearing clay at a horizon probably not more than 50 feet above the Bearpaw. The material is very soft, friable sandy shale and clay and contains no perfect leaves. The following determinations of fragmentary material from this horizon were made by F. H. Knowlton:

7656. From sec. 23, T. 6 N., R. 39 E.:
Populus sp.
Zizyphus? sp.
Populus cuneata Newberry.
Fragments of several dicotyledons.

The *Populus* identified with a fair degree of certainty is a Fort Union species, according to Knowlton.

The following section measured from the mouth of Armells Creek, in sec. 23, T. 6 N., R. 39 E., eastward along the Yellowstone Trail to Smith Creek, thence southward up Smith Creek to sec. 12, T. 5 N., R. 40 E., illustrates the nature of the Hell Creek member of the Lance formation in the Forsyth field:

Interval to Bearpaw shale about 50 feet.	636+

TULLOCK MEMBER

The Tullock member of the Lance formation is made up of light-colored sandstone, sandy shale, and several thin but fairly persistent coal beds. The base of the member is drawn at the base of the Wright coal bed and its top at the base of the Big Dirty coal bed. Its thickness is fairly uniform throughout the field and ranges from 240 to 270 feet. Along Armells and Smith Creeks the Tullock crops out in a steep escarpment (see pl. 2, *B*), which in some places may be obscured by a mantle of river gravel. The top of the Tullock is marked by a very resistant calcareous sandstone rim rock 2 to 15 feet thick, which may be underlain by either a much softer sandstone or a sandy shale. The sandstone rim rock is overlain by the Lebo shale, which crops out in gentle slopes slightly back of the edge of the Tullock escarpment, producing a striking physiographic contrast. The sandstones of the Tullock are light yellow, evenly bedded, calcareous, and rarely massive, unlike the sandstones of the Tongue River member of the Fort Union formation.

Only two coal beds were mapped in the Tullock—the Wright bed at its base and the Hamre bed about 35 feet below its top. These beds, in common with all other coal beds in the Tullock member, are usually persistent but only locally contain coal. Several sections measured on the west side of Armells Creek and the east side of Reservation Creek failed to show any coal more than a foot thick in the member.

TERTIARY SYSTEM

FORT UNION FORMATION

The Fort Union formation in the Forsyth field is readily separable on lithologic grounds into two members, a lower one, the Lebo shale, and an upper one, consisting of yellow sandstone, sandy shale, and coal beds, called the Tongue River member.

LEBO SHALE MEMBER

The Lebo shale member of the Fort Union formation is made up of dark-gray to black clay and shale, largely of volcanic origin. By its somber aspect it is readily distinguished from the underlying Tullock member of the Lance formation and the overlying Tongue River member of the Fort Union. (See pl. 3, *A*.) It contains beds of soft, gray cross-bedded sandstone, some of which may be as much as 10 feet thick, but none are persistent for more than a few hundred feet. Ironstone concretions occur in the Lebo in great numbers and usually collect in piles where they have been washed out of small bare buttes or slopes. Some of the ferruginous concretionary layers are not more than 6 inches thick and are fairly persistent horizon markers.

The base of the Lebo is drawn at the base of the Big Dirty coal bed, which rests directly on the rim rock making the top of the Tullock member of the Lance formation. The top of the member is drawn at the point where there is a change from somber-colored clay to yellow sandstone and sandy shale. The thickness of the Lebo ranges from 105 to 170 feet and is least in the western part of the field.

Because of its infertile character the Lebo supports only a little vegetation, chiefly sagebrush. On the divides the Lebo forms a broad zone of rolling, treeless country between the escarpment-forming sandstones of the Tullock member of the Lance and the Tongue River member of the Fort Union. In the stream valleys,

Exhibit 31

however, because of its softness and thinness, it erodes readily into a narrow zone of badlands most intricately dissected and almost worthless for any use. Representative sections of the Lebo in the Forsyth field are given below.

TONGUE RIVER MEMBER

The Lebo shale grades upward through a transition zone of sandy shale into a group of beds of light-colored sandstone, sandy shale, carbonaceous shale, and coal, which constitute the Tongue River member of the Fort Union formation. There is 1,686 feet of the member in the Forsyth field, included between the top of the Lebo shale and the clinker that makes the cap rock on Wolf Mountain. The rocks in this member are much more resistant than the Lebo clays and usually crop out in steep bluffs above Lebo lowlands or badlands. The lower 125 feet contains no workable coal. The succeeding 600 feet, however, contains eight coal beds ranging in thickness from 3 to 30 feet. These beds constitute the principal coal deposits of the field. The thick coal beds in this interval have burned along their outcrops and baked the overlying strata to various shades of red and brown. The slag or clinker thus formed is a distinctive feature of this part of the section, not only in the Forsyth field but elsewhere in Montana, and serves to distinguish the coals from those of the Tullock member, which occur in strata similar in color and lithology but are rarely burned. The clinker is much more resistant than the underlying rocks, and where it has been cut through by narrow stream gorges it makes a protective cap rock above steep and bare slopes. Where a thick coal bed has been burned over a considerable area remnants of its clinker form the summits of the divides, which may be less than half a mile wide and more than 5 miles long.

Exhibit 31

On the accompanying map (pl. 7) the areas thus covered by clinker are designated by a special pattern. The principal use for clinker at the present time is for road metal or railroad ballast.

The most prominent sandstone in the Tongue River member is that which commonly occurs above the Rosebud coal bed. (See pl. 5, *A*.) In places this sandstone is 150 feet thick and crops out as a persistent and easily recognized ledge at the base of a yellow bluff of softer sandstone and shale. It is especially well developed near Castle Rock, in Miller Coulee, and along Rosebud Creek and its tributaries. In the Rosebud Creek area it is split into two benches separated by the Lee coal bed. It is grayish-yellow, fine grained, usually massive, and arkosic. Castle Rock, in sec. 31, T. 2 N., R. 40 E., is an outlier of this sandstone about 60 feet high. Other similar but larger outliers of this sandstone occur in Richard Coulee, in T. 1 S., R. 41 E.

The Sawyer coal bed, which occurs about 725 feet above the base of the member, is the uppermost of the thick coal beds of considerable economic value in the section. Above the Sawyer bed is about 1,000 feet of sandstone, sandy shale, and thin but persistent coal beds. In the Wolf Mountain area (see p. 43) the sandstone and sandy shale are normally yellow. The sandstones, however, are usually well bedded, in contrast to those in the lower part of the member. Somber-colored clay occurs in many places in the Wolf Mountain section but nowhere through an interval greater than 30 feet.

The following fossils from the Tongue River member are Fort Union forms, according to F. H. Knowlton:

7657. From a sandstone above the Proctor coal bed, sec. 18, T. 1 N., R. 40 E.:

OLIGOCENE OR MIOCENE (?) GRAVEL

The oldest gravel deposit in the field caps a plateau on the divide between Armells and Sarpy Creeks in the northwest corner of T. 3 N. and the southwest corner of T. 4 N., R. 39 E. (See pl. 7.)

Exhibit 31

Gravel occurs at the same level on the tops of the highest hills and ridges in the northern part of T. 4 N., R. 41 E. These gravel deposits are small remnants of a much larger river terrace and stand 1,050 to 1,100 feet above Yellowstone River. The gravel, which is 60 feet thick, is thoroughly cemented at the base into a conglomerate. The deposit contains boulders a foot or more in thickness and consists of igneous rocks ranging in composition from granite to basalt, particularly andesitic porphyries. Agate, silicified wood, and fragments of coal clinker occur in it, indicating that at least some of the coal has been burned along its outcrop before the gravel was deposited.

This gravel terrace is equivalent to similar terraces in the Tullock Creek field described by Rogers,[11] which stand 1,100 feet above the Yellowstone. In the area south of Huntley deposits of gravel and conglomerate make prominent plateaus at an altitude of 3,900 to 4,000 feet, or about 1,000 feet above the Yellowstone River, and are probably equivalent to the deposits just described.[12] On the divide between the Yellowstone and the Missouri, north of Terry, remnants of a gravel terrace 1,200 feet or more above the Yellowstone probably represents this same level.

According to Alden[13] the amount of cutting by Yellowstone River since these gravel deposits were laid down and a study of relative altitudes suggest that they are to be correlated either with the gravel capping the Cypress Hills in Canada, which McConnell[14] and Lambe[15] determined by fossils to be of Oligocene age, or with the Flaxville gravel, of Miocene or Pliocene age, in northeastern Montana.[16]

The northern edge of the Oligocene or Miocene (?) gravel deposits is about 12 miles south of the terrace along the Yellowstone River, and the vertical interval between them is 900 to 1,000 feet. The area intervening between the Oligocene (?) gravel deposits and the well-defined terraces bordering the Yellowstone is covered with a mantle of gravel which is not arranged in any well-defined system

Exhibit 31

of terraces and has been reworked so many times that its relations are obscured. A small remnant of a terrace with gravel locally cemented to a conglomerate 10 feet thick, in the central part of T. 5 N., R. 41 E., stands 700 feet above the river. If the higher gravel corresponds to that on the Cypress Hills, this may correspond to the Flaxville gravel, of late Tertiary age.

QUATERNARY SYSTEM

PLEISTOCENE DEPOSITS

A broad and well-defined terrace borders the Yellowstone River on the south about 200 feet above the river flood plain. The gravel capping this terrace consists of smoothly rounded unconsolidated pebbles of many kinds of igneous rock, quartz, jasper, and limestone and is undoubtedly of Pleistocene age. This terrace is well preserved at somewhat varying heights above the Yellowstone throughout much of the river's course in eastern Montana. Farther west it extends for several miles up the southern tributaries of the river and is especially well developed on the Big Horn River and Fly and Pryor Creeks in the Huntley field.[17]

RECENT ALLUVIUM

The fine sand, silt, and gravel now being deposited in the flood plain of the Yellowstone River and its tributaries constitute the most recent deposit in the Forsyth field. It ranges in thickness from a few feet to about 40 feet and underlies some of the best agricultural land in the field. This land is irrigated and produces large crops of sugar beets and alfalfa. (See pl. 7.) The flood plains of the larger tributaries of the Yellowstone range from half a mile in width near their mouths to a few hundred feet near their sources, and all of them are cut up into small areas by the meandering of the streams.

STRUCTURE

The Forsyth field lies in a broad, shallow syncline or structural trough pitching gently southeastward, which connects the Powder River Basin and the structural depression of the Bull Mountains. The axis of this syncline in the Forsyth field follows closely a line drawn between Castle Rock and the northeast corner of T. 1 S., R. 41 E., and separates the Big Horn and Porcupine uplifts on the west and north, respectively. The strongest dips in the field occur in its northwest corner, where the rocks are affected by the Porcupine uplift. The sandstone member of the Judith River formation, which

[17] Rogers, G. S., and Lee, Wallace, op. cit. Hancock, E. T., op. cit.

Exhibit 31

is the lowest formation brought to the surface by the uplift, dips 3° SE. in this area. Dips of like amount were observed on concretionary layers in the Bearpaw shale. The basal sandstone of the Lance crops out in a prominent escarpment striking about east and dipping 2°–3° S. South of the escarpment, however, the rocks flatten out appreciably and over large areas have a normal southeasterly inclination of less than 1°. The western limb of the sandstone member of the Judith River dips beneath the alluvium of the Yellowstone River at an angle of about 2° a few miles upstream from the western limit of the field.

Within the major structural depression between the Big Horn and Porcupine uplifts the rocks are gently folded into several small anticlinal and synclinal folds. Nearly all the dips are less than 1° and they are determined only by noting the altitudes of coal beds and the distribution of their outcrops. Two gentle anticlines belonging to the Porcupine dome system of uplifts cross the area approximately parallel to the axis of the major syncline. One of these anticlines follows a line drawn between the northwest corner of sec. 2, T. 1 S., R. 41 E., and the southeast corner of sec. 11, T. 3 N., R. 39 E. Gentle doming, which has affected the position of the outcrop of coal beds, occurs along the axis of this fold near the SW. ¼ sec. 29, T. 1 N., R. 41 E., sec. 12, T. 1 N., R. 40 E., and sec. 11, T. 3 N., R. 39 E. West of the line of folding the rocks dip gently into the axis of the major syncline, west of which they rise uniformly westward at an angle less than 1°. Another line of folding, modified by a fault zone, also crosses the field in a northwesterly direction from the northwest corner of T. 2 N., R. 41 E. Several small normal faults, having maximum throws of about 60 feet, occur near the axis of this uplift along the boundary between T. 3 N., R. 40 E. and T. 3 N., R. 41 E. Further details regarding the structure are included in the township descriptions.

ECONOMIC GEOLOGY

COAL

GENERAL SECTION

The coal in the Forsyth field occurs in the Tullock member of the Lance formation and in the Lebo shale and Tongue River members of the Fort Union formation. The strata are nearly horizontal, and the coal beds crop out in regular order one above another from the vicinity of Forsyth southward to the top of Wolf Mountain. The coals of the Tullock member though persistent are generally too thin and dirty to be of much economic importance in this area, which contains a number of thicker beds near by.

Exhibit 31

Only one coal bed, the Big Dirty bed, was mapped in the Lebo shale member of the Fort Union. The Big Dirty bed, as its name implies, is usually dirty and consists of carbonaceous shale, carbonaceous sandstone, bone, and thin stringers of coal. Locally, as described below, it contains as much as 11 feet of apparently clean coal, though it is suspected that an analysis of this coal would show a high ash content. The Lebo member contains several carbonaceous zones above the Big Dirty bed, but the layers of coal in them are only an inch or two thick and alternate with much thicker beds of shale.

The principal coal reserves in the field occur in the Tongue River member of the Fort Union formation. There are eight coal beds, ranging from 3 to 30 feet in thickness, in the lower 725 feet of this member, and these will best repay attention by persons interested in the exploitation of the coal. The upper 1,000 feet of the Tongue River member contains four coal beds of extremely irregular thickness. These beds all crop out in the rough, timbered country at the foot and in the slopes of Wolf Mountain and at present are valuable only as sources of domestic fuel for individual homesteaders living near by.

The stratigraphic position of the coal beds in the Forsyth field and their relations to the coals of the Tullock Creek field are shown graphically in Plate 8. The following brief summary gives the names of the principal coal beds and the average intervals between them:

Some of the beds listed above contain workable coal in parts of their extent in the Forsyth field, and the distribution of the tracts containing valuable coal reserves is outlined in the following descriptions of the several beds.

THE COAL BEDS

The coal beds in the Forsyth field were mapped by stadia traverses tied to land corners. The outcrop lines of practically all accessible coal beds of workable thickness and quality as thus determined are shown on Plate 7. The numbers along the outcrop lines indicate the locations where the coal beds were measured and refer to Plate 10 where the measurements are represented graphically. A more detailed description of the character of the coal beds than that given below will be found in the township descriptions.

COALS OF THE TULLOCK MEMBER OF LANCE FORMATION

Wright bed.—The Wright bed, at the base of the Tullock member of the Lance formation, is the lowest coal in the Forsyth field. Because of its stratigraphic position it crops out nearer the Yellowstone Valley than any of the overlying coals and has been mined for a number of years to supply local demand in Forsyth. In several mines in the basins of Smith and Armells Creeks and vicinity it ranges from 3 to 4 feet in thickness. (See pls. 7 and 10.) This bed crops out in the rough country at the base of the bluffs on the east side of Armells Creek and extends about 2 miles up the forks of the creek before it passes beneath the stream level. Along Armells

Exhibit 31

Creek it ranges from a foot or less to 3 feet in thickness and at many points occurs in two benches about 26 feet apart. (See pl. 10, locations 22, 23, 24, 25.) On the west side of Armells Creek below its forks and along Reservation Creek the Wright bed is persistently present but nowhere was observed to contain more than a foot of coal.

Hamre bed.—The Hamre bed occurs at an average interval of 200 feet above the Wright bed and crops out at the base of the heavy sandstone which makes the rim rock at the top of the Tullock member. It averages 3 feet in thickness and for the most part is made up of carbonaceous shale and coal, interbedded with which are innumerable thin stringers of carbonaceous sandstone. On the east side of Armells Creek, in T. 5 N., R. 40 E., it contained locally as much as 3 feet of coal in its basal part, and its outcrop was mapped for a little more than 3 miles. (See pl. 10, secs. 7–13.) The Hamre bed was recognized at many other places in the northwestern part of the field, but because of its generally worthless character it was not mapped.

In the interval between the Wright and Hamre beds there are several thin beds of coal which in places may attain a maximum thickness of 2 or 3 feet on their outcrops. They are, however, very narrow lenses, and because of their uneven thickness they were not mapped.

COALS OF THE LEBO SHALE MEMBER OF FORT UNION FORMATION

Big Dirty bed.—The Big Dirty bed, which lies at the base of the Lebo shale member of the Fort Union formation and 35 feet above the Hamre bed, ranges from 3 to 13 feet in thickness and usually consists of carbonaceous shale, carbonaceous sandstone, and thin lenticular beds of coal. (See pl. 10.) Locally where it is more than 6 feet thick its lower part may contain as much as 3 feet of coal. The only place in the field where the Big Dirty bed was observed to contain coal of workable thickness and quality was along the boundary between T. 3 N., R. 40 E., and T. 3 N., R. 41 E., and along the East Fork of Armells Creek near by, where it contains from 6 to 11 feet of what is apparently a fair grade of coal. (See pl. 10, secs. 76, 77, 79, etc.) Along the tributaries of the West Fork of Armells Creek in T. 3 N., Rs. 39 and 40 E., the Big Dirty bed locally contains 3 feet of coal in its lower part overlain by 7 feet of carbonaceous shale and thin beds of coal some of which attain in places a thickness of 3 feet or more. (See pl. 10, secs. 46, 47, 70, 71.)

As previously stated, thin layers of coal associated with beds of carbonaceous shale occur elsewhere in the Lebo member within the Forsyth field, but they are of no value and will not be described.

Exhibit 31

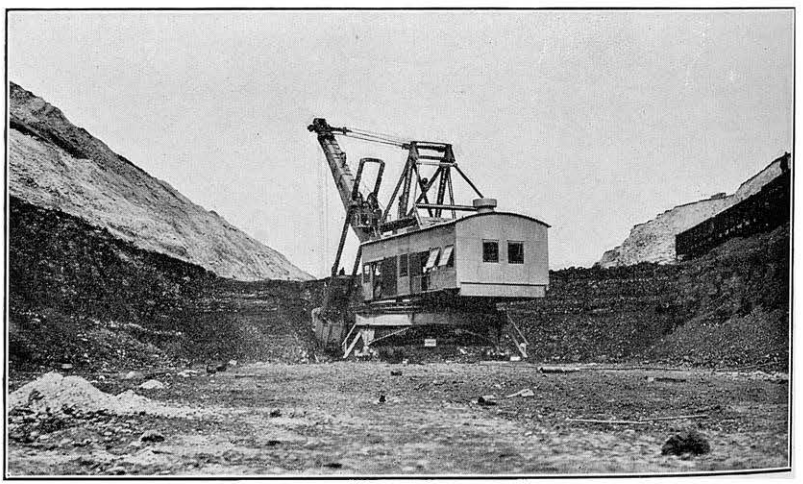
A



B

STRIP PIT OF THE NORTHWESTERN IMPROVEMENT CO. AT COLSTRIP, MONT.

Exhibit 31

COALS OF THE TONGUE RIVER MEMBER OF FORT UNION FORMATION

Burley bed.—The Burley bed, 130 feet above the base of the Tongue River member of the Fort Union, is the lowest of the valuable coals in the field. It is extensively burned in the vicinity of the Burley ranch, in the SE. ¼ sec. 24, T. 3 N., R. 41 E., where it contains about 5 feet of coal. (See pl. 10, locations 83–85.) Measurements of this bed along the West Fork of Armells Creek in T. 2 N., Rs. 38 and 39 E. (pl. 10, secs. 41, 119, 120), showed that its average thickness for that area is about 3 feet.

Robinson bed.—In the Armells Creek area the Robinson bed occurs 43 feet above the Burley bed, and its outcrops can be traced almost continuously across the field. East of the East Fork of Armells Creek, in T. 2 N., R. 41 E., it ranges from 2½ to 4½ feet in thickness. (See pl. 10, secs. 148, 149.) In the valleys of the West Fork of Armells Creek and its tributaries, in T. 2 N., R. 39 E., it attains a maximum thickness of about 8 feet. (See pl. 10, sec. 114.) On the east side of the Sarpy Creek-Tullock Creek divide, in T. 3 N., R. 39 E., it maintains an average thickness of 5 feet and is correlated with bed M of the Tullock Creek coal field.[18] (See pl. 10, secs. 52–58.)

Stocker Creek bed.—The Stocker Creek bed lies 130 feet above the Robinson bed and crops out in that part of the field northwest of the northwest corner of T. 1 N., R. 41 E. Measurements of this bed along Stocker Creek and on tributaries of the West Fork of Armells Creek, in T. 2 N., R. 40 E., showed its average thickness to be about 6 feet. (See pl. 10, secs. 123–128.) The maximum thickness of the bed observed in the field was 9 feet in the SW. ¼ sec. 15, T. 2 N., R. 38 E. (See pl. 10, sec. 97.)

McKay bed.—Throughout a large part of this field the McKay bed may be considered a split of the Rosebud bed, for many measurements showed that the interval between them in several places is less than 7 feet. (See pl. 10, secs. 221, 222.) The maximum observed interval between the Rosebud and McKay beds in the field is 30 feet at location 95, in the NE. ¼ sec. 3, T. 2 N., R. 38 E.

Rosebud bed.—The Rosebud bed, about 360 feet above the base of the Tongue River member of the Fort Union, is the most valuable coal bed in the Forsyth field and is exploited by the Northwestern Improvement Co. at Colstrip. Although outcrops of the bed are rare, its position where unexposed can be determined very closely by tracing the contact of the heavy and conspicuous slag formed by the burning of the bed with the unburned overburden, it being assumed that burning of the bed has not taken place through more than a few

[18] Rogers, G. S., and Lee, Wallace, Geology of the Tullock Creek coal field, Montana: U. S. Geol. Survey Bull. 749, pp. 75, 76, 1923.

Exhibit 31

hundred feet beyond the point where the clinker abuts against unbaked rock.

North of the divide between Rosebud Creek and the East Fork of Armells Creek, the Rosebud bed maintains an average thickness of about 20 feet, as estimated from measurements of part of the bed and thicknesses reported from drill holes. The maximum observed thickness for this part of the field was 23 feet at location 102, in the SW.¼ sec. 35, T. 2 N., R. 39 E. (See pl. 10.) The best exposures of the Rosebud bed occur in small tributaries of Miller Coulee in the southeastern part of T. 1 N., R. 41 E. (pls. 5, *B*; 6, *B*), where it crops out in cut banks at locations 221 and 222 and has clean exposures of about 28 feet of coal. (See pl. 10.) The lack of exposures along Rosebud Creek prevented the detailed mapping of the Rosebud bed in that area though a number of measurements of part of the bed were made. Observations in Lee Coulee, in Tps. 1 N. and 1 S., R. 41 E., suggest that the Rosebud bed in the general area of Rosebud Creek is replaced by sandstone and sandy shale in many places, and this condition would account for the small number of exposures of the bed.

Lee bed.—The Lee bed, which lies about 115 feet above the Rosebud bed, is not present in that part of the field north of the area drained by Rosebud Creek. Along Rosebud Creek it ranges from a thin trace up to 11 feet in thickness.

Popham bed.—The Popham bed, though it does not average more than 3 feet in thickness, is very persistent. It lies 50 feet below the Sawyer bed, or about 290 feet above the Rosebud bed. It was mapped in detail only in T. 1 N., R. 40 E.

Sawyer bed.—The Sawyer bed, 336 feet above the Rosebud bed, has been burned out over a large area, and its slag now makes a resistant cap rock on the divides along the main drainage lines. It is unburned in the rough and inaccessible country along the foothills of Wolf Mountain and ranges from a thin trace to 20 feet in thickness. It is replaced by carbonaceous shale northwest of T. 1 N., R. 40 E.

Proctor bed.—The Proctor bed lies 90 feet above the Sawyer bed and was mapped only in the rough country at the base of Wolf Mountain in T. 1 N., R. 39 E., at locations 164 to 168, where its average thickness is slightly more than 3 feet. (See pl. 10.)

Richard bed.—The Richard bed crops out at the base of Wolf Mountain and was mapped for about 3 miles in the southeastern part of T. 1 N., R. 39 E. It contains an average of 3½ feet of coal but is of no economic value because of its general inaccessibility.

Exhibit 31

PHYSICAL AND CHEMICAL CHARACTER

The coal in the Forsyth field is of subbituminous rank, has a conchoidal fracture, and is shiny black on a freshly exposed surface. This coal, like that of the Sheridan field, slacks after a short exposure to weather. Owing to loss of moisture it becomes dull black, and a network of cracks, some of which are at right angles to each other, develops in it, so that the small pieces which fall off as the coal crumbles are roughly cubical.

Of the several samples taken in the field, the analyses of which are given below, that from the unweathered Rosebud bed at the Colstrip mine of the Northwestern Improvement Co. (No. 19659) most nearly represents the true character of the coals. The sample of the Wright bed (No. 96584), the lowest coal in the field, was taken 50 feet from the entry of the Wright mine, in sec. 7, T. 5 N., R. 40 E. This mine has been abandoned for a year or more, and the sample consequently consisted of weathered coal. The sample of the Sawyer bed (No. 96587) was taken from an open pit at location 206A in a coulee, where a face of coal about 75 feet long had been cut back by settlers a maximum distance of 25 feet. Care was taken to obtain as fresh coal as possible under these conditions, but it was slightly weathered. The sample of the Lee bed at the McKay mine (No. 96583) was cut from a face of coal 150 feet from the entry of a drift mine less than a week after the mine had been active for a short time. The thickness of the Lee bed at this mine is nearly 11 feet, but only the upper 6 feet is mined, and only that part was sampled. It should be remembered, therefore, in comparing the value of the coal in the Forsyth field with that of coals from other fields where fresh samples have been cut by standard methods in underground mines, that the analysis of the Rosebud bed is the only one truly representative of the Forsyth coals given in this report, the heating values of the other samples as shown in the table of analyses on page 30 and in Figure 1 being probably somewhat too low.

In the following table analyses of representative samples from Williston, N. Dak.; Glendive, Miles City, Red Lodge, Bear Creek, Bull Mountain (Roundup), and Sand Coulee, Mont.; Sheridan, Wyo.; Hocking Valley, Ohio; and Pittsburgh, Pa., are also given in order to afford a basis of comparison between the Forsyth coal and other coals with which it will have to compete in the market. These analyses are given in four forms: Form A represents the composition of the sample as it is received in the laboratory. The amount of moisture contained in a sample "as received" is proportional to the amount of moisture and water in the mine at the

Exhibit 31

several analyses of samples from the same bed may differ widely. Form B represents the composition of the sample after it has been air-dried under uniform conditions until its weight becomes constant. This form of analysis is best adapted for general comparisons. Form C shows the theoretical composition of the coal after all the moisture has been eliminated. Form D represents the composition of the coal as it would be if all the ash and moisture were removed. Forms C and D represent conditions that do not actually exist in nature.

The Lance coal (No. 96584) in the Forsyth field shows a high ash content. Its sulphur content, however, is no higher than that of the three Fort Union coals in the same area (Nos. 19659, 96583, and 96587). Its heating value is equal to that of the Sawyer bed (No. 96587), which showed a similar amount of weathering when sampled. The coal from the Rosebud bed (No. 19659) is the most representative of the several samples. A comparison of this sample with the average of 20 fresh samples from the Sheridan field shows that the Forsyth coal is slightly inferior in quality to the Sheridan coal. From the analyses given above Figure 1 has been prepared in order to give a rough means of comparison of the coals. This figure shows clearly that the coals of the Fort Union formation in North Dakota, Montana, and Wyoming rise in rank the nearer they approach the areas of mountainous uplift. This is seen on comparing the heating value of the Williston lignite, which lies in nearly flat undisturbed rocks, with that of the coal from the Sheridan field, which is nearer the Big Horn Mountains.

In Figure 1 the line marked "coal as mined" represents the heating value of the coal as it is received from the mine—that is, its heating value in approximately the condition in which it will be put on the market and consumed. The line marked "pure coal" shows the heating value of the coals after their ash and moisture have been theoretically eliminated. The line marked "coal as mined" shows the relative value of the coals to the consumer, and the coals rank in the order in which they stand in Figure 1, Williston lignite being the lowest grade of coal given and Pittsburgh bituminous the highest. Figure 1 shows that the unweathered samples of Forsyth coal are only slightly lower in rank than the

Exhibit 31

time the sample was taken, therefore the amount of moisture in fresh samples from the Sheridan field and that both are somewhat lower than the Red Lodge, Bear Creek, and Bull Mountain coals. From a study of these comparative values it can be concluded, therefore, that the coals with which the Forsyth field will have to compete are those from Sheridan and vicinity, Red Lodge, Bear Creek, the Bull Mountains, and Sand Coulee.

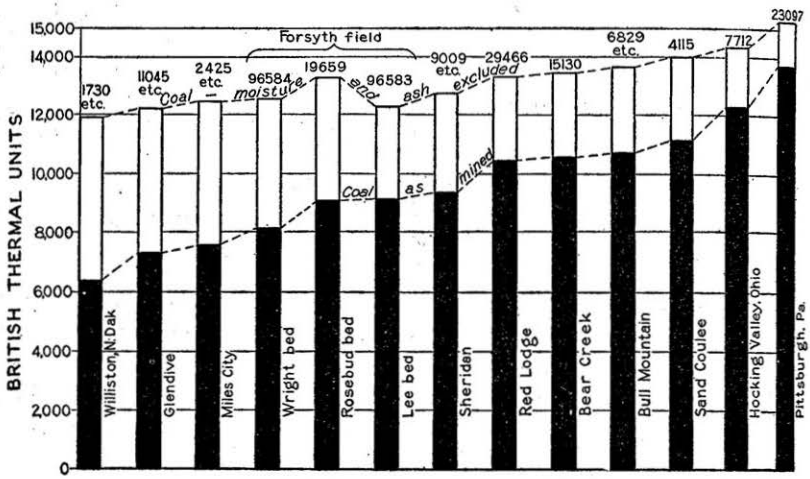

FIGURE 1.—Heating value of coals from Forsyth, Mont., and some other coals

COAL CLINKER

Where the rocks of the Tongue River member of the Fort Union formation crop out in the Forsyth field the clinker or "scoria" formed by the fusing and baking of clay, shale, and sandstone by a burning coal bed is very conspicuous. Because it offers greater resistance to erosion than the associated rocks the clinker usually occurs as a cap rock on buttes, ridges, and divides. The coal beds in the Tullock and Lebo members of the Lance and Fort Union formations, respectively, are burned in few places, and those that have been burned are only a few inches thick.

The burning of coal beds on the outcrop is probably due to spontaneous combustion or occasionally to fires set by man. Where a thick coal bed has burned slowly for a considerable period the slag thus formed may be 100 feet or more in thickness. The slag of the Sawyer bed, which is well exposed on the divide between the East Fork of Armells Creek and Rosebud Creek in the central part of T. 1 N., R. 41 E., and elsewhere in the southern part of the field, and that of the Rosebud bed in the Armells Creek area average about

Exhibit 31

50 feet in thickness. The Burley and Lee beds are clinkered extensively along their outcrops, and so are several thinner beds in the upper part of the Tongue River member of the Fort Union.

The amount of rock fused or baked by the burning of the coal depends upon the thickness of the coal bed and upon the proportion of lime in the rock. Where the cover is thick burning probably does not extend back more than 75 feet from the outcrop. If the coal bed lies flat and the cover is fairly thin the bed may burn over several square miles. Where two thick coal beds are separated by a small interval and both have burned to some extent the great quantity of clinker either in place or slumped down makes it impossible in some places to determine the amount of coal left unburned in the two beds, particularly in the lower bed. This is well illustrated in the Armells Creek area, where the McKay bed, which lies from 7 to 21 feet below the Rosebud bed and averages 7 feet in thickness, can not be mapped accurately because it is usually concealed by débris from the overlying Rosebud clinker.

The rapidity of the burning is determined by the supply of air. When heated to a kindling temperature the coal smolders until slumping takes place and crevices are formed along which air is admitted as through natural chimneys. The heat close to these vents becomes intense, and the overlying rocks are fused into a vesicular slag. Back from the outcrop and away from natural vents the burning becomes slower until a point is reached where no free oxygen is present and burning ceases.

The character of the clinker depends partly on the amount of heat to which the rock has been subjected, and partly on the amount of lime in the heated rock. Near the sources of air supply, or where the absence of lime renders the rocks readily fusible, their original texture has been destroyed and they are converted into a bright reddish-green or purple vesicular slag with flow structure. In the upper part of the slag the rocks have been merely baked to a brick-red color and retain their original texture. It is common to find perfectly preserved fossil plant impressions in the upper part of thick clinkers. Further details of the physical and chemical changes accompanying the formation of clinker are given in a paper by Rogers.[19]

DEVELOPMENT

At the time when the Forsyth field was examined development of the coals was restricted to its northern part, where several

[19] Rogers, G. S., Baked shale and slag formed by the burning of coal beds: U. S. Geol. Survey Prof. Paper 108, pp. 1–10, 1918.

Exhibit 31

small mines within 5 or 6 miles of Forsyth exploit the Wright bed to supply the local market. Several openings, referred to as the Lore mines, have been driven in on the Wright bed in secs. 1 and 2, T. 5 N., R. 41 E. The largest of these openings is about 200 feet long and comprises several rooms. The Wright mine, in sec. 7, T. 5 N., R. 40 E., was opened to supply Forsyth in times of coal shortage but is now abandoned. The Woodward and Griggs mines, on Smith Creek in sections 22 and 23, respectively, of the same township, are small entries from which coal is mined only part of the year. An attempt was made to mine the Hamre bed near the W. ½ sec. 29, T. 5 N., R. 40 E., but after an entry had been driven about 100 feet it was abandoned because of the poor quality of the coal.

The thick coal beds in the Tongue River member of the Fort Union formation have been used for years as a source of fuel by settlers. The usual procedure is for several settlers working together to obtain their winter's supply of coal by blasting it off from the face of one of the several well-known outcrops in the field. Practically all the prominent exposures of coal are in this way sources of domestic fuel, and for this reason they are discussed in detail only in the individual township descriptions. Several small timbered entries have been driven on the Lee bed on Rosebud Creek.

The completion of the Armells Creek branch of the Northern Pacific Railway has made accessible an enormous tonnage of subbituminous coal contained in the Rosebud and other coal beds. The coals are thick, persistent, and comparatively free from partings. Furthermore, a great quantity of this coal can be recovered by strip mining, and until this supply is exhausted there will probably be no attempts to mine the coal from underground diggings.

The Northwestern Improvement Co. is strip mining the Rosebud coal bed on a large scale at Colstrip, where the bed averages about 28 feet in thickness. The coal is mined in a completely electrified open pit, the power being supplied by the Montana Power Co., which extended its 55,000-volt 3-phase 60-cycle power line from Billings to Colstrip, a distance of 100 miles.

The pit was opened by a Marion model 360 electric stripper, with a 155-foot drag-line boom with 6-yard bucket and a 90-foot shovel boom with 6-yard bucket. The coal-loading shovel is a Bucyrus model 175–B, with a 75-foot boom and 7-yard bucket. Other electrical equipment in the pit consists of one gasoline drag-line 2½-yard bucket, with a 60-foot boom; one 20-ton locomotive crane, two 60-ton electric storage-battery locomotives, one electric well drill, and two portable-type air compressors. The coal is first blasted and then loaded directly into standard 50-ton steel coal cars,

Exhibit 31

which run on a track laid on top of the coal. The shovel loads a 50-ton car in about 6 minutes, or a 10-car train in approximately 1 hour. At the present time about 3,300 tons of coal are mined daily. The coal is used by the Northern Pacific Railway between Jamestown, N. Dak., and Missoula, Mont.

Excellent conditions for stripping the Rosebud bed exist on the low divide between the headwaters of the West Fork of Armells Creek and Stocker Creek, near Castle Rock, in Tps. 1 and 2 N., R. 40 E. A spur track about 9 miles long up the valley of Stocker Creek would make this area accessible. Further details of the mining conditions in the field are included in the several township descriptions.

Timber necessary for mining is abundant, especially in those areas where the Tongue River member of the Fort Union formation crops out. It is not believed that a water supply from artesian flows will be obtained where coal mining on a large scale is likely to be undertaken. Wells drilled to a depth of 600 to 1,400 feet below the Rosebud coal will undoubtedly encounter beds containing water, which will rise part way to the surface but will not flow. The water in the well 1,520 feet deep at Colstrip stands about 400 feet below the top of the casing. Flood waters impounded in reservoirs may be more satisfactory for use in boilers than well water, which may cause foaming.

Profitable strip mining of the Rosebud coal bed will depend upon the thickness and nature of the cover overlying the bed. For the Rosebud bed at Colstrip 100 feet has been arbitrarily considered to be the maximum thickness of overburden that can be economically removed by steam shovels under ordinary conditions. As shown by the sections on pages 18 and 19, the greater part of the 100-foot interval above the Rosebud bed in this field in places consists of hard massive sandstone, which must be blasted before it can be removed by shovels. At Colstrip and in the Castle Rock area this sandstone has been largely eroded or is loosely consolidated and should present no serious obstacle to stripping, except possibly in and near low divides where its basal portion may be more indurated.

Springs issue from the bases of most of the coal beds in the field, owing to the presence of an impervious shale bed beneath the coal. For this reason it is suggested that drift mines and other openings on coal beds be so located that the entries will follow the rise of the beds and supply a natural drainage of the mine.

Exhibit 31

Estimated quantity of coal present and recoverable in the Forsyth coal field, by townships, in net tons

[1] Beds less than 3 feet thick not included in the estimate.

TOWNSHIP DESCRIPTIONS

In the following pages are presented detailed data upon the stratigraphy and structure of the rocks in the several townships, with especial emphasis laid upon the position, character, and thickness of the coal beds. General conclusions drawn from these data have been given in preceding pages. All coal beds mapped are represented on Plate 7, and the location of points where detailed sections were measured along outcrop lines are indicated by numbers. Corresponding numbers are used in Plate 10, in which the coal sections are represented graphically.

On the map the outcrop lines of the coal beds where exposed, inferred, or represented by slag are indicated by distinctive patterns, and so are those areas where the Rosebud coal bed can be worked by strip mining. The townships are described in tiers from west to east, beginning with the northern township in each tier.

T. 6 N., R. 38 E.—The alluvial plain of the Yellowstone River in T. 6 N., R. 38 E., is bordered on the south by a bluff of the sandstone member of the Judith River formation and terrace gravel. (See pl. 2, *A*, and pp. 8–9.) The remainder of the township is occupied by Bearpaw shale overlain by terrace gravel and presents a rolling, monotonous type of topography, unbroken except where crossed by the larger streams. The outcrop of the sandstone member of the Judith River represents the highest structural point in the Forsyth field and the dip of the member is about 3° SE. This township contains no coal.

T. 5 N., R. 38 E.—The southern part of T. 5 N., R. 38 E., where the Hell Creek member of the Lance formation crops out, has been extensively dissected

Exhibit 31

by Reservation Creek and its tributaries, making it rough and almost impassable. The northern part of the township has the Bearpaw shale as the highest formation, and this shale and the terrace gravel produce a rolling, grass-covered country devoid of prominent topographic features. The strata in the township are on the southern limb of the Porcupine uplift and, as near as could be determined, dip about 2° S. No coal of any value occurs in this township.

T. 4 N., R. 38 E.—The southern part of T. 4 N., R. 38 E., is moderately rough and is unsettled. Its central part is occupied by the divide between East Bear and Blacktail Creeks, which is covered with a mantle of terrace gravel. The land in the northern part of the township is very rough and inaccessible. A fair road follows the valley of East Beaver Creek and forks in section 26, one branch crossing the divide in section 25 into the basin of Reservation Creek, and the other branch taking a southerly direction to the crest of the gravel-capped terrace in sec. 1, T. 3 N., R. 38 E.

The Hell Creek and Tullock members of the Lance formation and the Lebo shale and Tongue River members of the Fort Union formation crop out in this township as shown on Plate 7. The Hell Creek member consists here of light-colored sandstone and sandy shale similar to the beds of the overlying Tullock member, which is exposed in an escarpment striking nearly east in the northern part of the township. The Lebo shale weathers into low, rounded hills capped with terrace gravel, becoming approximately level as the crests of the divides are approached. The Tongue River member crops out as a conspicuous gravel-covered escarpment in the southeastern part of the township. In the SE. ¼ sec. 36, there is a small remnant of the Oligocene or Miocene (?) gravel terrace standing at an altitude of about 3,650 feet. Reworked gravel from this horizon is spread over practically the entire township.

The structure in the township is exceedingly simple. The rocks are slightly affected by the southwest end of the Porcupine uplift and dip uniformly southward at an angle of not more than 1°.

No exposures of coal were observed in the Tullock member in the township, and if any are concealed in the gravel slopes they are in all probability too thin to be of any value. Only one exposure of the Big Dirty bed was seen, at location 26 in section 28, where the overlying gravel had been removed and 4 feet 8 inches of dirty coal was found. Although the Big Dirty bed was not mapped in detail its position is shown with a fair degree of accuracy on Plate 7 by the line of contact between the Tullock and Lebo members. The only coal bed that should occur in the Tongue River member in this township is the Burley bed, and its outcrop should be restricted to the extreme southeastern part of the township. No outcrop of this bed or any other Tongue River coal was observed in this area, however.

T. 3 N., R. 38 E.—The divide between the drainage basins of Sarpy Creek and Armells Creek, in the southeastern part of T. 3 N., R. 38 E., is so heavily forested and so rugged that it is accessible only by saddle horse. In the northern part of the township a fair road crosses the divide and follows a northwesterly direction along the valley of East Beaver Creek. The township is everywhere maturely dissected. The streams are all intermittent and flow in narrow canyons, the walls of which are usually of massive sandstone. The main divide rises about 400 feet above the lowest parts of the township in sections 23 and 24 and is composed of massive light-colored sandstone, capped in sections 14 and 23 by remnants of the Oligocene or Miocene (?) river gravel bench.

The upper part of the Lebo shale member of the Fort Union formation and the lower 400 feet of the Tongue River member crop out in T. 3 N., R. 38 E.

Exhibit 31

Rock exposures are generally poor owing to the presence of timber. A detailed section of the coal-bearing rocks in the township is given on page 20.

The Burley bed was measured at location 44, where it contained 2 feet 8 inches of coal. (See pl. 10.) At location 41 it is 4 feet thick and crops out in the bottom of the North Fork of Trail Creek near the Robinson ranch. At the Thompson prospect, in the SW. ¼ sec. 1, a bed assumed to be the Burley contained 3 feet 10 inches of coal. An abandoned prospect on this same bed at location 43 was reported to have shown a thickness of 3 feet of coal. In the central and northern parts of the township the mantle of gravel caused by the disintegration of an Oligocene or Miocene (?) gravel deposit has concealed the Burley as well as the coal beds above it.

The Robinson bed is well exposed in a cut bank along a narrow ravine at location 35 (pl. 10), where it contains 7 feet of coal. It is somewhat clinkered in the general vicinity of this location. It crops out again under similar conditions at location 36, where it contains 6 feet 5 inches of coal with a 3-inch clay parting. No exposures of it were observed farther north on the west side of the main divide and its crop line as shown on Plate 7 is inferred. Only one outcrop of the Robinson bed was observed on the east side of the divide, at location 37, where is was 7 feet 1 inch thick.

The Stocker Creek bed was measured on the side of a hill at location 40 (pl. 10), where it consists of an upper and a lower bench of coal 1 foot and 1 foot 7 inches thick, respectively, separated by 3 feet of carbonaceous shale. At location 42 it crops out in the bottom of a narrow coulee and is 2 feet 10 inches thick.

The Rosebud bed is nowhere well exposed in this township. Positive evidence as to its position is supplied by a partial section showing 4 feet 11 inches of coal, measured at location 38 (pl. 10), and the crop line of the basal part of the massive sandstone which lies above it. This sandstone as a rule is exceptionally well developed in this area. The McKay bed lies from 27 to 30 feet below the Rosebud in this township, and their crop lines nearly coincide. The clinkered outcrop of the Rosebud bed is very conspicuous just beneath the summit of the high divide in sections 23 and 24. The McKay bed is slightly more than 29 feet below the Rosebud bed at location 38 and contains 2 feet 3 inches of coal. At location 39 the McKay bed is 2 feet 7 inches thick and crops out about 30 feet below a moal blossom which undoubtedly represents the basal portion of the Rosebud bed. The McKay bed is 2 feet thick at location 94, but no outcrop of the Rosebud bed was observed in the heavy timber at this place.

T. 2 N., R. 38 E.—In T. 2 N., R. 38 E., the northward extension of Wolf Mountain makes the divide between Sarpy Creek and the West Fork of Armells Creek. The southeastern part of the township is rough, heavily timbered, and unsettled. In the central and northern parts the main north-south divide rises abruptly several hundred feet above the surrounding country and, though very narrow, proves a great obstacle to travel. A single road crosses the divide through a pass in section 14 and affords communication between the valleys of Sarpy and Armells Creeks.

The rocks which crop out in T. 2 N., R. 38 E., belong to the Tongue River member of the Fort Union formation and consist of light-colored sandstone, sandy shale, and coal, included in the 1,250 feet of rocks lying above the base of the Burley coal bed. The Sawyer bed is represented by carbonaceous shale in this township, but practically all other beds in the Tongue River member of the Fort Union are present, though none higher than the Rosebud were mapped.

Exhibit 31

The Stocker Creek bed crops out in the valley of Horse Creek along the western border of the township and in the northern part of section 1. In a cut bank at location 97 (pl. 10) it contains 9 feet of clean coal. At location 96 its upper 7 feet crops out in a bench rising above a grass-covered knoll. No other outcrops of the bed were observed in the township, and its inferred position as shown on Plate 7 was determined by mapping the basal part of a massive sandstone which lies just above it. At location 99 a somewhat lower bed exposed in the bottom of a small tributary of Horse Creek showed two 1-foot benches of coal separated by 2 inches of clay.

The Rosebud bed crops out on both sides of the Sarpy Creek-Armells Creek divide and in places is heavily clinkered. No measurements of its thickness could be obtained in sections 21 and 28, though its position was easily determined by tracing clinker mounds in the grass-covered slopes. In that part of the township west of the old Crow Reservation fence it is clinkered over a large area. At location 92 (pl. 10) the Rosebud bed is 8 feet thick, showing a pronounced thinning from east to west in this particular township. In a coulee at location 91 the upper 4 feet of the Rosebud crops out, and the bed is fully exposed at location 90, where it contains 12½ feet of coal in its lower part, above which is a clay parting 8 inches thick and then 8 inches of coal. A few hundred feet downstream and 30 feet lower the McKay bed crops out at location 95 (pl. 10) and is 3 feet thick. At location 93 the McKay bed is 3 feet 5 inches thick, but the Rosebud bed where it would crop out is in the heavy timber and is not exposed. The outcrop of the Rosebud bed enters the eastern part of the township near the northwest corner of section 24, and the bed is exposed in cut banks along several small streams which have their sources at the base of the eastward-facing bluffs. In the North Fork of Donley Creek at location 86 (pl. 10) it contains 14 feet of coal in its lower part, overlain by about 4 feet of coal and bone, most of which, however, is coal. A similar measurement of the bed was made less than a quarter of a mile farther north, at location 87. The base of the coal was not exposed at either of these locations. At location 88 its upper part as exposed contains 9½ feet of coal split by a 4-inch carbonaceous shale parting. At location 89 it crops out in a cut bank, where it has been the source of fuel for settlers for many years. When the examination was made the basal part of the bed was concealed by débris. The total thickness of the bed at this location is about 25 feet, and the upper 13 feet of the bed is badly split by clay partings. (See pl. 10.)

As a rule the Rosebud bed in this township appears only in coulee bottoms and is overlain with too much overburden to be stripped advantageously. In the central and southwestern parts of section 13, however, there are several amphitheater-shaped depressions between long, narrow divides where the coal could be taken out by stripping, but it is not believed that there is a sufficient quantity available to make such an undertaking profitable at present.

Nearly all the valuable coal beds of the Tongue River member of the Fort Union formation are found in this township. It is estimated that the total tonnage of the Rosebud bed alone under the fractional part of the township here described is 300,000,000 tons.

T. 1 N., R. 38 E.—In T. 1 N., R. 38 E., the East Fork of Sarpy Creek, which is a perennial stream, contains only a little water during the summer. The land along the creek is rolling and is excellently adapted to farming. Almost all of the township is on the west side of Wolf Mountain; hence it receives a heavier rainfall than those areas east of the mountain. As a consequence of this abundant water supply the diversity of crops is far greater here than in any other part of the Forsyth field. On the northeast side of the East Fork

Exhibit 31

of Sarpy Creek the land rises rapidly toward Wolf Mountain (pl. 4, *A*), which stands approximately 1,200 feet above the creek. The western slopes of Wolf Mountain are rough, unsettled, and accessible only by saddle horse.

The rocks exposed in T. 1 N., R. 38 E., are included in the 1,050 feet of rocks lying above the Stocker Creek coal bed.

The rocks are well exposed in the deep and narrow ravines which lead up to the top of Wolf Mountain, but on the divides they are usually concealed by grass or timber. The rocks have an inclination to the east and southeast of less than 1° and consist of alternating sandstone and sandy shale of a light-yellow color, intercalated with which are coal beds of differing thickness and persistency.

The Stocker Creek bed crops out just above creek level at location 154 (pl. 10), where it is 4 feet thick. No other exposure of this bed occurs in the township.

The Rosebud bed is extensively clinkered in the valley of the East Fork of Sarpy Creek, so the unburned coal in it is rarely exposed. A measurement of part of the Rosebud bed was obtained at location 151 (pl. 10), where its upper 5 feet crops out in a grassy hillside. A similar exposure occurs at location 152, where the upper 6 feet of the bed crops out in a natural cut beside an old wagon trail. In a ravine at location 153 the total thickness of the Rosebud bed, which is here 14 feet, is exposed. In the same ravine a few hundred feet west of the west line of section 4 the bed has been stripped by settlers.

A detailed section measured from the top of the Rosebud bed upward 1,000 feet failed to reveal any coal beds thicker than 3 feet. It is reported that a well drilled for the Tennessee Oil & Gas Co. in the SW. ¼ sec. 34 reached the depth of 1,000 feet and was then abandoned. The log of this well is not available, and no information can be given regarding the number, position, and thickness of the coal beds penetrated.

The total tonnage of coal in the Rosebud bed in this township is estimated to be 327,600,000 tons, nearly all of which could be mined by underground methods only. This fact, together with the geographic position of the township in relation to railroad lines either built or likely to be built, makes it highly improbable that the coals in the township will be exploited on a large scale in the near future.

Tps. 1 and 2 S., R. 38 E.—The eastern two tiers of sections of T. 1 S., R. 38 E., and not quite two full sections of T. 2 S., R. 38 E., are included in the Forsyth field. These areas lie on the western slopes of Wolf Mountain and are rough and heavily timbered. The surface strata belong to the Tongue River member of the Fort Union formation and, though not mapped in detail, are known to contain valuable coals.

T. 6 N., R. 39 E.—In T. 6 N., R. 39 E. the outcrop of the Bearpaw shale south of the alluvial plain of the Yellowstone River makes a strip of low, rounded gravel-capped hills that become progressively wider westward. The lower part of the Hell Creek member of the Lance formation crops out in a prominent pine-clad sandstone escarpment which strikes northeast; east of Armells Creek it composes the bluffs rising abruptly above the flood plains.

The distribution of the outcrops is determined by the Porcupine uplift, and the average inclination of the strata is about 3° SE. The township contains no coal.

T. 5 N., R. 39 E.—Armells Creek, in T. 5 N., R. 39 E., is bordered on both sides by very rough country. Travel is restricted to the main county road along Armells Creek; elsewhere the township, except for a trail leading up Cottonwood Creek a few miles, is inaccessible to vehicles.

Exhibit 31

The Bearpaw shale crops out in parts of sections 5 and 6 and is bordered by a pine-clad escarpment of the lower sandstone of the Hell Creek member of the Lance. This sandstone is massive and usually forms barriers to travel that are almost impassable even on horseback. The most prominent topographic feature is the mesalike hill of sandstone of the Tullock member, which caps the divide between Reservation and Armells Creeks in section 31.

The attitude of the strata is determined by the Porcupine uplift, their inclination being to the southeast and ranging from a maximum of 4° in section 6 to less than 1° in the southeastern part of the township. A detailed hand-level section, measured from the mouth of Cottonwood Creek, in section 36, to the top of the mesalike hill in section 31, gave 401 feet as the thickness of strata of the Hell Creek member of the Lance formation exposed along the line traversed. The lower 165 feet of the Tullock member crops out in section 31 and contains several coals, none of which are more than 18 inches thick in this township.

T. 4 N., R. 39 E.—East of the divide between Armells and Reservation Creeks and in the northwestern part of T. 4 N., R. 39 E., the land is rough, broken, and unsettled, but the area at the head of Reservation Creek has a rolling surface and is easily accessible. The divide between the two creeks is capped by terrace gravel and is fairly level.

The Hell Creek member of the Lance formation crops out in the bluffs along Reservation Creek in the northwestern part of the township and is made up of grayish-yellow sandstone and sandy shale. The Tullock member is well exposed along Reservation Creek and in the maturely dissected areas east of the main divide, where its uppermost sandstone forms a resistant cap rock on the divides between the eastward-flowing streams. The Lebo shale member of the Fort Union formation crops out in a narrow strip having low relief. The Tongue River member of the Fort Union is the surface formation in the southwestern part of the township and is made up of yellow sandstone and sandy shale standing in bluffs above the surrounding Lebo lowlands. The crest of the main divide is formed by a narrow remnant of the Oligocene or Miocene (?) terrace, the reworked gravel from which has concealed the rocks at lower levels.

Several coal beds 1 foot or less in thickness were observed in the Tullock member in the eastern part of the township, but in its western part no coal beds were found. The Big Dirty coal bed, at the base of the Lebo shale, is persistent but is too dirty to be of any value. At location 27 it contained 3 feet 6 inches of carbonaceous shale with thin and irregular layers of coal. The Hamre bed is persistent but is also valueless. A measurement of it at location 28 gave 2 feet 6 inches of carbonaceous sandstone and coal. The bluffs of Tongue River rocks are covered with gravel washed down from the Oligocene or Miocene (?) terrace and exposures are relatively few. As only the lower part of the member is exposed, it can be safely assumed that no coals of economic importance are concealed beneath the gravel. At location 30 a coal bed 1 foot 1 inch in thickness crops out.

T. 3 N., R. 39 E.—The land west of the West Fork of Armells Creek for a maximum distance of 3 miles is broken and rough, owing to the erosion of the nonresistant sandstone and sandy shale of the Tullock and Lebo members of the Lance and Fort Union formations. The central part of the township, where the Tongue River member of the Fort Union crops out, is rolling, treeless country of moderate relief and is well adapted to dry farming. The most prominent topographic feature is the bold escarpment of Tongue River rocks which rises about 300 feet above the surrounding lowlands along the western

Exhibit 31

edge of the township. The top of this escarpment is composed of the Oligocene or Miocene (?) terrace gravel and stands at an altitude of about 3,675 feet.

The lowest coal bed that crops out in the township is the Big Dirty bed, measurements of which made at locations 45 to 50 (pl. 10) show that it contains about 9 feet of carbonaceous shale and coal. The Robinson bed was measured at locations 52 to 58 (pl. 10) in the rough country at the base of the Tongue River escarpment; it averages 5 feet in thickness.

The only measurement of the Rosebud bed in this township was obtained at location 51 (pl. 10) where it contains 7 feet 2 inches of coal split by a 1-inch parting. Smaller beds were measured at location 59, in the NW. ¼ sec. 19, 160 feet below the Rosebud bed, where two benches of coal 1 foot 7 inches and 5 inches thick are separated by a 2-inch parting of carbonaceous shale, and at location 60 in the SW. ¼ sec. 30, 30 feet above the Robinson bed, where 1 foot 9 inches of coal was found.

An axis of gentle anticlinal folding passes across the northeastern part of the township and local doming on it occurs in section 11. Strong southwest dips were observed in section 23 and gentle southeast dips in the western parts of the township.

T. 2 N., R. 39 E.—The lower part of the Tongue River member of the Fort Union formation crops out in the northern part of T. 2 N., R. 39 E., and forms a rolling plain of moderate relief. In the central part of the township the Rosebud clinker forms a plateau dissected by many streams. The clinker makes a prominent rim rock along the creek valleys, and the slopes below it are covered with débris, which effectively conceals the coal beds. In the southern part of the township, where the Rosebud bed is unburned, the land is of moderate relief near the outcrop of the bed, but at a short distance back it becomes rough and broken.

The Burley bed crops out on the West Fork of Armells Creek at locations 119 and 120 and averages 4 feet in thickness. (See pl. 10.) West of the creek it is either concealed or absent and no measurements of it were obtained.

The Robinson bed is usually concealed where its outcrop line occurs in the bluffs, and measurements of it are obtainable only where streams have cut through it. Measurements made at locations 111 to 114 on the West Fork of Armells Creek show that it contains about 5 feet of coal in its lower part, overlain by about 3 feet of coal split by bone partings. (See pl. 10.) At location 115 a measurement of part of the bed showed more than 4 feet of coal. At location 116, in the bottom of the South Fork of Donley Creek, 3 feet of the bed crops out and its top is eroded. At locations 117 and 118, in the South Fork of Trail Creek, it is more than 3 feet thick.

The Stocker Creek bed, which occurs near the base of a rather prominent sandstone, was measured at locations 105 to 110 (pl. 10); it contains on the average 6 feet of coal overlain by 3 feet of coal and carbonaceous shale.

The Rosebud bed underlies a portion of the southern part of the township and is exposed, either wholly or in part, in narrow ravines. At location 101 (pl. 10) 5 feet of coal crops out in the side of a small mound. In the bottom of a ravine, at location 102, its total thickness of 23 feet is exposed, and at location 103 its upper 15 feet crops out. At location 104 its upper 12 feet is exposed in a cut bank. West of location 104 there are no exposures of the Rosebud bed and the position of its outcrop line as shown on Plate 7 was determined by mapping the contact of baked and unbaked rock.

The Rosebud can be mined by stripping in the E. ½ sec. 33 along the South Fork of Donley Creek. The land adjoining the creek is fairly level over

Exhibit 31

approximately half a section, and the measurement at location 104 indicates that the coal is more than 12 feet thick.

From the measurements given above it is estimated that there are 125,000,000 tons of Rosebud coal in the township, most of which can be taken out only by underground mining.

T. 1 N., R. 39 E.—Almost all of T. 1 N., R. 39 E., lies in the rough country composing Wolf Mountain, which crosses the southwestern part of the township and makes the divide between Armells and Sarpy Creeks. The summit of the mountain is formed by a thick clinker, which stands about 1,300 feet above the surrounding country. The mountain slopes are heavily timbered and accessible only by saddle horse.

The rocks that crop out in the township belong to the Tongue River member of the Fort Union formation, and as the relief is great, about 1,300 feet of the member is exposed. (See pp. 18–19.)

The Rosebud bed crops out at locations 155 and 156 and is more than 15 feet thick. (See pl. 10.)

The Popham bed averages 4 feet in thickness and was measured at locations 157 to 163. (See pl. 10.)

The Proctor bed also averages about 4 feet in thickness and is represented on Plate 10 by locations 164 to 168.

The Richard bed crops out along the east line of the township, and measurements made at locations 169 to 173 (pl. 10) show that its average thickness is about 3½ feet.

Two unnamed coal beds are clinkered along their outcrops on both sides of Wolf Mountain, and no measurements of their thicknesses were obtainable. The position of their outcrop lines as shown on Plate 7 is only approximate.

Tps. 1 and 2 S., R. 39 E.—Tps. 1 and 2 S., R. 39 E., are crossed by Wolf Mountain and are rough, heavily timbered, and unsettled. The rocks which crop out in these areas are included in the interval between the Sawyer coal bed and the clinker making the summit of the mountain. The absence of thick coal beds and the general inaccessibility of this area make it unlikely that the coal in these townships will be exploited in the near future. A reconnaissance examination of the area was made and the following section was measured.

T. 6 N., R. 40 E.—That part of T. 6 N., R. 40 E., which lies within the Forsyth field is rough and broken. West of Smith Creek the Yellowstone is undercutting its south bank, but east of the creek it swings northward, making a flood plain about a mile wide on which Forsyth is situated. The bluffs south of Forsyth rise abruptly several hundred feet above the flood plain and are capped with river gravel.

The rocks which crop out in this township belong to the Hell Creek member of the Lance formation and consist of alternating light and dark colored sandstone and sandy shale showing marked lateral variation and dipping slightly eastward. The nature of the Hell Creek member is indicated by the general section on pages 11–12. No coal occurs in this township.

T. 5 N., R. 40 E.—In T. 5 N., R. 40 E., the divide between Armells and Smith Creeks breaks off suddenly on the west, making a conspicuous escarpment which stands about 600 feet above the level of Armells Creek. (See pl. 2, *B*.) The crest of the divide is covered with terrace gravel and slopes gently toward the Yellowstone River. The drainage basin of Smith Creek consists of very rough land, and travel within it is restricted to the main valley and the divides. The southeastern part of the township consists of badlands and is inaccessible to vehicles.

The Hell Creek member of the Lance formation crops out at the base of the bluffs along the western edge of the township and is overlain by the escarpment-forming Tullock member. (See pl. 2, *B*.) Similar conditions exist on Smith Creek, although the area occupied by the Hell Creek member is larger. Representative sections of the Tullock member measured in this township are given on pages 13 and 14.

The Lebo shale member of the Fort Union formation crops out in the southern and eastern parts of the township and is eroded into almost impassable badlands. The basal sandstone and sandy shale of the Tongue River member make conspicuous bluffs above the Lebo badlands in section 36 and occur as outliers on a gravel-covered Lebo plain in sections 24 and 25.

The Wright coal bed, at the base of the Tullock member of the Lance formation, is the only coal bed of economic importance in the township and has been opened in three places to supply domestic fuel to Forsyth. At the Wright mine, in section 7, it contains 4 feet 2 inches of coal split by a 1-inch clay parting. (See pl. 10.) There are two timbered entries at this mine; the larger one is about 100 feet long and 5 feet high. At the time of examination the mine was abandoned and badly caved. Coal sample No. 96584 (p. 30) was taken at the Wright mine. Other measurements of the Wright bed in this vicinity are given in sections 2 to 4, Plate 10. At location 2 it is 1 foot 1 inch thick, and for nearly 4 miles to the south it was not mapped in detail. At location 5 it is 2

Exhibit 31

feet 6 inches thick, and to the north it is concealed in terrace gravel. At the Griggs mine, in section 23, the Wright bed is 4 feet 4 inches thick and is all clean coal. This mine was formerly equipped for drift mining on a small scale, but at the time of examination most of the equipment had been removed and the mine was idle. The Woodward mine, in section 22, consists of two entries, each about 200 feet long, in which the Wright bed is 4 feet 1 inch thick. No outcrops of the Wright bed were observed in the gravel-covered slopes in the northeastern part of the township. At location 1, in section 30, the Wright bed suddenly thickens and contains 3 feet 5 inches of coal cropping out in a ravine at the base of the Tullock escarpment.

The Hamre bed crops out about 35 feet below the sandstone that makes the rim rock on the Tullock escarpment and consists of a mixture of coal and carbonaceous sandstone. An entry about 100 feet long was driven in on the outcrop of the Hamre bed at location 10, but was abandoned because of the bony character of the coal. At locations 7 to 9 and 11 to 14 (pl. 10) it contains a maximum amount of 3 feet 5 inches of dirty coal in its lower part, which may be replaced by carbonaceous shale and bone within a few hundred feet of the point where the measurements were made.

At location 17 a coal lens 60 feet below the Hamre bed gave the following measurements:

Section at location 17, T. 5 N., R. 40 E.

	Ft.	in.
Coal		4
Sandstone		½
Coal		3
Sandstone		1
Coal	2	3
	2	11½

The Big Dirty bed crops out at several places in the township, but because it is impure it was not mapped in detail. The following measurements illustrate its character.

Section at small prospect in sec. 24 (Big Dirty bed), T. 5 N., R. 40 E.

	8	6

The Hamre bed near this prospect consists of 7 feet of carbonaceous shale, bone, and thin lenses of coal; the thickest lens of coal measures 7 inches. At location 18 the Big Dirty bed crops out as shown in the following section:

Exhibit 31

T. 4 N., R. 40 E.—Armells Creek and its forks in T. 4 N., R. 40 E., flow in relatively narrow valleys bordered by nearly vertical bluffs of sandstone and sandy shale several hundred feet high, which make natural barriers to travel across drainage lines. Outside the valleys of the creeks the land is rough, broken, and unsettled.

The Hell Creek member of the Lance formation here consists of somber-colored sandstone and clay. The Tullock member makes a conspicuous escarpment along the creek valleys which extend several miles up the larger tributaries. Here, as farther north, the top of the member consists of a resistant sandstone which makes a persistent and conspicuous rim rock. The Lebo shale member of the Fort Union formation, as usual, makes a low, featureless plain above the Tullock escarpment. The outcrop of the Tongue River member is restricted to a narrow promotory in section 1.

The Wright bed is the only coal of value in T. 4 N., R. 40 E.; it crops out near the base of the bluffs along Armells Creek. The bed occurs in two benches separated by a maximum interval of 27 feet. Both benches are persistent in position, but rarely do both contain coal at the same location. At location 19 the lower bench contains 2 feet 4 inches of coal in two layers separated by 1½ inches of carbonaceous shale. Similar measurements of the lower bench were made at locations 20, 21, 24, and 25. (See pl. 10.) Both benches of the Wright bed are present at location 22, where the lower bench contains 2 feet 8 inches of coal split by a 1-inch parting of carbonaceous shale and the upper bench 1 foot 4 inches of carbonaceous shale overlain by a like amount of coal. At location 23 on the promontory between the forks of Armells Creek, the upper and lower benches contain 2 feet 4 inches and 2 feet 2½ inches of coal, respectively, and are 26½ feet apart. No exposures of the Wright bed were observed in the northwestern part of the township west of Armells Creek.

The Big Dirty bed was not mapped in detail in this township. Its character is indicated by the following measurement:

Section of Big Dirty bed at location 61, in the SW. ¼ sec. 36, T. 4 N., R. 40 E.

Coal		3
Bone		8
Coal		11
	3	1

T. 3 N., R. 40 E.—The land on both sides of the divide in T. 3. N., R. 40 E., is rough and generally inaccessible. The escarpment of the Tullock member of the Lance formation is a prominent topographic feature in the western part of the township and is overlain by the Lebo shale member of the Fort Union formation, which makes a fairly level top on the divide but is more dissected where it lies on the slopes. (See pl. 4, *B*.) The Tongue River member of the Fort Union occurs as outliers on a plain of Lebo shale in the northern part of the township and underlies a much larger area in its southern part, where it gives rise to rolling country of moderate relief.

A line of gentle anticlinal folding passes diagonally across the eastern part of the township. A fault with a throw of about 50 feet occurs on the east limb of this fold in sections 13 and 14.

The Big Dirty coal bed crops out persistently and contains about 10 feet of coal and carbonaceous shale. At location 70 its upper part contains 4 feet 10 inches of coal, and this is the maximum thickness of coal observed in a single part of it in the township. Other sections of the Big Dirty bed, measured at locations 62, 63, 69, and 71, are represented in Plate 10.

A coal bed which contains about 4 feet of coal and is probably equivalent to the Burley crops out at locations 73 and 74. (See pl. 10.) This bed was not observed at its horizon in adjacent coulees and is probably a small lens produced by the abrupt thickening of a thin seam of coal.

The Hamre bed is of no value in this township, and only one section of it is given here;

Section of Hamre bed at location 72, SE. ¼ sec. 36, T. 3 N., R. 40 E.

	Ft.	in.
Carbonaceous shale	2	5
Bony coal		9
Carbonaceous shale	1	1
Bone and bony coal	3	9
	8	

T. 2 N., R. 40 E.—In the northern part of T. 2 N., R. 40 E., the land is rolling, and exposures of beds other than the sandstone rim rocks are poor. In the southern part of the township, where the coal-bearing part of the Tongue River member crops out, the land is rough and broken. The creeks flow in narrow valleys rimmed by massive sandstone and clinker. The sandstone above the Rosebud bed averages about 60 feet in thickness and makes a conspicuous wall at the base of the highest bluffs. (See pl. 6, *A*.)

Exhibit 31

The Robinson, Stocker Creek, and Rosebud beds underlie parts of the township. Measurements of the Robinson bed on the west side of the main divide were made at locations 129 to 133 (pl. 10), where it contained about 4 feet of coal. The Robinson bed could not be traced in the northern part of this township. At location 136 what is probably the Robinson bed contains 3 feet 2 inches of coal. A bed in the stratigraphic position of the Robinson contains about 3 feet of coal at locations 134 and 135. (See pl. 10.) A small outlier at location 137 is encircled by a coal bed 4 feet 8 inches thick, which may be the Robinson bed.

Several measurements of the Stocker Creek bed showed that it is 60 feet below the Rosebud and ranges from 3 to 6 feet in thickness. Sections of it are shown by locations 123 to 128. (See pl. 10.)

The Rosebud bed underlies the divide in the southwestern part of the township and several outliers in section 21 and vicinity, where it is not entirely burned. The only exposures of the bed observed were at locations 121 and 122, where 5 feet and 10½ feet, respectively, of unburned coal crops out. It is estimated that the total quantity of Rosebud coal underlying the township is 42,000,000 tons, of which 13,000,000 tons can be advantageously recovered by strip mining.

T. 1 N., R. 40 E.—The valley of the East Fork of Armells Creek in T. 1 N., R. 40 E., is about a mile wide and is well adapted to dry farming. It is separated from the valley of Stocker Creek on the north by a narrow divide about 300 feet high, which is crossed by several roads and trails. The divide between the East Fork of Armells Creek and Lee and Richard Coulees, tributaries of Rosebud Creek, occupies the central part of the township and is fairly accessible on its north side. On its south side, however, clinker escarpments stand about 250 feet above the bottom strips along the creeks, and the land is rough and broken, becoming almost impassable on the slopes of Wolf Mountain in the southwestern part of the township.

The axis of the syncline between the Big Horn and Porcupine uplifts crosses the central part of the township and is paralleled on the east by a line of gentle anticlinal folding, on which local doming has occurred in section 12. The position of this dome is outlined by the outcrop of the Rosebud coal bed, which rises above the level of the East Fork of Armells Creek in the NE. ¼ sec. 7, T. 1 N., R. 41 E., and dips beneath the creek again in the SW. ¼ sec. 11, T. 1 N., R. 40 E. (See pl. 7.)

The rocks that crop out in the township belong to that part of the Tongue River member of the Fort Union formation which is included in the interval between the Rosebud and Richard coal beds. The rocks other than coal beds consist of light-colored sandstone and sandy shale.

The gentle doming of the strata in section 12 has exposed the Rosebud bed at location 176 (pl. 10), where nearly 11 feet of it crops out. No other exposures of the bed occur in this immediate vicinity, as its outcrop is clinkered. At location 175 the upper 13 feet of the Rosebud bed crops out in a cut bank, and its total thickness at this location is reported to be 28 feet. The outcrop of the Rosebud bed is extensively clinkered west of location 175, and no exposures of unburned coal were observed. A well drilled near the Cooley ranch in section 4 is reported to have penetrated 24 feet of coal beginning at a depth of 6 feet below the surface.

The Lee bed crops out at location 177, in section 35, and contains nearly 9 feet of coal split by two thin partings of sandy shale. (See pl. 10.) The Lee bed is not developed in the northern part of the township.

Exhibit 31

The Popham bed crops out 45 feet below the Sawyer bed and although it averages only about 4 feet in thickness was mapped in detail. Sections along its outcrop line at locations 178 to 200 are given on Plate 10.

The Sawyer bed is unburned only in the western part of the township and has a maximum thickness of more than 17 feet at location 213. (See pl. 10.) It thins rapidly toward the northwest and at location 203 is only 1 foot 8 inches thick. Other sections of the Sawyer bed are represented in Plate 10 by sections 201, 202, 204–a, 205, 206, 206–a, and 209 to 213. At location 206–a, in the NW. ¼ sec. 30, the Sawyer bed is 6 feet 8 inches thick and a face of it about 75 feet long has been cut back a maximum distance of 25 feet. Coal sample 96587 was taken at this location. (See p. 30.)

A measurement of the Richard bed made at location 215, at the south quarter corner of section 31, showed 6 feet 4 inches of coal, and one made at location 217, in the SW. ¼ sec. 19, showed 3 feet 2 inches of coal overlain by 3 inches of carbonaceous shale.

At location 204, in the SW. ¼ sec. 18, a coal bed 1 foot 3 inches thick crops out 78 feet above the Popham bed.

Conditions excellent for the recovery of a large tonnage from the Rosebud bed by strip mining exist in parts of sections 4, 5, and 6 of this township and in parts of secs. 31 and 32, T. 2 N., R. 40 E. The land lies in a topographic saddle between the headwaters of Stocker Creek and the West Fork of Armells Creek and is fairly level. The record of the well at the Cooley ranch, in section 4, and exposures at locations 155 and 156, in sec. 1, T. 1 N., R. 39 E., show that the Rosebud bed is more than 20 feet thick. The approximate outline of the area from which coal in the Rosebud can be taken out by strip mining, including tracts in sections 11, 12, 13, and 14, is shown on Plate 7. A rough estimate of the coal thus recoverable in this township is placed at 39,000,000 tons.

T. 1 S., R. 40 E.—The principal tributaries of Rosebud Creek in T. 1 S., R. 40 E., are separated by long, narrow, and level clinker-capped divides, which stand about 250 feet above the valley bottoms. The clinker makes a resistant cap rock above bluffs of yellow sandstone and sandy shale and protects dissected remnants of a former extensive slag-covered plateau. The coals are unburned in the western part of the township, and the land is very rugged and inaccessible. Trails extend part way up all the creeks, and most of them end at deserted ranches. The inaccessibility of the area and the lack of good drinking water have served to keep this township almost unsettled.

The rocks in the township belong to that part of the Tongue River member of the Fort Union formation which is included in the interval between the Lee and Richard coal beds. The dip is uniformly about 1° SE. The Lee bed crops out near the base of the bluffs throughout the township and is extremely clinkered. Its maximum thickness in Slough Grass Creek is 6 feet 4 inches at location 249. Other measurements of it in Slough Grass Creek are given on Plate 10 by locations 250 to 254. Only one measurement of it was obtained in Little Cottonwood Creek, at location 255, where it contains 5 feet 7 inches of coal split by 3 inches of shale. At location 256 slightly more than 2 feet remains unburned. At location 257 it is nearly 14 feet thick but includes a sandstone parting more than 5 feet thick in its middle part in addition to several smaller partings. (See pl. 10.)

The Sawyer bed crops out in the almost impassable badlands in the western part of the township. On the Middle Fork of Richard Coulee, at location 258, it is more than 9 feet thick and is badly split by partings. (See pl. 10.) Its maximum observed thickness occurs at location 265, where it consists of an

Exhibit 31

upper and a lower bench, containing 4 feet 5 inches and 8 feet 5 inches of coal, respectively, separated by a bed of carbonaceous shale 15 feet thick. Other sections are given in Plate 10 by locations 259 to 264 and 266. The Popham bed crops out in the township, but because of its close vertical proximity to the Lee and Sawyer beds it was not mapped in detail. Its general character in the township is illustrated in Plate 10 by sections 267 and 268.

T. 2 S., R. 40 E.—That part of T. 2 S., R. 40 E., which was examined includes slightly less than two tiers of sections lying north of the Cheyenne Indian Reservation. The land included in this area is very rugged and is largely occupied by the divide between Big Cottonwood Creek and Lynch Coulee.

On Big Cottonweed Creek, at location 278, 4 feet 10 inches of coal, with its base unexposed, crops out in the stream bottom and may be the top of the Rosebud bed. The Lee bed is 4 feet 9 inches thick at location 269. The Sawyer bed is extensively burned along its outcrop and no measurements of its thickness could be obtained.

T. 6 N., R. 41 E.—The alluvial plain south of the Yellowstone River in T. 6 N., R. 41 E., is less than a quarter of a mile wide and is bordered by gravel-capped bluffs about 200 feet high. The rest of the township is occupied by a terrace of Pleistocene river gravel, which is traversed by good roads and is well settled.

The Hell Creek and Tullock members of the Lance formation underlie the terrace gravel in this township and crop out at irregular intervals along Slaughter House Creek and in the bluffs of the Yellowstone River. No coal was observed in this township.

T. 5 N., R. 41 E.—The divide which occupies the central part of T. 5 N., R. 41 E., stands about 700 feet above the level of the Yellowstone River. Its summit is composed of terrace gravel locally cemented into a conglomerate 10 feet thick and represents a river terrace intermediate in age between the Oligocene or Miocene (?) bench in T. 4 N., Rs. 39 and 41 E., and the main terrace along the Yellowstone River. As indicated on pages 20–22 this deposit may represent the Flaxville gravel, of Miocene or Pliocene age. East of the main divide and in the drainage basin of West Rosebud Creek the land is very rough and broken and is traversed by only one road, which follows the creek bottom. In the western part of the township a mantle of terrace gravel has produced a rolling type of topography which becomes increasingly rough toward the head-waters of West Rosebud Creek.

The contact line of the Hell Creek and Tullock members of the Lance formation as shown on Plate 7 is inferred, for the lack of continuous exposures makes it impossible to draw a well-defined line between them. The Lebo shale member of the Fort Union formation underlies the divide in the central part of the township and makes an extensive badlands area along the West Fork of Rosebud Creek. The Tongue River member of the Fort Union crops out on long, narrow spurs and outliers in sections 30 and 31.

The Wright coal bed has been opened at six places along a coulee in sections 1 and 2 to supply domestic fuel to Forsyth. These openings are referred to as the Lore mines. The largest opening extends in 200 feet and comprises several rooms. The main openings are 5 feet high and 5 feet wide and have a soft sandstone roof. The section on page 51 illustrates the character of the Wright bed at these openings.

A coal bed 2 feet 4 inches thick was seen in the bluffs on the West Fork of Rosebud Creek, at the center of section 25, but thinned to less than 1 foot within a few hundred feet. The Hamre bed crops out below the Tullock rim rock as follows:

The Big Dirty bed averages about 6 feet in thickness and is made up of carbonaceous shale and dirty coal. The best exposure of it in the township occurs on the narrow ridge in the NW. ¼ sec. 22, where it is nearly 7 feet thick but very dirty. The Big Dirty bed was not mapped in detail, but its outcrop is represented with fair precision on Plate 7 by the contact line between the Tullock and Lebo shale members.

T. 4 N., R. 41 E.—The plateau-like divide which crosses T. 4 N., R. 41 E., ranges in width from less than a mile in its southern part to a maximum of about 5 miles in its northern part. Its most prominent topographic features are several flat-topped hills and ridges capped with Oligocene or Miocene (?) gravel, which rise several hundred feet above the general level of the divide in sections 8, 14, 15, and 16. (See pl. 7.) The land on either side of the divide is exceedingly rough and has neither roads nor trails.

The upper part of the Tullock member of the Lance formation crops out in the stream bottoms along the borders of the township. The Lebo shale member of the Fort Union formation is nearly 170 feet thick (see p. 16) and crops out in a relatively narrow band between the escarpment-forming sandstones of the Tullock and Tongue River members. The lower 208 feet of the Tongue River member crops out in bold escarpments above the somber-colored Lebo clays and is made up of yellow sandstone and thin lenticular coal beds. (See p. 20.)

No coal of value occurs in the township. The Hamre bed contains 18 inches of coal at location 33 in the SW. ¼ sec. 19. The Big Dirty bed is persistent but thinner and more bony than at any other place along its outcrop in the entire field. The following measurements show its character and thickness:

T. 3 N., R. 41 E.—The divide in the northern part of T. 3 N., R. 41 E., is characterized by long narrow ridges of Tongue River sandstone, bordered by badland slopes of Lebo shale. In the southern part of the township near the East Fork of Armells Creek the land is of moderate relief but becomes rougher as the main divide is approached, and west of the creek is so dissected as to be almost impassable.

The East Fork of Armells Creek flows along the axis of a syncline paralleling an anticline which crosses the southwestern part of the township. West of the creek the rocks rise at an angle of about 3°, which is sufficient to expose the upper part of the Tullock member in the stream bottoms. This line of folding is modified by a northwestward-trending fault zone which runs slightly east of the anticlinal axis. The faults are normal and are dropped on the west about 60 feet. (See pl. 7.)

At location 75, in the NE. ¼ sec. 6, the Big Dirty bed contains about 4 feet of coal and carbonaceous shale. At location 76, about 1½ miles to the south, it is 6½ feet thick and of fair quality. Along the fault zone in the southeastern part of the township it attains a maximum thickness of 11 feet at location 77 and appears to consist of a good grade of subbituminous coal. Other measurements of this bed are represented in Plate 10 by sections 78, 79, and 80. At locations 81 and 82 it again assumes its normal dirty character, as the following sections will show:

Exhibit 31

The Burley bed underlies the highest part of the divide in the central and southern parts of the township and is in places extensively burned. Outcrops of the bed are rare, however, on account of the rolling, grass-covered nature of the country. It was measured at locations 83, 84, and 85 (pl. 10) and showed an average thickness of 4½ feet.

T. 2 N., R. 41 E.—In the northern part of T. 2 N., R. 41 E., the East Fork of Armells Creek is bordered by bluffs that rise 300 feet above the level of the creek, and in the southern part of the township the clinker made by the burning of the Rosebud coal bed has produced a continuous line of bluffs and rounded hills along the creek. In those areas along the creek where the Rosebud bed has not been burned the land is gently rolling and rises in smooth grass-covered slopes to higher and rougher areas in sections 31 and 32. The Armells Creek branch of the Northern Pacific Railway and the main road to Forsyth follow the valley of the East Fork of Armells Creek, and a branch road to Castle Rock follows Stocker Creek.

In the southern part of the township the rocks have an average dip eastward of about 20 feet to the mile, the dip increasing slightly toward the west. In the central and northern parts of the township the dip is about 30 feet to the mile to the east, and there may be a slight reversal of dip in sections 17 and 18.

The Burley coal bed crops out at the head of Sprague Basin in sections 1 and 2 and at the base of the bluffs along the east side of the East Fork of Armells Creek. At location 143 (pl. 10) it contains 5 feet of coal, and at the Wimer place, location 144, some 2 feet of the bed shows in a spring, and it is reported to be 6 feet thick. At location 145 the bed shows 4 feet 4 inches of coal, and at location 146 it contains 4 feet of coal. A bed which may be the Burley bed contains 3½ feet of coal at location 147. It was impossible to trace this bed in the grass-covered and forested areas along Stocker Creek.

The Robinson bed crops out at the base of a sandstone which makes a prominent rim rock near the base of the bluffs on the east side of the East Fork of Armells Creek and is 50 feet above the Burley bed. Although exposures of this bed are few its position is easily determined by noting the outcrop of the massive sandstone immediately above it. At location 148 (pl. 10) it contains 2½ feet of coal; at location 149 it contains 4½ feet of coal. The outcrop line south of location 148 shown for it on Plate 7 is inferred.

The McKay and Rosebud beds are extensively burned in this township. The divide between the East Fork of Armells Creek and Stocker Creek and the divide between the East Fork of Armells Creek and Spring Creek in sections 13, 14, and 15 consist largely of clinker formed by the burning of these beds. Both beds are burned in sections 25 and 36 also. In the absence of outcrops the present margin of the Rosebud bed was mapped by reference from the contact of its clinker with cover, it being assumed that the coal would lie unburned back of this contact a distance directly proportional to the thickness of the cover. The McKay bed lies from 8 to 21 feet below the Rosebud bed and where unburned itself is usually concealed by clinker of the Rosebud bed. At location 150 (pl. 10) it is exposed directly beneath the Rosebud slag in a coulee and is more than 6 feet thick.

On Pony Creek, at location 142 (pl. 10), the upper 10 feet of the Rosebud bed is exposed, and is extensively burned in the next township on the east. At location 217, some 6 feet of the Rosebud bed crops out in a reservoir just south of the township line. At location 141 a 14-foot bed of coal, containing two bone partings 1 and 10 inches thick, crops out in a narrow ravine, with the base of the bed unexposed. Measurements of part of the bed at locations 138, 139, and 140 (see pl. 10), averaged about 6 feet. The average thickness of the Rosebud

Exhibit 31

bed in this township, as determined by drill records, is reported to be 28 feet. On Plate 7 those areas in this township where the coal in this bed can be recovered by strip mining are shown in stippled pattern. It is estimated that the Rosebud bed contains 187,000,000 tons of coal in T. 2 N., R. 41 E., of which about 78,000,000 tons can be taken out by stripping.

T. 1 N., R. 41 E.—The flood plain of the East Fork of Armells Creek is about a quarter of a mile wide in T. 1 N., R. 41 E., and the land on each side of the creek bottom for about half a mile is made up of smooth rounded slopes which become rougher farther away from the valley. The divide between Armells and Rosebud Creeks is capped by clinker from the burning of the Sawyer coal bed and stands about 375 feet above the level of the surrounding country. Miller Coulee and its tributaries occupy a basin about 3 miles wide which is almost surrounded by precipitous clinker-capped bluffs of sandstone and sandy shale. The topographic features along Lee Coulee are similar to those of Miller Coulee, though its valley is narrower. Roads traverse the valleys of the larger streams along the township borders, but none cross the inaccessible divide in its central part.

In the central and eastern parts of the township the rocks rise westward about 25 feet to the mile. Gentle doming of the strata occurs near the southwestern corner of section 29 along the axis of a minor anticlinal fold. (See p. 23.) Similar doming on the same anticlinal axis occurs in sec. 12, T. 1 N., R. 40 E., and has increased the westward rise of the rocks in secs. 6 and 7, T. 1 N., R. 41 E., to about 1½°.

The rocks that crop out in T. 1 N., R. 41 E., belong to that part of the Tongue River member of the Fort Union formation included in the interval between the McKay and Sawyer coal beds. (See p. 19.) The sandstone above the Rosebud coal bed is about 140 feet thick in Miller and Lee Coulees, where it makes a conspicuous ledge at the base of the precipitous bluffs. (See pl. 5, *A*.)

The upper 6 feet of the Rosebud bed crops out in a small reservoir at location 217. (See pl. 10.) Along the East Fork of Armells Creek west of location 217 the Rosebud bed is covered until brought above stream level by the increased westward rise of the rocks, and at location 216 it crops out 11½ feet. At the Kimball ranch in the SW. ¼ sec. 6, a coal bed 8 feet thick 40 feet below the surface was penetrated in a well and is probably the Stocker Creek bed. At location 218 the Rosebud bed is 18 feet thick at an abandoned prospect, and at location 218–a (pl. 10) the McKay bed is 7 feet thick. The Rosebud and McKay beds are fully exposed in cut banks at locations 221 and 222 and are about 28 and 10 feet thick, respectively. (See pls. 5, *B*; 6, *B*; and 10; and p. 19.) No other exposures of the Rosebud bed were observed in Miller Coulee, and the outcrop line of the bed as shown on Plate 7 was mapped largely by reference to the contact of baked and unbaked rock. At location 223 the upper 11 feet of the Rosebud bed crops out and is cut off by a fault having a throw of about 32½ feet. (See pl. 7.) The McKay(?) bed is unburned at locations 227 and 228 and has a maximum thickness of 4 feet 5 inches. At an abandoned prospect at location 224 the Rosebud bed is 10 feet thick, and farther downstream it is only a foot thick, having been almost entirely replaced by sandstone and sandy shale. No other exposures of the Rosebud bed were observed in Lee Coulee, though heavy clinker at its horizon in sections 29 and 30 indicates that it is at a slight depth below the surface.

The Lee bed is 105 feet above the Rosebud and first appears along Lee Coulee, where it is heavily clinkered. Only one measurement of it was made, at location 225, where its upper 6 feet crops out.

The Sawyer bed is unburned at location 226 (pl. 10) and is 11 feet thick.

Exhibit 31

Those parts of the township where the coal of the Rosebud bed can be recovered by strip mining are indicated on Plate 7 by stippled pattern. The best belt for strip mining lies along the East Fork of Armells Creek, where the coal is at a depth of less than 60 feet over a considerable area, and the overburden is loosely consolidated sandstone and sandy shale. Smaller stripping areas occur in SE. ¼ sec. 12 and in and near the northern part of section 24. It is estimated that the total quantity of coal in the Rosebud bed (exclusive of the McKay bed) within the township is 843,000,000 tons, of which approximately 107,000,000 tons can be recovered by strip mining.

T. 1 S., R. 41 E.—In T. 1 S., R. 41 E., Rosebud Creek has a flood plain ranging from a few hundred feet to nearly half a mile wide. Its tributaries occupy U-shaped valleys separated by continuous and rather narrow clinker-capped divides, which stand about 350 feet above the stream bottoms. (See pl. 7.) Good water is obtained from drilled wells at ranches along Rosebud Creek, but in other parts of the township the water is too alkaline for drinking. The road between Forsyth and Sheridan follows Rosebud Creek and is graded. Other roads and trails which traverse the township are shown on Plate 7.

The rocks in the township belong to that part of the Tongue River member of the Fort Union formation which lies between the Rosebud and Sawyer coal beds. The interval between the Rosebud and Lee coal beds is 115 feet and is largely occupied by massive sandstones. A similar sandstone about 60 feet thick crops out above the Lee bed, so that a double sandstone bench appears to run along the creek valleys.

The maximum thickness of the Rosebud bed reported in the township is 12 feet in a well near the Groves place, at location 232. Measurements made at locations 229, 230, 231, 233, and 234 are shown graphically in Plate 10. It was impossible to obtain more measurements of the bed because of the soil cover at its horizon along the valleys of the creeks. The general westward rise of the rocks and an occasional small clinker mound near stream level suggest, however, that it is at only a slight depth beneath the surface on all the western tributaries of Rosebud Creek.

On the west side of Rosebud Creek the Lee bed crops out high in the bluffs and is nearly everywhere inaccessible. East of Rosebud Creek it has been opened at two places by settlers. At the McKay mine, in the SW. ¼ sec. 34, it is about 11 feet thick, but only 6 feet of it is mined. This mine has been driven in about 150 feet and is well timbered. Coal sample No. 96583 was taken at this mine. (See p. 30.) The Lynch mine, in the SE. ¼ sec. 25, has a timbered entry about 150 feet long on the Lee bed, the upper 7 feet of which crops out in a coulee beneath a massive sandstone. Other measurements of the Lee bed in this township are represented in Plate 10 by sections 236 to 245.

No unburned coal of the Sawyer bed remains in the township.

T. 2 S., R. 41 E.—Approximately the northern third of T. 2 S., R. 41 E., is included in the Forsyth field. The rocks exposed in this area belong to the Tongue River member of the Fort Union formation and crop out in nearly vertical bluffs rising about 350 feet above Rosebud Creek.

The Rosebud bed has a maximum observed thickness of 13 feet at location 247. Other measurements were made at locations 246 and 248. (See pl. 10.) No exposures of the Lee bed were observed in the bluffs. East of Rosebud Creek the Sawyer bed is unburned in places on the divide between Rosebud and Rye Grass Creeks, but its outcrop is everywhere heavily clinkered.

MONTANA FIRST JUDICIAL DISTRICT COURT
LEWIS AND CLARK COUNTY

MONTANA ENVIRONMENTAL INFORMATION CENTER and SIERRA CLUB, Plaintiffs, v. MONTANA DEPARTMENT OF ENVIRONMENTAL QUALITY, Defendant, and WESTERN ENERGY COMPANY, Defendant-Intervenor.	Cause No. CDV-2012-1075 **MEMORANDUM AND ORDER ON JUDICIAL REVIEW**

Plaintiffs filed this action December 21, 2012, challenging a permit issued to Western Energy Company (WEC) by the Montana Department of Environmental Quality (DEQ) on September 14, 2012. Plaintiffs allege violation

Exhibit 30

of both the federal Clean Water Act (CWA) and the Montana Water Quality Act (WQA) by issuance of Final Modified Permit number MT0023965, effective in modified form September 8, 2014. The permit allows the discharge of pollutants by the Rosebud Mine (owned and operated by WEC) into surrounding waters.

Plaintiffs also seek a determination and declaration that the Montana system for issuance of the permit is unlawful pursuant to both federal and Montana law, given its failure to ensure water quality standards. Finally, Plaintiffs seek "reasonable attorneys' fees and expenses as damages," as well as the costs of the lawsuit. (Verified Compl. & Application Writ Mandate & Declar. Relief, at15 (Dec. 21, 2012).)

All parties have moved for summary judgment. Plaintiffs seek summary judgment on its assertions stated above. WEC seeks summary judgment, asserting that Plaintiffs do not have standing to bring this lawsuit and that the permit process and resulting permit is not violative of law. DEQ seeks summary judgment on similar bases.

STANDARD OF REVIEW

The parties agree the Montana Administrative Procedure Act (MAPA) does not apply in this case[1] and assert the standard of review of DEQ's administrative decisions is set out by the Montana Supreme Court in *Clark Fork Coalition v. Department of Environmental Quality*, 2012 MT 240, ¶¶ 19-20, 366 Mont. 427, 288 P.3d 183:

> An agency's interpretation of its rule is afforded great weight, and we will defer to that interpretation unless it is plainly inconsistent with the spirit of the rule. *Clark Fork Coalition v. Dep't of Envtl.*

[1] No party asserts this is a contested case as defined in MAPA or argues the plain language of Montana Code Annotated § 2-4-702(2)(d).

Quality, 2008 MT 407, ¶ 20, 347 Mont. 197, 197 P.3d 482. We will sustain an agency's interpretation of a rule so long as it lies within the range of reasonable interpretation permitted by the wording. *Clark Fork Coalition*, ¶ 20. Of course, we need not defer to an incorrect agency interpretation. *Clark Fork Coalition*, ¶ 20.

We review an agency decision not classified as a contested case under the Montana Administrative Procedure Act to determine whether the decision was arbitrary, capricious, unlawful or not supported by substantial law. *Clark Fork Coalition*, ¶ 21. In reviewing an agency decision under the arbitrary and capricious standard, we consider whether the decision was "based on a consideration of the relevant factors and whether there has been a clear error of judgment." *N. Fork Preservation Ass'n v. Dep't of State Lands*, 238 Mont. 451, 465, 778 P.2d 862, 871 (1989) (citing *Marsh v. Oregon Natural Resources Council*, 490 U.S. 360, 378, 109 S. Ct. 1851, 1861, 104 L. Ed. 2d 377 (1989)). Although our review of agency decisions is narrow, we will not automatically defer to the agency "'without carefully reviewing the record and satisfying [ourselves] that the agency has made a reasoned decision . . . .'" *Friends of the Wild Swan v. Department of Natural Res. & Conservation*, 2000 MT 209, ¶ 28, 301 Mont. 1, 6 P.3d 972 (quoting *Marsh*, 490 U.S. at 378, 109 S. Ct. at 1861).

BACKGROUND

The applicable federal law regarding water quality is called the Clean Water Act (CWA), found within the Federal Water Pollution Control Act. 33 U.S.C. § 1251, et seq. The CWA applies to water flowing out of an area such as the Rosebud Mine and to the quantities, rates, and concentrations of components or elements (chemical, physical, biological) in the water.

The federal and state laws in this realm dovetail, as both refer to each other and state the same goals and similar requirements. For example, both federal and state law provide for permits for discharges to navigable waters

(National Pollutant Discharge Permit System (NPDPS), Montana Pollutant Discharge Elimination System (MPDES)). In this case, the MPDES permit is at issue, but there is applicable and relevant federal law. It is undisputed that the permitting process is meant to control and assure water quality through establishment and maintenance of water quality standards, as well as monitoring of water-affecting activities.

As stated by the Eighth Circuit Court of Appeals:

> Since 1972, the states and the federal government have worked together "to restore and maintain the chemical, physical, and biological integrity of the Nation's waters," in a partnership governed by the Clean Water Act (CWA). 33 U.S.C. § 1251(a). With this goal in mind, the CWA authorizes states to establish water quality standards for bodies of water within its borders. 33 U.S.C. § 1313(a)-(c). Water quality standards "define[] the water quality goals of a water body, or portion thereof, by designating the use or uses to be made of the water and by setting criteria necessary to protect the uses." 40 C.F.R. § 131.2. **They comprise (1) the designated use(s) of the waters (e.g., water supply, propagation of fish, or recreation), 40 C.F.R. § 131.10; (2) the water quality criteria necessary to safely permit those designated uses, 40 C.F.R. § 131.11; and (3) antidegradation requirements to protect waters whose quality is better than required, 40 C.F.R. § 131.12. 40 C.F.R. § 131.6.** States must review their water quality standards at least every three years. 33 U.S.C. § 1313(c)(1). And under the CWA, each state must create a "continuing planning process" (CPP) to, among other things, govern the process for revising its water quality standards. 40 C.F.R. § 130.5(a). "In designating uses of a water body and the appropriate criteria for those uses, the State shall take into consideration the water quality standards of downstream waters and shall ensure that its water quality standards provide for the attainment

/////

/////

and maintenance of the water quality standards of downstream waters." 40 C.F.R. § 131.10(b).

El Dorado Chem. Co. v. United States EPA, 763 F.3d 950, 952-53 (8th Cir. 2014) (footnote omitted; emphasis added); *see also PUD No. 1 v. Wash. Dep't of Ecology*, 511 U.S. 700, 704-05; *Pennaco Energy, Inc. v. Mont. Bd. of Envtl. Review*, 2008 MT 425, ¶ 10, 347 Mont. 415, 199 P.3d 191.

DEQ's consideration of water quality in Montana must involve application of standards, practices, and compliance with both federal and state law. Title 75, chapter 5, of the Montana Code Annotated sets out the statutes relevant to water quality. Montana Code Annotated § 75-5-103(30) (a) defines "pollution" as:

> (i) contamination or other alteration of the physical, chemical, or biological properties of state waters that exceeds that permitted by Montana water quality standards, including but not limited to standards relating to change in temperature, taste, color, turbidity, or odor; or
>
> (ii) the discharge, seepage, drainage, infiltration, or flow of liquid, gaseous, solid, radioactive, or other substance into state water that will or is likely to create a nuisance or render the waters harmful, detrimental, or injurious to public health, recreation, safety, or welfare, to livestock, or to wild animals, birds, fish, or other wildlife.

Title 17, Chapter 30 of the Administrative Rules of Montana relate to water quality. Both Montana statutes and administrative rules refer to applicable federal law.

In Montana, we also have a constitutional mandate regarding our environment:

////

> **Protection and improvement.** (1) The state and each person shall maintain and improve a clean and healthful environment in Montana for present and future generations.
>
> (2) The legislature shall provide for the administration and enforcement of this duty.
>
> (3) The legislature shall provide adequate remedies for the protection of the environmental life support system from degradation and provide adequate remedies to prevent unreasonable depletion and degradation of natural resources.

Mont. Const. art. IX, § 1. *See Montana Envtl. Info. Ctr. v. Dep't of Envtl. Quality*, 1999 MT 248, ¶¶ 64-80, 296 Mont. 207, 988 P.2d 1236.

The administrative record in this case establishes there has been and will be water quality concerns related to the large geographic area disturbed by the Rosebud Mine and the affected surface waters. By its very nature, the practice of disturbing large tracts of land as described in the permit increases the probability of discharge of pollutants.

While the study and implementation of water quality standards involves a high level of scientific analysis, common sense has a role in the application of the legal standards. For example, review of the maps included in the administrative record reveals that a segment of East Fork Armells Creek is surrounded by the Rosebud Mine. There are many claims and much argument in the parties' briefs regarding this segment of the stream, but it is undisputed that the downstream segment of the stream is impaired. DEQ's responsibility for maintaining Montana water quality requires full study and recognition of the effect of the Rosebud Mine on the entire East Fork Armells Creek and the waters into which it flows.

/////

It is also clear that compliance issues arise regularly with regard to discharges by the Rosebud Mine, which are handled or not handled by state and federal regulators. This is a permit case, rather than a compliance case, but there is a general issue regarding the cumulative effect of the mine on Montana's water quality in the streams (ephemeral or not) into which the Rosebud Mine discharges. The renewal process is consistent with the requirement that DEQ regularly revisit our water quality. Yet the years taken by DEQ to renew this permit negate these requirements, or at least the effectiveness of the required procedures.[2]

The following timeline is relevant to the issues raised:

1. December 1, 1999 - DEQ Authorization to Discharge Under the Montana Pollutant Discharge Elimination System (MPDES) issued to WEC for the Rosebud Mine in or near Colstrip, Montana. The 17-page permit was a renewal of a permit issued in 1989. The named receiving waters include nine creeks, two coulees, and one reservoir. Admin. R. at 1836-52.[3] The permit expired at midnight September 30, 2004. Admin. R. at 1836.

/////

[2] "It is the national policy that to the maximum extent possible the procedures utilized for implementing this Act [33 USCS §§ 1251 et seq.] shall encourage the drastic minimization of paperwork and interagency decision procedures, and the best use of available manpower and funds, so as to prevent needless duplication and unnecessary delays at all levels of government." 33 USCS §§ 1251(f).

[3] References to the administrative record provided by DEQ (in the form of a computer disc) are to "Admin. R." and page numbers shown in the administrative record in the lower right hand corner of each page. The computer disc is Exhibit A to an Affidavit of Melissa Sjolund filed October 10, 2014. The record consists of documents and attachments totaling over 2,300 pages. It was provided in only moderately organized fashion and with confusing labels. And rather than providing a single, succinct chronology of events related to the process used by DEQ, the parties filed multiple briefs on the three motions for summary judgment.

2. The five-page Statement of Basis relevant to the 1999 permit renewal (dated July1, 1999) describes the processes by which discharges [4] happened at the Rosebud Mine:

> Western Energy Company is a surface coal producer, with an average annual production rate of approximately 8 million tons of sub-bituminous coal from the Rosebud Mine, located adjacent to the town of Colstrip. Coal is surface mined through dragline-implemented overburden removal, followed by a truck and shovel coal extraction operation.
>
> The coal mining process at the Rosebud mine requires surface disturbance of approximately 400 acres annually. The surface runoff generated by precipitation events occurring over these disturbed drainages is the primary source of wastewater involved in Western Energy's mining operation. Secondary sources of wastewater include groundwater inflow into the open mine pits from bisected overburden, coal and alluvial aquifers, and municipal (Colstrip) water used to wash coal dust from coal handling and loadout facilities. Under typical operational scenarios, these secondary sources provide limited quantities of water, representing only a nominal percentage of most discharges.
>
> ...

[4] "Discharge" is defined in Administrative Rule of Montana 17.30.1304(21) as follows: "[W]hen used without qualification, means the discharge of a pollutant."

> 'Discharge of a pollutant' and 'discharge of pollutants' mean any addition of any pollutant or combination of pollutants to state waters from any point source. This definition includes additions of pollutants into water of the state from: surface runoff which is collected or channeled by man; discharges through pipes, sewers, or other conveyances owned by a state, municipality, or other person which do not lead to a treatment works. This term does not include an addition of pollutants by any 'indirect discharger.'

Admin. R. Mont. 17.30.1304(22). In the 2010 draft permit, the permit dated September 14, 2012, and the modified permit dated September 8, 2014, "discharge" is defined as "the injection, deposit, dumping, spilling, leaking, placing, or failing to remove any pollutant so that it or any constituent thereof may enter in to state waters, including ground water." Admin. R. at 1397, 1702. This mirrors the definition stated in Administrative Rule of Montana 17.30.602(8).

Exhibit 30

> Sediment Ponds and traps located upstream of outfalls are designed to contain a volume of water equivalent to the runoff volume associated with the 10-Year, 24-Hour design precipitation event within an individual sub-watershed.
>
> Mine pits bisect adjacent sub-watersheds at various locations, combining runoff intercepted from multiple sub-watersheds and any groundwater inflow present. Pit dewatering is performed as operationally required, by pumping water into sediment control facilities, or loading water directly into water wagons for haulroad dust suppression.
>
> With storm runoff being the main component of WECo's wastewater and operational requirements largely dictating the disposition of this water, discharge volumes from specific outfalls are variable, and difficult to predict. However, due to the nature of runoff, the quality of the discharged wastewater is relatively constant between individual outfalls, being more dependent upon retention time prior to discharge than on source location.

Admin. R. at 2134-35. The Statement of Basis notes "sediment control facilities" which are on the perimeter of active mine area and 170 outfall[5] locations identified in the original permit. Some outfall locations were downstream of land disturbed by the mine and some were associated with future mining areas.

3. As to water quality, the 1999 Statement of Basis states:

> The limits set in the permit were based on baseline concentrations collected in the 1980's and incorporated in to the original permit issued in 1989. These limits were considered Water Quality Based Nondegradation Limits because they allowed no increase over background conditions (MCA, 75-5-306). Water Quality Based Nondegradation Limits (iron, oil and grease, sulfate, and boron) will remain in effect during stormwater events. The stream segments were

[5] The word "outfall" does not appear in Title 75, chapter 5, regarding water quality. Administrative Rule of Montana 17.30.201 states "[f]or purposes of this rule, the definitions contained in ARM Title 17, chapter 30, subchapter 10 and subchapter 13 are incorporated by reference. The following definitions also apply in this rule: . . . (k) 'outfall' means a disposal system through which effluent or waste leaves the facility or site."

> [sic] discharge takes place are ephemeral which not considered "high quality waters" (MCA, 75-5-103(10)(b)(ii)) and as such nondegradation does not apply (ARM, 17.30.705(2)(b)). This is not a new or increased source of pollution so again the nondegrdation [sic] rules do not apply (ARM, 17.30.705(1)).

Admin. R. at 2135.

4. April 15, 2004 - DEQ received WEC's permit renewal application. Admin. R. at 1719.

5. September 19, 2004 - Letter from the DEQ environmental engineer specialist to WEC stated that its application "is substantially complete." "Under ARM 17.30.1313, since you have submitted a complete renewal application, your present permit is administratively extended and remains in full force and effect until the effective date of the new permit." Admin. R. at 171

6. 2010[6] - Segment of East Fork Armells Creek from Colstrip, Montana, north to the mouth of Armells Creek was listed on State of Montana 2010 list of impaired waters. Admin. R. at 1511.

////

////

////

[6] The administrative record provided by DEQ shows no action by DEQ regarding the renewal of the permit between the letter of September 2004 and June 2009. At that point, DEQ notified WEC that the draft permit and fact sheet were available to them "pre-public notice." Admin. R. at 1710. In August 2009, DEQ granted WEC's request for deferral of public notice regarding a draft permit. (The request, stated in a letter to DEQ, expressed concern regarding water classification, "appropriateness of the data used to characterize water discharged from the mine," and sampling equipment at outfalls.) Admin. R. at 1781-84. DEQ states in its brief that it developed the renewed permit in March 2010. (Br. Supp. Pls.' Mot. S.J. at 10 (Feb. 13, 2016).)

The DEQ "MPDES - Administrative Record Tracking Sheet & Checklist" shows April 18, 2011, as the date the application for a renewed permit was received and November 18, 2011, as the date the application was deemed complete. Admin. R. at 1116.

7. August 24, 2010 - DEQ issued a 41-page draft permit.[7] The maps included in the administrative record show the location of the Rosebud Mine, surrounded by the creeks and coulees into which discharges are allowed by the permit. East Fork Armells Creek flows east through or between property owned by the Rosebud Mine before it reaches Colstrip, Montana, and flows north/northwest thereafter.

8. August 26, 2010 - Written comments from Plaintiff's counsel include, among other claims, the claims made in this action.

9. September and October 2010 - The water quality documents added to the administrative record in this case during this time note the following regarding the segment of East Fork Armells Creek from Colstrip, Montana, north to the mouth of Armells Creek: "One or more uses are impaired and a TMDL [total maximum daily load] is required." Admin. R. at 1511. While the assessment had not been started, there was no description of the segment as ephemeral and the category titled "Overall Condition of Segment" includes the following:

> Physical/Chemical: East fork Armells is typical of most streams in this region. The water is very hard, saline, and high in sulfates. Where TSS data was available (2005), concentrations were low. Mining activities (including water pumped from the Yellowstone River to seeping ponds) likely have contributed to increased TDS concentrations and "water logging" below Colstrip. DEQ correspondence in 1998 estimated a 50% increase in TSC concentrations in the EFAC alluvium from 1977 to 1997. Water logging may not currently be occurring. The elevated SC concentrations make this water unsuitable for irrigation under

[7] No public notice regarding this draft permit was found by the Court in the administrative record. Plaintiffs' comments dated August 26, 2010 note a public notice dated July 12, 2010 which failed to recognize the waters listed as impaired. Admin. R. at 1630.

Exhibit 30

ordinary circumstances. This water is acceptable for use with livestock accustomed to its use, but is not recommended for pregnant or lactating cows. Data from the 1970's show the NO2+NO3 regularly exceeded criteria, although this was not the case in 2005.

In 2005, TKN at the lower site moderately exceeded the contact recreation criteria, and slightly exceeded the contact recreation criteria, and slightly exceeded the aquatic life criteria. At the middle site, contact recreation and aquatic life criteria were slightly exceeded. The most reliable metals data is from the 2005 assessment, which showed no exceedences [sic].

Other: TSS does not appear to be an accurate cause of impairment. The macroinvertebrate samples, field observations, and historical and 2005 water chemistry data indicate that nutrients may be a source of impairment. The SC values do not appear to be vastly different from other drainages in the region; however, the probable impact from municipal sources and industrial pond seepage cannot be ignored. The past and present impacts from changes in groundwater chemistry, surface flow, and atmospheric deposition merits further investigation. Salinity/TDS/chlorides will remain a cause of impairment.

Admin. R. at 1524. The same Water Quality Standards Attainment Record ends with reference to the stream segment as "Waters where one or more applicable beneficial uses have been assessed as being impaired or threatened, and a TMDL is required to address the factors causing the impairment or threat." Admin. R. at 1527.

10. May 14, 2012 - A public notice was issued by DEQ regarding MPDES MT0023965. In the notice, DEQ claimed there was no need to set TMDL standards, as the permit was not new.

11. September 14, 2012 - DEQ issued the renewed permit Number 0023965 for the Rosebud Mine. The permit had been changed from the 2010 draft permit, as outlined in a letter to the vice president and general manager of

Exhibit 30

WEC dated the same day. Admin. R. at 1348-50. The 2012 permit is 59-pages long. The related permit fact sheet is 73-pages long. Although it makes reference to it as an attachment to the renewed permit, the administrative record does not include any statement of basis attached to the 2012 permit.

12. The Permit Fact Sheet related to the 2012 permit (dated March 2012) "identifies the legal requirements and technical rationale that serve as the basis for the requirements" of the permit. Admin. R. at 1411. As stated by DEQ in this fact sheet, the coal seam accessed and removed by WEC "is approximately 100 feet below the surface, with an average thickness of 24 feet." Admin. R. at 1411. "The average annual production rate of the mine is approximately 10-12 million tons of coal, requiring about 400 acres of surface disturbance per year." Admin. R. at 1412.

13. As to the characteristics of East Fork of Armells Creek, the 2012 fact sheet states:

> The State of Montana 2010 integrated 303(d) list and 305(b) Water Quality Report lists . . . East Fork Armells Creek segment MT42K002_110 from Colstrip to the mouth is listed as a category 5 water body, indicating that one or more beneficial uses have been assessed as being impaired or threatened and a TMDL is required. This segment of East Fork Armells Creek is listed as partially supportive of aquatic life and of warm water fisheries. The probable causes of impairment are nitrate plus nitrite, electrical conductivity, TDS, and total Kjehldahl nitrogen, with agriculture and coal mining transfer of waters as probable sources of impairment. As this segment is directly downstream of the mine, the permit contains monitoring requirements or limitations for electrical conductivity, TDS, and nitrate plus nitrite to address the discharge of these pollutants from the Facility. It is not anticipated that the Facility is a source of total Kjehldahl nitrogen. If a TMDL is adopted an approved for these pollutants, the Permit may be re-opened to include effluent limitations

Exhibit 30

based on appropriate wasteload allocations (WLAs) from the TMDL for this parameter.

Admin. R. at 1429.

As to the new outfalls in the permit, the Permit Fact Sheet states that 12 outfalls "constitute new or increased sources; accordingly, the discharge is subject to Montana Nondegradation Policy (75-5-303, MCA; ARM 17.30.705)." Admin. R. at 1452.

14. June 13, 2012 - Written comments from Plaintiff's counsel include, among other claims, the claims made in this action. Admin. R. at 109-26.

15. In its undated "Response to Public Comment," DEQ maintains the positions it now defends in this Court. Admin. R. at 1488-1510.

16. May 8, 2014 - Permit renewal application received by DEQ. WEC stated that its average annual coal production rate is approximately 10 to 12 million tons of sub-bituminous coal at the Rosebud Mine. It asserts that the mine disturbs approximately 350 acres per year. Admin. R. at 241.

17. May 2014 - Permit Fact Sheet states:

> The following modifications are included:
>
> A. Correct the identification of certain "new" source outfalls that were previously permitted and are "existing" sources;
>
> B. Transfer fifteen outfalls to Western Alkaline Standards;
>
> C. Revise water quality-based effluent limitations
>
> D. Revise effluent monitoring requirements; and
>
> E. Remove three representative monitoring outfalls.

Admin. R. at 76. The fact sheet states the new outfalls or sources either do not require the setting of new standards, or the discharges involved do not violate the applicable standards. Admin. R. at 79-80.

Exhibit 30

18. June 9, 2014 - Public notice by DEQ regarding modification of the 2012 permit. It includes the following language:

> This is a major modification of the MPDES permit for the Western Energy company rosebud Mine. The facility discharges to East Fork Armells Creek, Stocker Creek, Lee Coulee, west fork Armells Creek, Black Hank Creek, Donley Creek, Cow Creek, Spring Creek, and Pony Creek. The modification includes the following actions; correct the identification of certain "new" source outfalls that were previously permitted and are "existing" sources; transfer fifteen outfalls to Western Alkaline Standards; revise water quality-based effluent limitations; revise effluent monitoring requirements; and remove three representative monitoring outfalls.
>
> As specified in the Administrative Rules of Montana at ARM 17.30.1361 and ARM 17.30.1365(4)(b) only the permit conditions described above are reopened and subject to this public notice and comment period. All other provisions of the permit remain in effect and are not reopened.

Admin. R. at 149-50.

19. September 8, 2014 - DEQ issued the 2012 permit Number 0023965 in modified form for the Rosebud Mine. There is a decrease in the number of outfalls designated as "new" from twelve to four. The permit expires October 31, 2017.

DISCUSSION

A. Plaintiffs' Standing

Plaintiff MEIC relies on the facts related by Steve Gilbert, a member of MEIC and outdoor recreationalist in Montana, to establish its standing to bring this lawsuit. The facts are set out in a deposition taken by the parties on February 13, 2014, as well as an affidavit of Gilbert filed February 13, 2015. Gilbert lives in Helena, Montana, and has been a resident of Montana since 1967.

Exhibit 30

He describes his employment as a "biological consultant," and for 25 years he was "part owner and president of an environmental consulting company that specialized in wildlife, aquatics/fisheries, soils, vegetation, forestry, range and hydrology." With regard to the area of the Rosebud Mine, Gilbert has traveled regularly to the area for various purposes. He worked in the area for years and has personal knowledge of East Fork Armells Creek, Cow Creek, and Rosebud Creek. He hunted in relevant areas during the time the renewal application was before DEQ.

Gilbert's recreational use and enjoyment of the area near the Rosebud Mine has been affected and will be affected, partially because of the water pollution caused by the mining activity. He has knowledge relevant to the environmental impacts of the mine based on his personal observations and his MEIC connections. Gilbert was a member of MEIC during the years that it was involved in the administrative processes associated with this permit. He was a voting member of the MEIC council when the decision was made to file this lawsuit.

Gilbert's more recent visits to the area of Rosebud Mine have been to hunt upland game birds and to visit friends. He intends to continue those activities and is concerned regarding the degradation and pollution of the waters in the area due to the Rosebud Mine.

The standard for determining whether Plaintiffs have standing is set out in *Friends of the Earth, Inc., v. Laidlaw Environmental Services (TOC), Inc.*, 528 U.S. 167, 183-85 (2000):

> We have held that environmental plaintiffs adequately allege injury in fact when they aver that they use the affected area and are persons "for whom the aesthetic and recreational values of the area

will be lessened" by the challenged activity. *Sierra Club v. Morton*, 405 U.S. 727, 735, 31 L. Ed. 2d 636, 92 S. Ct. 1361 (1972). See also *Defenders of Wildlife*, 504 U.S. at 562-563 ("Of course, the desire to use or observe an animal species, even for purely esthetic purposes, is undeniably a cognizable interest for purposes of standing.")

. . .

[The] affidavits and testimony presented by FOE in this case assert that Laidlaw's discharges, and the affiant members' reasonable concerns about the effects of those discharges, directly affected those affiants' recreational, aesthetic, and economic interests. These submissions present dispositively more than the mere "general averments" and "conclusory allegations" found inadequate in *National Wildlife Federation*. 497 U.S. at 888. Nor can the affiants' conditional statements -- that they would use the nearby North Tyger River for recreation if Laidlaw were not discharging pollutants into it -- be equated with the speculative "'some day' intentions" to visit endangered species halfway around the world that we held insufficient to show injury in fact in *Defenders of Wildlife*. 504 U.S. at 564. . . . [W]e see nothing "improbable" about the proposition that a company's continuous and pervasive illegal discharges of pollutants into a river would cause nearby residents to curtail their recreational use of that waterway and would subject them to other economic and aesthetic harms. The proposition is entirely reasonable, the District Court found it was true in this case, and that is enough for injury in fact.

See also Mont. Envtl. Info. Ctr. v. Dept. of Envtl. Quality, 1999 MT 248, ¶¶ 41 - 45, 296 Mont. 207, 988 P.2d 1236.

Gilbert's contact with the streams and land in the area of the Rosebud Mine, together with the effect of the mine on his use and enjoyment of the area, establish injury in fact. Therefore, MEIC's standing is established. One party with standing satisfies the standing requirements for other parties. *Aspen Trails Ranch v. Simmons*, 2010 MT 79, ¶ 45, 356 Mont. 41, 230 P.3d 808.

Exhibit 30

B. Classification of Streams

The record before this Court is not consistent as to the classification of waters involved. While much of the record lists waters as "C-3" pursuant to Administrative Rule of Montana 17.30.611(1)(c), DEQ also states that the waters are ephemeral pursuant to Administrative Rule of Montana 17.30.615 and .637(4). The classification of Montana's waters was and is the starting point for determination of applicable water quality standards.

The determination that the waters are C-3 waters cannot be changed without compliance with applicable law. Administrative Rule of Montana 17.30.615 requires:

> (2) Prior to reclassifying a specific water body classified in ARM 17.30.607 through 17.30.614 under one of the water-use classifications identified in (1)(a) through (h) and before the U.S. Environmental Protection Agency's approval of the water body's revised classification, a use attainability analysis must be conducted in accordance with 40 CFR 131.10(g), (h), and (j).

This clearly applies to the waters that are currently classified as C-3 waters and which DEQ now wishes to treat as ephemeral (with reduced water quality standards). Any reclassification regarding the waters must be pursuant to statutory requirements (Mont. Code Ann §§ 75-5-103, -301), including the required public process. *See* Admin. R. Mont. 17.30.606.

////

////

////

////

////

While DEQ now admits within the context of this lawsuit that a portion of East Fork Armells Creek is not ephemeral,[8] its lack of consideration of the evidence in the administrative record showing that a portion of East Fork Armells Creek is not ephemeral during the renewal process at issue shows a clear error of judgment by DEQ during the permitting process.

DEQ maintains further modification of the permit (due for consideration in the year 2016) will address the situation as to the applicable water quality standards. There is no basis to find the situation could not have been addressed at some point between the September 30, 2004 expiration of the permit and the modification that became effective November 1, 2014. In the end, this is one example of the overall failure by DEQ to protect the relevant waters by engaging in a lengthy, arbitrary process of permitting.

DEQ's determination in the current permit that all applicable waters are ephemeral also affects the agency's conclusions regarding the need for determining TMDLs and all standards applicable to the new discharges through new outfalls. For example, it appears the agency relies on the conclusion regarding streams being ephemeral to ignore the water quality records noting that TMDLs need to be determined for a segment of East Fork Armells Creek. Given DEQ's concession that not all of the relevant streams are ephemeral, this conclusion is arbitrary and not supported by the applicable law. Mont. Code Ann §§ 75-5-103, -301; Admin. R. Mont. 17.30.615. And, as noted by DEQ in its notices and briefs, the law applicable to the system of classification of streams,

[8] In an affidavit signed February 13, 2015, Melissa Sjolund, DEQ employee and author of the permit issued in 2012 and modified in 2014, states that since the 2014 permit modification, another modification is being sought because "a recent hydrologic assessment of East Fork Armells Creek indicated that a portion of that stream . . . may be intermittent." (Br. Supp. Pls.' Mot. S.J. (Feb. 13, 2016), Ex. 1, Aff. Melissa Sjolund, at 4.)

Exhibit 30

setting of water quality standards, and issuance of permits presumes a determination of standards such as TMDLs as prerequisite to determining whether water quality standards will be violated by discharges to any identified surface water.

Given the undisputed fact that DEQ's permit process is integral to protection of Montana's water quality, its conclusions that are not supported by the relevant objective and scientific data in the administrative record must be deemed arbitrary and unsupported and, thus, unlawful. *See Ravalli County Fish & Game Ass'n v. Mont. Dep't of State Lands*, 273 Mont. 371, 381, 903 P.2d 1362, 1369 (1995).

C. Use and Monitoring of Outfalls

The significance of the location and monitoring of outfalls at the Rosebud Mine is clearly established in the record. The outfalls are the locations where mine pollutants may touch the earth. In fact, if there is a discharge of a pollutant, it may only be at an outfall. The language of the 2012 permit, as modified in 2014, is that "[t]he authorization to discharge provided under this permit is limited to those outfalls specially designated below as discharge locations. Discharges at any location not authorized under an MPDES permit is a violation of the Montana Water Quality Act. . . ." Admin. R. at 19. "The location of each outfall regulated by this permit shall be permanently identified in the field." Admin. R. at 28.

Yet DEQ seems inconsistent in its approach to outfalls. For example, during the modification process between 2012 and 2014, public comment was made regarding the fact that some of the outfalls set out in the renewal

Exhibit 30

application by WEC were the same as previous outfalls, but identified in the 2012 permit as new outfalls. The response by DEQ was:

> Neither the permit writer nor the permittee cross referenced the geographic coordinates of the 151 outfalls contained in the renewal application with coordinates of outfalls contained in previous MPDES permits issued to WECo for the Rosebud Mine. Such cross referencing would not routinely be a part of MPDES permit application review.

Admin. R. at 8. Given the importance of outfall locations and monitoring, DEQ's procedures that do not specify and confirm the location of outfalls appear indefensible.

It is undisputed that the four new outfalls permitted by DEQ in 2014 involve new discharge points and potentially new discharge of pollutants points. It is also undisputed that nondegradation review is applicable. Admin. R. Mont. 17.30.701-08.

The current permit does not require that all outfalls be monitored in the same way or on the same schedule. The permit first identifies 151 outfalls to the relevant receiving waters or mixing zones. It then lists "Final Effluent Limitations and Monitoring Requirements" for each of the creeks and coulee, with the monitoring requirements set at the frequency of once per day, week, month, or year. The monitoring is to occur "at the overflow structure where effluent discharges as overflow from the sediment control structure, or at the end of the discharge pipe when pumped or drained, and prior to contact with the receiving water." Outfalls are associated with each creek and the coulee. This monitoring relates to 136 outfalls. Admin. R. at 23-28.

////

The permit then sets out "Alternate Numeric Effluent Limitations and Monitoring Requirements" applicable to the same 136 outfalls "applied to discharges driven by precipitation events and/or snowmelt." Admin. R. at 29-34. These appear to be in addition to the initial monitoring requirements.

But then the permit states:

> Due to the number of outfalls at the facility and inaccessibility of remote outfalls, representative monitoring will be allowed only for discharges resulting from precipitation events. Discharges consisting of stormwater runoff from areas . . . may be sampled at the representative outfalls listed in Table 16, corresponding to 20% of total outfalls.

Admin. R. at 34. Table 16 lists 20 outfalls, four of which are not within the 136 listed in the first two sections regarding monitoring. The relevant permit fact sheet adds:

> Discharges consisting of stormwater runoff from areas classified as "Alkaline Mine Drainage" (40 CFR 434 Subpart D) are materially similar in terms of activities taking place in each area, the characteristics of soil types present, the expected runoff pollutant concentrations, the type of stormwater treatment and best management practices. Therefore, the Department has determined representative sampling may be obtained at 20% of outfalls to obtain representative samples of precipitation-driven discharge.

Admin. R. at 1447. Finally, the permit lists 69 outfalls subject to "Western Alkaline Coal Mining Standards." Admin. R. at 35-38.

The language of the permit (before and after modification) leaves the permit reader with no firm knowledge regarding what monitoring practices will be applied in any given situation. Even with consideration of the administrative record in this case, there is inadequate or inaccurate bases for the

Exhibit 30

monitoring types, locations, and frequencies. As to DEQ's conclusion that monitoring of 20 percent of the outfalls is sufficient, there is only a conclusory statement regarding soil types, runoff, and treatment. There is a distinct lack of scientific analysis supporting the conclusion that the remaining 80 percent of the outfalls previously deemed necessary no longer will be used as "representative" of the large-scale activity of the mine. There seems to be as much deference by DEQ to the logistical issues of monitoring raised by WEC as there are to the need to monitor the affected surface waters.

Plaintiffs claim the permit allows monitoring by WEC that does not adequately protect Montana's water in that it allows monitoring tailored to WEC's claims of circumstances making monitoring difficult. DEQ and WEC respond that federal regulations allow representative monitoring. DEQ and WEC assert the language of 40 CFR 122.41(j)(1) that "[s]amples and measurements taken for the purpose of monitoring shall be representative of the monitored activity." Plaintiffs cite 40 CFR 122.44 (i)(1)(ii), which provides, with regard to similar federal permits, the monitoring requirements include "[t]he volume of effluent discharged from each outfall."

Given the lack of analysis present in the record as to DEQ's decision to reduce the monitoring of outfalls, the decision is unsupportable. Failure to monitor will certainly reduce the chances of finding discharges and will certainly reduce the regulation of the water quality in an active mining area. The size of the mine, the number of outfalls, and the logistics of monitoring are relevant circumstances, but are not found within the law applicable to the ultimate goal of adequately protecting surface waters and do not mitigate DEQ's responsibilities

//////

Exhibit 30

for regulation. In this case, the reduced monitoring and modified standards for the waters at issue are arbitrary.

SUMMARY

When viewed in its totality, the record of DEQ's decisions as to Final Modified Permit number MT0023965 show clear errors of judgment regarding the protection of the waters into which the Rosebud Mine discharges. Rather than making reasoned decisions, the decisions are arbitrary and not supported by the law applicable to the permitting process.

Based on the foregoing, the issuance of Final Modified Permit number MT0023965, effective November 1, 2012 and modified September 14, 2014, is hereby declared invalid, and this matter is remanded to DEQ for consideration consistent with this opinion.

IT IS SO ORDERED.

DATED this 14 day of March 2016.

Ms. Dicki Peterson
Western Energy Company
Rosebud Coal Mine Area B, C1984003B
P.O. Box 99
138 Rosebud Lane
Colstrip, MT 59323-0099

Permit ID: C1984003B
Revision Type: Amendment
Permitting Action: Deficiency
Subject: AM4, Seventh Round Acceptability Deficiency

Dear Dicki:

The Department of Environmental Quality (DEQ) has completed its acceptability review regarding Western Energy Company's application for Amendment AM4. The following deficiency must be adequately addressed before DEQ can determine the application acceptable:

17.24.314(4) and (5): A more complete explanation of the hydrologic response of East Fork Armells Creek to mining is needed. This information is needed to better determine the impacts to the hydrologic balance caused by current mining as well as to confirm that the proposed operation has been designed to minimize impacts to the hydrologic balance and prevent material damage to the hydrologic balance outside the permit area.

More information is needed to anticipate and predict the long-term effects of mining on stream flow and water quality of the stream and alluvium. Please provide a water budget that includes inputs to the stream from:

- the release of pond and pit water
- infiltration from sediment ponds adjacent to the stream
- disposal of water from operations and domestic use at the Area A facilities

Please indicate how the additional sources of water associated with mine activity have affected stream flow.

Review of the available data indicates the stream and alluvial wells adjacent to the facilities area are showing steadily increasing concentrations of ionic water quality components. These components have narrative standards based on uses. Please address the following:

- What is the source of the increase and at what point is the concentration expected to reach equilibrium or begin to decrease in concentration?

- How is the increased saturation of spoil adjacent to the stream likely to affect long term water quality in the stream and alluvium? What is the TDS concentration expected to be at full saturation of the spoil?
- What are the long term implications for stream and alluvial water quality associated with inputs from the facilities area, including the fate and breakdown products of lignin sulfonate?
- How have increases in specific water quality parameters affected the uses identified below and how are those uses likely to be affected with future predicted water quality changes?

EFAC existing and anticipated uses include water for livestock, wildlife, and aquatic life. Please confirm, based on current and future anticipated concentrations in the stream, that uses have not or will not be impaired. Three aquatic life surveys were completed in the 1970's but there have been none since that time. Please conduct a current aquatic survey along stretches of EFAC adjacent to the Rosebud Mine permit areas (Areas A, B, and C) to identify assemblages of aquatic life using the stream habitat. This information also will be useful for future permit revisions in Area A and Area C.

Please feel free to contact Robert D. Smith at 406-444-7444 with questions regarding this letter.

Sincerely,

Exhibit 28

GEOCHEMICAL PROCESSES IN GROUND WATER RESULTING FROM SURFACE MINING OF COAL AT THE BIG SKY AND WEST DECKER MINE AREAS, SOUTHEASTERN MONTANA

By David W. Clark

Abstract

A potential hydrologic effect of surface mining of coal in southeastern Montana is a change in the quality of ground water. Dissolved-solids concentrations in water in spoils aquifers generally are larger than concentrations in the coal aquifers they replaced; however, laboratory experiments have indicated that concentrations might decrease if ground water flows from a spoils aquifer to a coal aquifer. This study was conducted to determine if the decreases indicated in laboratory results occur onsite and, if so, which geochemical processes caused the decreases. The Big Sky and West Decker Mine areas were chosen for study as both contain coal of the Tongue River Member of the Paleocene Fort Union Formation, but have differences in mineralogy, ground-water quality, and flow processes.

Solid-phase core samples of spoils, unmined overburden, and coal and samples of ground water were collected from 16 observation wells at the two mine areas. Selected solid-phase samples were analyzed for elemental concentrations, exchangeable cations, and mineral constituents. Water samples were analyzed for major and trace constituents, selected isotopes, and dissolved gases.

In the Big Sky Mine area, changes in ground-water chemistry along an inferred flow path from an upgradient coal aquifer to a spoils aquifer probably were a result of dedolomitization caused by the irreversible dissolution of gypsum at or near calcite-dolomite saturation. Dissolved-solids concentrations were unchanged as water flowed from a spoils aquifer to a downgradient coal aquifer.

In the West Decker Mine area, dissolved-solids concentrations apparently decreased from about 4,100 to 2,100 milligrams per liter (mg/L) as water moved along an inferred flow path from a spoils aquifer to a downgradient coal aquifer. Apparent decreases in selected constituent concentrations included: sodium, from 1,500 mg/L to less than 900 mg/L; bicarbonate, from about 3,000 mg/L to less than 2,400 mg/L; and sulfate, from 1,100 mg/L to less than 100 mg/L. Data for solid-phase and aqueous geochemical characteristics, including types of reactive minerals, isotopic ratios, and dissolved-gas concentrations, were used to develop geochemical models to analyze changes in water chemistry. Geochemical processes postulated to result in the decrease in dissolved-solids concentrations along this inferred flow path include: bacterial reduction of sulfate utilizing the organic matter in coal as an energy source; reverse cation exchange of sodium ions for calcium or magnesium ions within the coal; and precipitation of carbonate and iron-sulfide minerals. Even though these processes are thought to be those most likely occurring, they are considered nonunique and might not be the only feasible processes. Questions about the sulfate system, the rate of sulfate reduction, the isotopic composition of the coal, the existence of secondary carbonates and amorphous iron-sulfide minerals in the coal, and other questions need to be resolved before the geochemical processes occurring in the system are fully understood.

INTRODUCTION

One of the potential hydrologic effects of surface coal mining in southeastern Montana is a change in the quality of ground water. Dissolved-solids concentrations in water in spoils aquifers are about 1,000 mg/L larger (Davis, 1984a) than in the coal aquifers they replaced. Laboratory experiments (Davis, 1984a; Davis and Dodge, 1986) have indicated that dissolved-solids concentrations might decrease by several hundred milligrams per liter when ground water flows from an aquifer in coal mine spoils (hereinafter referred to as spoils and spoils aquifer) back through a coal aquifer. Geochemical modeling of the results of those experiments indicated that several geochemical processes were occurring, including mineral dissolution and precipitation, and either exchange or adsorption reactions.

Exhibit 28

The Big Sky and West Decker Mine areas in southeastern Montana offered unique opportunities to study such geochemical processes onsite. Both mines are located in the Tongue River Member of the Paleocene Fort Union Formation, but distinct differences between the mine areas in mineralogy and ground-water flow processes have resulted in differences in water quality. The Big Sky Mine area has a local ground-water flow system, with at least some recharge by direct infiltration of precipitation on permeable overburden and spoils, and a calcium-magnesium sulfate type water. The West Decker Mine area has a more regional ground-water flow system, with little or no recharge through the mine spoils by direct infiltration of precipitation on overburden or spoils, and a sodium bicarbonate type water (Davis, 1984a). Knowledge of the geochemical processes occurring in each mine area and the relation of those processes to the flow systems and mineralogy can be of considerable value in evaluating future mining and reclamation efforts. Therefore, this project was conducted in cooperation with the Montana Department of State Lands and the Bureau of Land Management to further understand the geochemical processes controlling the quality of water in areas with surface mining of coal.

Purpose and Scope

This report describes the geochemical processes that occur in ground water as a result of surface mining of coal at the Big Sky and West Decker Mine areas in southeastern Montana. The report is based on data obtained during 1988 through 1990 from intensive sampling and analysis of rock material and water at several points along flow paths extending from coal aquifers upgradient of each mine, through spoils aquifers to downgradient coal or other aquifers.

Data requirements included mineralogy, elemental chemistry, and ion-exchange capabilities obtained from solid-phase samples collected by core drilling during monitoring-well installation. These data were obtained by scanning electron microscopy (SEM), X-ray diffraction and other techniques. Other data include ground-water samples analyzed for major and minor chemical constituents, isotopic composition, and dissolved gases. The data were then analyzed with geochemical models.

Previous Investigations

Numerous geohydrologic studies have been conducted in the coal-producing areas of southeastern Montana by personnel of the U.S. Geological Survey, the Montana Bureau of Mines and Geology, and Montana State University. Davis (1984a) investigated the geochemistry and geohydrology of the Big Sky and West Decker Mine areas. Davis and Dodge (1986) reported the results of laboratory experiments related to spoils-aquifer water and coal in the same mine areas; the resulting report was the catalyst for this study. Dockins and others (1980) studied sulfate reduction in ground water of southeastern Montana. Davis (1984b) estimated ground-water inflow to the pits at the West Decker Mine area and Lee (1980) studied the regional geochemistry.

Geography

The study areas are in the coal-rich Powder River structural basin, which extends from southeastern Montana to northeastern Wyoming (fig. 1), in the northern Great Plains Physiographic Province. Both coal-mining areas are drained by tributaries of the Yellowstone River. The Big Sky Mine area, near the town of Colstrip, is drained by tributaries of Rosebud Creek; altitudes within this area range from about 3,600 ft above sea level near the northwest mine boundary to about 3,000 ft near Rosebud Creek. The West Decker Mine area is drained by the Tongue River; altitudes within the area range from about 4,000 ft at the west mine boundary to about 3,400 ft near the Tongue River.

The climate of most of the non-mountainous areas in southeastern Montana is semiarid. Figure 2 shows the annual precipitation at Colstrip and Decker from 1979-90, the time period of this and studies cited in the above Previous Investigations. Average annual precipitation for 1961-90 at Colstrip was 15.06 in., and at Decker was 12.69 in. About half of the annual precipitation occurs during April, May, and June, on the basis of records from the National Weather Service.

Exhibit 28

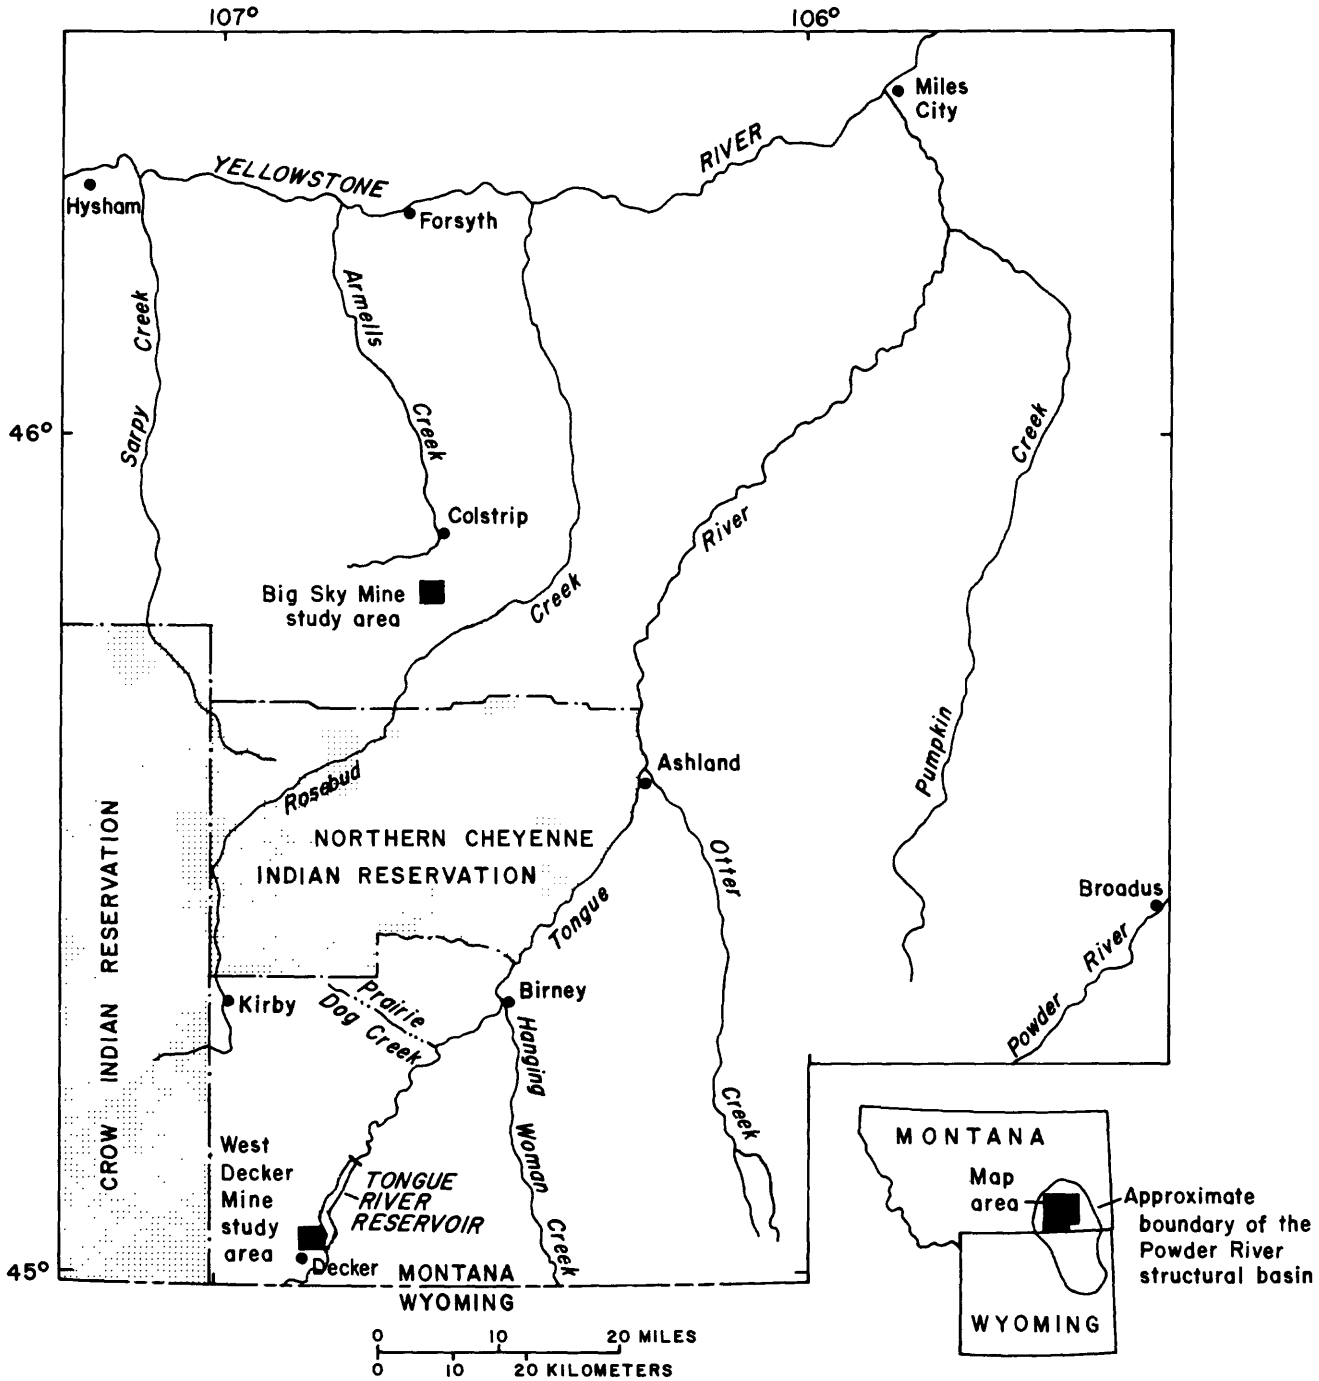

Figure 1. Location of study areas.

Exhibit 28

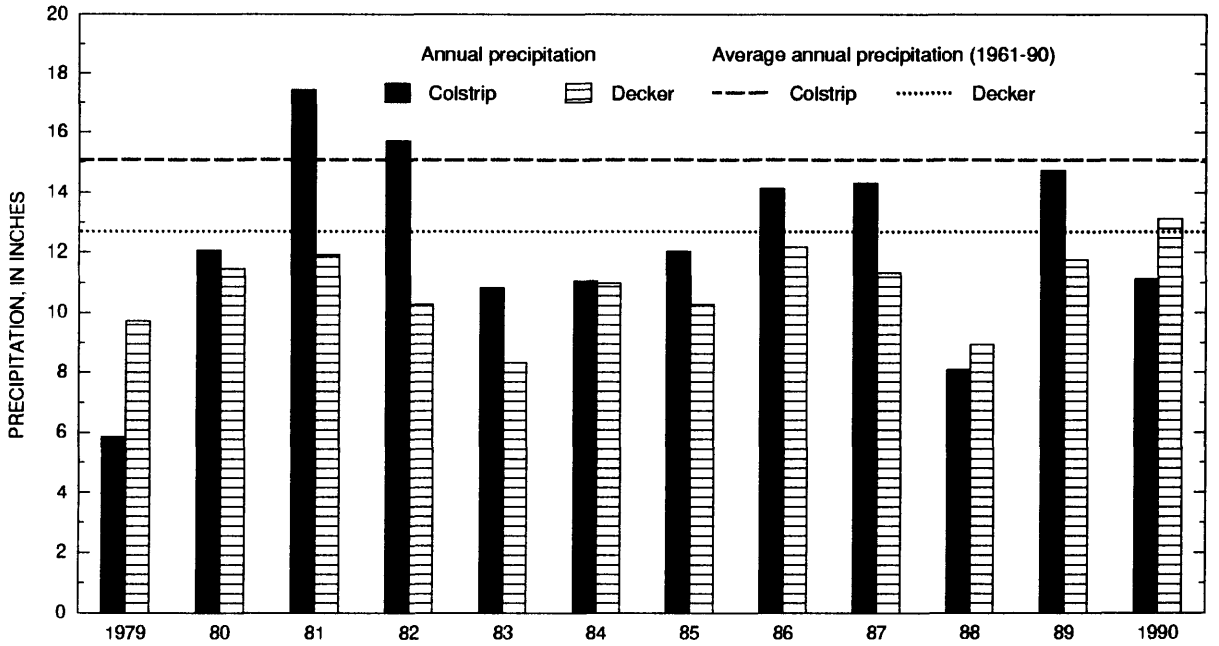

Figure 2. Annual and average annual precipitation at Colstrip and Decker, Montana.

Site-Numbering System

In this report, sites are numbered according to geographic position within the rectangular grid system used by the Bureau of Land Management (fig. 3). The site-identification number consists of 14 characters. The first three characters specify the township and its position north (N) or south (S) of the Montana Base Line. The next three characters specify the range and its position east (E) of the Montana Principal Meridian. The next two characters are the section number. The next four characters designate the quarter section (160-acre tract), quarter-quarter section (40-acre tract) quarter-quarter-quarter section (10-acre tract), and quarter-quarter-quarter-quarter section (2 1/2-acre tract), respectively, in which the well is located. The subdivisions of the section are designated A, B, C, and D in a counterclockwise direction, beginning in the northeast quadrant. The final two digits form a sequential number in order of inventory; for example, site 09S40E16BADC01 (fig. 3) is the first site inventoried in the SW1/4SE1/4NE1/4NW1/4 sec. 16, T. 9 S., R. 40 E.

Acknowledgments

The author appreciates the assistance and cooperation extended by employees of the Peabody Coal Company, the Decker Coal Company, and Peter Kiewit Sons, Inc. Many personnel of the U.S. Geological Survey also assisted in this study. In particular, acknowledgment is extended to Gene C. Whitney, Kenneth J. Esposito, and Joan J. Fitzpatrick, Branch of Sedimentary Processes (Denver, Colo.), for their assistance in the solid-phase sample analysis and interpretation. L. Neil Plummer and Donald C. Thorstenson (Reston, Va.) provided valuable assistance with the project design and data analysis and interpretation.

Exhibit 28

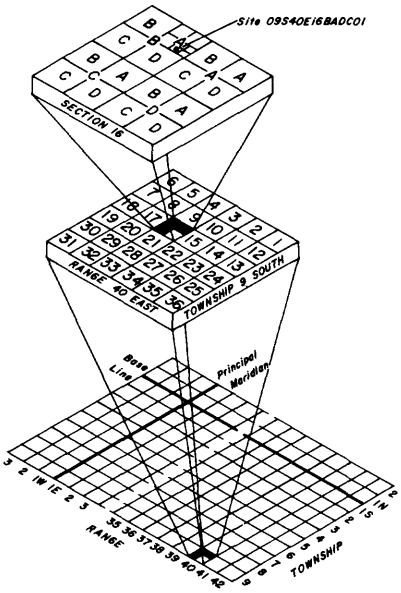

Figure 3. Site-numbering system.

METHODS OF STUDY

Changes in ground-water geochemistry within the coal mine areas were quantified primarily by the collection and analysis of solid- and aqueous-phase samples obtained through the drilling and installation of observation wells. At both mine areas, wells were completed in coal upgradient from the mine disturbance, mine spoils, and coal downgradient from saturated spoils. Details on well construction and measured water levels in the observation wells are shown in table 1. Solid-phase samples of spoils, unmined overburden, interburden, and coal were collected primarily from cores obtained during drilling. Water samples were collected by pumping or bailing after wells had been developed.

Solid-phase samples were analyzed for mineral constituents by X-ray diffraction, thin-section petrology, and scanning electron microscopy (SEM). Well-crystallized minerals were identifiable by X-ray diffraction if their abundance generally was greater than about 5 percent. Clay mineralogy was determined by X-ray diffraction of untreated samples, glycolated samples, and samples heated to 550 °C. Petrographic analysis and interpretations were completed for 10 rock samples, and petrographic analysis and analysis by SEM were completed for thin sections of selected coal samples. Solid-phase samples also were analyzed using SEM equipped with energy dispersive spectroscopy (EDS). Thin sections were prepared from cores of coal coated with a conducting layer of either carbon or gold. SEM photographs were taken and chemical constituents were analyzed with EDS for selected non-organic grains within the coal thin sections.

Cation and trace-element concentrations and exchangeable cations were determined for 20 selected core samples from overburden siltstone, sandstone, shale, clinker, and spoils by the Montana Bureau of Mines and Geology analytical laboratory. Nine coal samples collected from drill cores and one grab sample of coal were analyzed for 65 major and trace elements by the U.S. Geological Survey, Branch of Geochemistry laboratory. Selected coal samples were combusted at 800 °C to determine the percentage of ash. Fifteen mg of the ash were pulverized and sieved to pass 100 mesh and then chemically analyzed.

Ground-water samples were analyzed for a variety of properties and constituents. Analysis included major and trace dissolved constituents, onsite properties, dissolved gases, and isotopic composition. Water samples were analyzed for major and trace constituents by the Montana Bureau of Mines and Geology. Isotope and some trace-metal analyses were conducted by the U.S. Geological Survey National Water Quality Laboratory or private contractors.

Several properties and constituents including specific conductance, temperature, pH, dissolved oxygen, alkalinity, dissolved sulfide, and total and ferrous iron were measured onsite because of their potential instability. Specific conductance, temperature, pH and, where applicable, dissolved oxygen were measured in a flow-through

Exhibit 28

sampling chamber after the values had stabilized. At least three well volumes were withdrawn before water-sample collection. Water generally was pumped slowly from the well head into the sampling chamber to prevent or minimize degassing or other atmospheric interference. The dissolved sulfide and iron species were measured semiquantitatively using a field colorimeter. Samples for laboratory analysis that required filtering generally were filtered through a 0.45-µm membrane filter; some samples analyzed for dissolved aluminum, iron, and manganese were filtered through a 0.10-µm membrane filter to remove colloidal material.

Dissolved gases were collected using a sampling apparatus illustrated and described in detail by Hobba and others (1977). A sample of the vapor phase was analyzed by gas chromatographic procedures for nitrogen, argon, oxygen, carbon dioxide, methane, and ethane. Dissolved gases in water were analyzed by Donald C. Thorstenson of the U.S. Geological Survey.

Isotopic composition can be a useful indicator of hydrologic and geochemical conditions. Isotopic fractionation might occur in many elements during phase transitions and chemical and biological reactions. These fractionations are due to slight variations in the physical and chemical properties of various isotopes of an element and are proportional to the differences in their masses. The hydrologically significant isotopes considered in this report are the stable isotopes of oxygen, hydrogen, carbon, and sulfur, and tritium, a radioactive isotope of hydrogen. Samples for the stable isotopes were collected according to guidelines established by the U.S. Geological Survey National Water Quality Laboratory. Samples for carbon-13 analysis were treated onsite with a reagent of ammoniacal strontium chloride. Sulfur-34 for the sulfide ion was determined on a silver sulfate sample precipitated onsite from an acidified sample using gas stripping and a solution of silver nitrate.

Stable-isotope composition is expressed in δ (Del) notation, written as: $\delta^{18}O$ for the heavy oxygen isotope; δD for the heavy hydrogen isotope (^2H) given the name deuterium and the symbol D; $\delta^{13}C$ for the heavy carbon isotope; and $\delta^{34}S$ for the heavy sulfur isotope. Del notation (δ) is typically expressed as the per mil (‰) difference in the measured isotopic ratios of a sample and a standard given by the equation:

$$\delta = \left[\frac{R_{sample}}{R_{standard}} - 1\right] \times 1,000, \quad (1)$$

where R is the isotopic ratio of the element being considered. For example, the relation for sulfur isotopes is:

$$\delta^{34}S = \left[\frac{\left(^{34}S/^{32}S\right)_{sample}}{\left(^{34}S/^{32}S\right)_{standard}} - 1\right] \times 1,000. \quad (2)$$

The sulfur-isotopic ratios in the equation might be replaced by the ratios of $^{18}O/^{16}O$, D/H, or $^{13}C/^{12}C$ to obtain δ values for the other elements.

Stable carbon isotopes can be used to determine controlling chemical reactions and various sources of carbonate along an aquifer flow path. Dissolved carbon in ground water is derived primarily from carbonate sediments, soil organic matter, the decay of other organic material, and in some instances from atmospheric carbon dioxide (CO_2). Various sources of carbon generally have relatively distinct ranges of isotopic compositions. For example, the $\delta^{13}C$ is about 0 ± 3 ‰ for carbonate sediments, about -25 ± 5 ‰ for organic soil matter (wood and leaves), about -28 ± 4 ‰ for sedimentary organic carbon including coal, about -17 ‰ for soil CO_2 in arid climates, and about -7 ‰ for atmospheric CO_2 (Rightmire and Hanshaw, 1973, p. 959).

Sulfur isotopes can be used in geochemical studies to determine the amount of sulfate reduction that has occurred and to help define geochemical processes and flow paths. Sulfate-reducing bacteria such as *Desulfovibrio desulfuricans* reduce aqueous sulfate (SO_4^{2-}) to form hydrogen sulfide (H_2S or HS^-) in pH-neutral water. The sulfide is depleted in ^{34}S; therefore, the $\delta^{34}S$ of the remaining aqueous sulfate is enriched. When values of $\delta^{34}S$ are known for both sulfate and sulfide, the fractionation and the mass transfer of the sulfur system can be calculated. The primary source of sulfate in the study areas is $CaSO_4$, precipitated after the oxidation of pyrite and at least partly redissolved as the aquifer becomes saturated. At least part of the sulfide is derived from bacterial reduction of sulfate.

During an earlier study, Ferreira and others (1989) measured stable isotopes at 21 ground-water and 8 surface-water sites in the surface coal-mine areas of southeastern Montana in 1985. Stable-isotope ratios from the ground-

Exhibit 28

water samples ranged from -21.7 to -16.5 ‰ for $\delta^{18}O$, -167 to -134 ‰ for δD, -13.0 to 0.4 ‰ for $\delta^{13}C$, and -9.3 to 6.2 ‰ for $\delta^{34}S$. The median ground-water values, including water from alluvial, overburden, coal, and spoils wells, were -6.5 ‰ for $\delta^{13}C$ and 1.7 ‰ for $\delta^{34}S$.

Tritium concentration also can be an indicator of hydrologic and geochemical conditions. Natural tritium in precipitation ranged from about 3 to 25 TU (tritium units) prior to 1952. From 1952 to the mid-1960's, large amounts of tritium were released to the atmosphere during atmospheric testing of thermonuclear weapons. This large input of man-made tritium to the atmosphere, and the subsequent input to ground water by recharge from precipitation, makes interpretation of some ground-water tritium data ambiguous. Examples of data that are not ambiguous include tritium concentrations less than 1 TU, which indicate no contribution of post-1952 water, and tritium concentrations larger than 50 TU, which indicate the presence of a significant portion of post-1952 water (T.B. Coplen, U.S. Geological Survey, written commun., 1989).

Geochemical processes were determined by interpretation of the data, including the use of geochemical models. Equilibrium speciation calculations were determined for water samples using the computer program WATEQF (Plummer and others, 1978). These calculations provide saturation indices (SI) of minerals that may be reacting in the system. The SI of a particular mineral is defined as:

$$SI = \log \frac{IAP}{K_T} \tag{3}$$

where IAP is the ion-activity product of the mineral-water reaction and K_T is the thermodynamic equilibrium constant adjusted to the temperature of the given sample. Pertinent thermodynamic data used to calculate the saturation indices were revised from the original WATEQF (Plummer and others, 1978) and WATEQ4F (Ball and others, 1987) programs by Nordstrom and others (1990) and are summarized in table 2. The degree of saturation is expressed by the saturation indices; undersaturation is expressed as a negative saturation index, saturation is expressed as a value near zero, and supersaturation is expressed as a positive value. Saturation or supersaturation implies that the mineral might be present in the aquifer or unsaturated zone above the aquifer, whereas undersaturation implies limited contact between aquifer water and the mineral. Saturation indices, in conjunction with mineralogic information from the solid-phase samples, can be used to help determine the hydrological and geochemical processes that are important in the evolution of the observed ground-water quality.

Geochemical mass-balance models were constructed using the computer program NETPATH (Plummer and others, 1991) to determine the quantities of mineral or chemical species causing the observed changes in water quality. To solve the models, elemental concentrations and sets of plausible reacting phases for initial waters and plausible product phases for final waters are required. Mass-balance models simulate the net chemical reaction of the form:

Initial solution composition + reactant phases $\Rightarrow$ final solution composition + product phases,

where reactant and product phases represent constituents that enter or leave the aqueous phase. Possible reactant or product phases were selected using solid-phase mineralogic data, speciation calculations, geologic and hydrologic inferences, and SEM analysis. Mass-balance calculations were made using Rayleigh distillation reactions calculated with equations developed by Wigley and others (1978, 1979) to determine if a particular reaction was occurring and the isotopic composition of the final solution.

GENERAL GEOCHEMICAL PROCESSES

The quality of water in the coal and spoils aquifers in the study areas generally is controlled by one or more major geochemical processes that can occur in the unsaturated zone, such as in recharge areas, or within the saturated zone. The major geochemical processes are:

- dissolution and precipitation of carbonate minerals,
- oxidation of sulfide minerals such as pyrite,
- precipitation and dissolution of sulfate minerals such as gypsum,
- ion-exchange and adsorption reactions on clay minerals and organic material,
- sulfate reduction,
- production of sulfide and carbon-dioxide gas, and
- precipitation of sulfide minerals such as amorphous iron sulfide.

Exhibit 28

The magnitude of any of these processes depends primarily on the hydrologic and geologic characteristics of the specific area.

Carbonate minerals such as calcite ($CaCO_3$) and dolomite ($CaMg(CO_3)_2$), if present, might be dissolved in the near-surface unsaturated zone or in aquifers. Typical reactions might be expressed as:

$$CaCO_3 + H^+ \Leftrightarrow Ca^{2+} + HCO_3^- \quad (4)$$

and

$$CaMg(CO_3)_2 + 2H^+ \Leftrightarrow Ca^{2+} + Mg^{2+} + 2HCO_3^-. \quad (5)$$

The hydrogen ions (H^+) in reactions 4 and 5 can result from oxidation of pyrite or from reactions of water with CO_2 gas. Carbon dioxide gas from the atmosphere or organic decay reacts with water:

$$CO_2 + H_2O \Leftrightarrow H_2CO_3 \quad (6)$$

and the resulting carbonic acid (H_2CO_3) dissociates:

$$H_2CO_3 \Leftrightarrow H^+ + HCO_3^-. \quad (7)$$

The overall effects of carbonate-mineral dissolution are to increase the concentration of calcium (Ca^{2+}), magnesium (Mg^{2+}), and bicarbonate (HCO_3^-) ions and to increase pH.

Dissolution and precipitation of carbonate minerals occur primarily within the unsaturated zone as water percolates below land surface. Dissolution of carbonates is ultimately limited by the ion-activity product of the particular mineral and whether the system is open or closed with respect to CO_2. Within the unsaturated zone, CO_2 derived from the atmosphere, from the decay of modern plants and coal, or from root respiration will dissolve in infiltrating water until the partial pressures of CO_2 in the vapor and liquid phases are equal. Dissolution of carbonate minerals will then proceed until the constraints of the ion-activity product and the vapor-liquid CO_2 pressure equality are simultaneously satisfied. In waters containing large concentrations of sodium sulfate, ion pairing reduces the free calcium- and carbonate-ion activities and permits further dissolution of calcite at a particular unsaturated-zone partial pressure of CO_2.

Oxidation of pyrite (FeS_2) or other iron-sulfide minerals might occur in the undisturbed unsaturated zone or within the overburden that has been disturbed by mining. The process initially requires the presence of oxygen, which is available from infiltrating recharge water or the atmosphere. The oxidation process consists of several steps, some of which are catalyzed by bacteria. The generalized reaction for the principal process involved is:

$$4FeS_2 + 15O_2 + 14H_2O \Leftrightarrow 4Fe(OH)_3 + 8SO_4^{2-} + 16H^+. \quad (8)$$

If calcium ions are present, calcium sulfate can be formed:

$$Ca^{2+} + SO_4^{2-} \Leftrightarrow CaSO_4. \quad (9)$$

The overall effect of the oxidation process is to increase the acidity and the concentration of sulfate ions in solution. The acid produced as a result of reaction 8 is buffered by the dissolution of carbonate minerals (reactions 4 and 5), which are present in the overburden and spoils. The sulfate ions produced in reaction 8 are either transported in solution to the aquifer or are precipitated as gypsum or other sulfate minerals as in reaction 9. These sulfate minerals might later be dissolved and transported to the aquifer by recharge water or, in a semiarid environment where annual evapotranspiration exceeds annual precipitation, might accumulate in the near-surface unsaturated zone. When disturbed by mining and replaced at depth, the sulfate minerals become available for dissolution in the saturated zone of the spoils.

Ion-exchange and adsorption reactions probably are an important process in the unsaturated zone and in the saturated spoils and coal aquifers. Generally, the process involves reactions on clay minerals where calcium, and in some cases magnesium, ions are exchanged for sodium ions:

Exhibit 28

$$Na_2\,(clay) + X_{Mg}Mg^{2+} + (1-X_{Mg})\,Ca^{2+} \Leftrightarrow \left[Ca_{(1\text{-}X_{Mg})}, Mg_{(X_{Mg})}\right](clay) + 2Na^{+} \qquad (10)$$

where X_{Mg} varies between 0 for pure Ca/Na cation exchange and 1 for pure Mg/Na cation exchange. When reaction 10 proceeds from left to right, it results in a decrease in calcium or magnesium ions and an increase in sodium ions in solution. The decrease in calcium ions in solution can cause further dissolution of calcium carbonate or calcium sulfate minerals to maintain equilibrium. Magnesium and potassium might also be involved in ion exchange or adsorption reactions. However, calcium generally has a greater affinity for exchange than magnesium, magnesium has a greater affinity than potassium, and potassium has a greater affinity than sodium. The extent to which exchange occurs largely depends on the cation-exchange capacity of the clay mineral or possibly organic material, and on the concentration of the ions in solution.

In anaerobic conditions, sulfate can be reduced to sulfide when organic material and sulfate-reducing bacteria are present. In reaction 11, organic material is represented compositionally as CH_2O, implying that nitrogen and phosphorus in the organic material are not present in sufficient quantities to affect the pH or alkalinity:

$$2CH_2O + SO_4^{-2} \xrightarrow{\text{sulfate-reducing bacteria}} H_2O + CO_2 + HCO_3^{-} + HS^{-}. \qquad (11)$$

The sulfate-reducing bacteria *Desulfovibrio desulfuricans* were found in relatively large numbers in 25 of 26 observation wells sampled by Dockins and others (1980, p. 6) in southeastern Montana and apparently most of the sulfide in those wells resulted from bacterial sulfate reduction. Reaction 11 results in an overall decrease in sulfate concentration, an increase in bicarbonate concentration, and the production of sulfide and carbon-dioxide gas. The sulfide ions produced as a gas in the reaction may then be removed from solution by precipitation of sulfide minerals, especially iron sulfide. Because sulfate reduction requires anaerobic conditions, it generally is not a factor in newly replaced spoils or in other oxygenated systems, such as some shallow ground water.

BIG SKY MINE AREA

In the Big Sky Mine area, ground-water flow is of a local nature with at least some recharge from direct infiltration of precipitation. The geochemical changes that occur as the calcium-magnesium sulfate type water moves from the unmined Rosebud coal bed into the spoils and then downgradient into the McKay coal bed and potentially offsite are the primary focus of this part of the study.

Geohydrologic Setting

The coal being mined at the Big Sky Mine area is part of the Tongue River Member of the Paleocene Fort Union Formation in the Powder River structural basin (fig. 1). The Big Sky Mine area opened to mining in 1969. The coal beds being mined are the Rosebud coal, generally about 25 ft thick, and the underlying McKay coal, about 10 ft thick. Around the mine disturbance area (fig. 4), the coal beds generally have been eroded or burned, leaving clinker or sandy material of the Tongue River Member. The burning of coal, commonly ignited by spontaneous combustion or range fires over the past hundreds of thousands of years, hardens, sinters, or sometimes melts the overlying sandstone, siltstone, and shale. The resultant rocks, collectively called clinker, are resistant to erosion because they are harder than the unbaked rocks and because baking causes increased fracture permeability, which allows water to infiltrate and, therefore, minimizes surface runoff.

Spoils consist primarily of overburden and interburden that have been removed and replaced as a result of mining. Overburden is the primary spoils material where only the Rosebud coal bed has been removed. The spoils consist of a mixture of overburden and interburden where both coal beds have been removed. The spoils might be composed entirely of interburden where the Rosebud coal has been eroded or burned.

OBSERVATION WELL

The principal aquifers in the study area are the Rosebud and McKay coal beds, the spoils, and alluvium along Rosebud Creek. The coal aquifers have an average hydraulic conductivity of 8.8 ft/d and a median of 0.79 ft/d on the basis of nine aquifer tests (Davis, 1984a, p. 47). The spoils aquifer was created by placement of the removed overburden and interburden behind the advancing mine pit, creating a rubble zone of broken bedrock at the base overlain by granular material. The spoils aquifer is heterogeneous and has a large range of hydraulic-conductivity values, with an average value of 9.7 ft/d and a median of 0.028 ft/d on the basis of eight aquifer tests (Davis, 1984a, p. 47). Recharge in the Big Sky Mine area primarily is by infiltration of precipitation on nearby clinker outcrops. The relatively resistant and permeable clinker commonly caps the nearby knobs, ridges, and buttes and recharge water from these areas moves from the northwest to southeast as indicated by the potentiometric surface (fig. 4). The spoils are recharged primarily by lateral inflow from coal aquifers, and locally by infiltration of direct precipitation on sandy spoils material. Discharge from the spoils and coal aquifers primarily is by lateral flow southeastward to clinker or sand aquifers, with eventual discharge into alluvium along Rosebud Creek. Minor discharge from the coal aquifers is by domestic and stock-watering wells. Evapotranspiration from shallow parts of the aquifers might also be a source of some ground-water discharge.

The location of 10 wells drilled in the Big Sky Mine area during this study is shown in figure 5. Three wells (BSUMR1, BSUMSP1, and BSUMSP2) were drilled near the upper end of Miller Coulee with one well completed in coal and the other two wells completed in a downgradient spoils aquifer. The purpose of the wells was to quantify recharge into the mine area and geochemical changes that occur as water moves from the coal aquifer into the spoils aquifer. In this area, the Rosebud coal bed was mined during 1976 and 1977 and was replaced with spoils material that became saturated within a few years. Well BSUMR1 was completed in saturated Rosebud coal bed and the two other wells were completed in sandy spoils (table 3).

Seven wells were drilled along a downgradient flow path from the saturated spoils to the unmined McKay coal bed (fig. 5). In this area, the McKay coal was mined from 1969 to 1971, and the spoils material was replaced and became saturated within a few years. Wells BSLMSP3 and BSLMSP1 were completed in the spoils aquifer; wells BSLMMC1, BSLMMC2 and BSLMMC3 were completed in the aquifer in the unmined McKay coal bed; well BSLMMC5 was completed in an iron-rich sandstone at a depth contiguous with the McKay coal bed; and well BSLMSM1 was completed in gray sandstone of an interval stratigraphically lower than the McKay coal bed (sub-McKay) (table 3). The horizontal hydraulic gradient of about 0.01ft/ft might be at least partly controlled by an upgradient highwall pond, lateral flow from upgradient spoils (fig. 5), and infiltration of local recharge. Discharge from the unmined coal is offsite to stratigraphic equivalents and eventually to alluvium along Miller Coulee. Little or no water is thought to discharge to the sub-McKay. Additional information on the hydrology of the Big Sky Mine area is described by Davis (1984a).

Geochemistry and Geochemical Processes

The ground-water geochemistry at the Big Sky Mine area was studied to determine potential geochemical processes that might occur as water from the spoils flows into the downgradient aquifer in the McKay coal bed. Another objective was to determine processes related to changes in ground-water geochemistry as water flows from the aquifer in the unmined Rosebud coal bed into the spoils.

Results of Solid-Phase Analysis

Detailed analyses of samples from unmined consolidated rocks, spoils, and coal beds were essential to determine geochemical processes and water-rock interactions. Solid-phase samples were analyzed for mineralogy and for concentrations of major and trace elements and exchangeable cations. The samples of overburden of the Rosebud coal bed was composed of clayey siltstone and calcareous, fine-grained sandstone and included abundant dolomite cement, feldspars, some calcite, and traces of pyrite and glauconite. Clay in the overburden consisted of kaolinite with minor quantities of smectite, illite, and chlorite (tables 4, 5, 6). Spoils in this area created from Rosebud overburden were mineralogically similar to the unmined overburden, except that the spoils contained more calcite and less dolomite (table 5).

The mineralogy of a calcareous clayey siltstone in interburden between the Rosebud and McKay coal beds (samples from BSLMMC2, BSLMMC3, and BSLMSM1) consisted of abundant quartz, dolomite and calcite cements, muscovite, biotite, and sericite. The predominant clays were kaolinite, illite, and chlorite. Feldspars were common in most samples, gypsum was detected in minor quantities, and strontianite, and possibly thenaderite, were detected in trace quantities. Pure, crystalline gypsum, most likely a result of evaporation, was detected in fractures in a siltstone sample. Samples of spoils consisting of interburden (samples from BSLMSP3 and BSLMSP1) were mineralogically similar to samples of the unmined interburden except that the spoils generally contained more quartz, chlorite, and smectite and less calcite (tables 5, 6).

Exhibit 28

The concentrations of cations and trace elements were determined from 11 drill-core samples of spoils and unmined consolidated rock collected in the Big Sky Mine area (table 7). The predominant elements were aluminum associated with the clay minerals, calcium and magnesium associated with the carbonate cements, and iron, potassium, and silica likely associated with silicate minerals. Generally, the concentrations from the samples of unmined consolidated rock and the spoils were indistinguishable. Solid-phase samples from four cores (consisting of spoils or siltstone) were analyzed for exchangeable cations. Calcium was the most prevalent exchangeable cation, with lesser quantities of magnesium, sodium, and potassium (table 8). Results from analysis of the one spoils sample (well BSLMSP1) did not differ greatly from the analysis of the three siltstone samples.

The concentrations of major and minor oxides and trace elements were determined from laboratory ash of four samples of McKay coal (table 9). The median concentrations of selected constituents were within the range of, and generally similar to, the mean concentrations from the analyses of 410 samples from throughout the Powder River structural basin (table 10).

Results of Ground-Water Analysis

Water samples were collected 3 times from 4 of the observation wells, twice from 1 of the wells, and once from the other 5 wells. Results of analyses for major ions and trace elements are given in table 11. Predominant cations and anions are depicted on trilinear diagrams (fig. 6) for samples collected during October 1988 to illustrate the similarity in the chemical types. Water from well BSUMR1 completed in the upgradient coal bed had a dissolved-solids concentration of 2,150 mg/L and was a magnesium-calcium sulfate chemical type (fig. 6). Water from wells completed in the spoils or downgradient coal bed had an average dissolved-solids concentration of about 3,800 mg/L and also was a magnesium-calcium sulfate chemical type. The dissolved-solids concentrations are similar to the mean dissolved-solids concentration of 2,700 mg/L from 19 coal wells and 3,700 mg/L from 18 spoils wells as reported by Davis (1984a, p. 51). Stiff diagrams of coal and spoils water (fig. 6) indicate that magnesium, calcium, and sulfate concentrations increase and bicarbonate concentrations decrease as water flows from the upgradient Rosebud coal bed (well BSUMR1) into the spoils of Rosebud overburden (well BSUMSP1). Major-ion concentrations in water from the spoils of Rosebud overburden, the interburden spoils (BSLMSP3), and the downgradient McKay coal bed (well BSLMMC2) are similar.

Water samples for laboratory determination of dissolved-gas concentration were collected from five observation wells (table 12). Oxygen, carbon dioxide, and methane were the gases of primary interest. Dissolved-oxygen concentrations larger than 1.0 mg/L were detected in water from wells BSUMR1 and BSUMSP2, whereas only a trace was detected in water from wells BSLMSP1, BSLMMC1, and BSLMMC2 in the downgradient flow path. Large concentrations of carbon dioxide were detected in water from wells BSLMSP1, BSLMMC1, and BSLMMC2, which are completed in the downgradient spoils and coal beds. Smaller concentrations were detected in water from wells BSUMR1 and BSUMSP2.

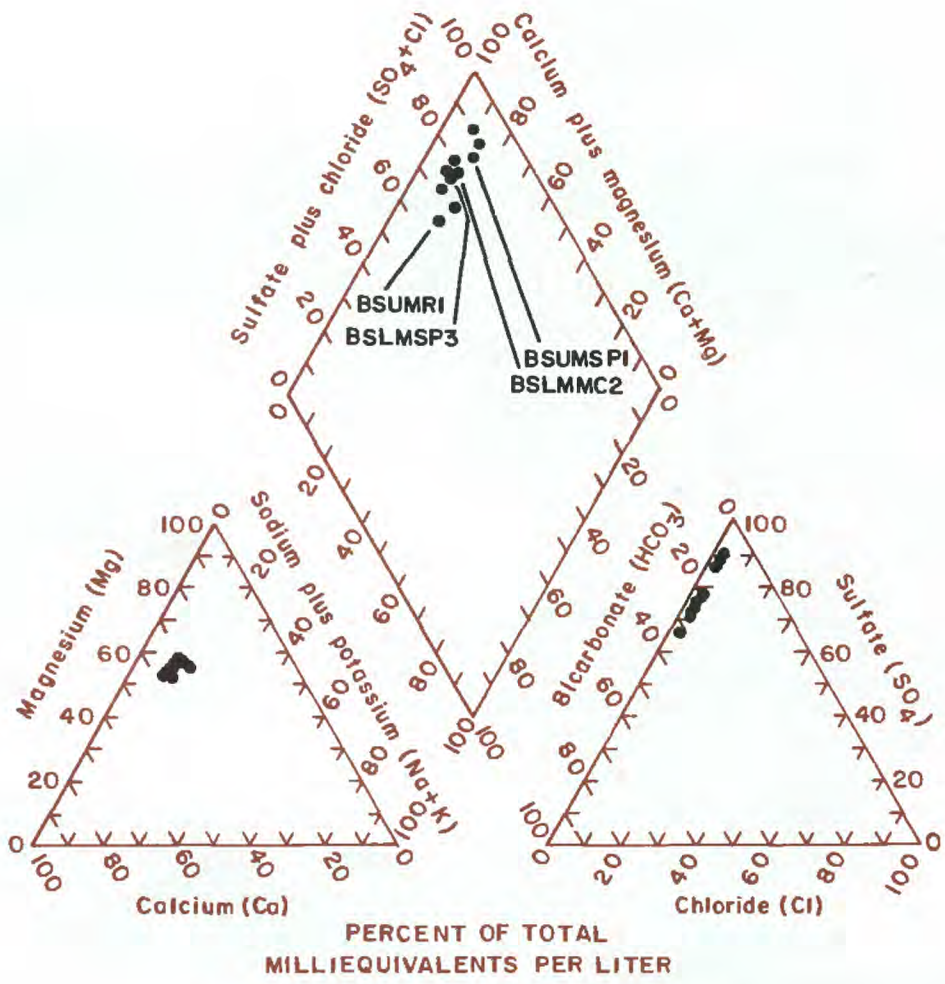
Water samples were collected for analysis of isotopic ratios or activities from five of the observation wells (table 13). Analytical results for the isotopes are virtually the same for water from the spoils well (BSLMSP1), and wells completed in the McKay coal bed (BSLMMC1 and BSLMMC2). The main isotopic dissimilarity is the difference in tritium activity between water from well BSUMR1 in the Rosebud coal bed (5.7 pCi/L) and water from well BSUMSP2 in the spoils (64 pCi/L).

Mineral-Water Equilibrium and Relation to Geochemical Processes

Thermodynamic equilibrium calculations for ground water from the Big Sky Mine area using the program WATEQF (Plummer and others, 1978) are listed in table 14. Calculations result in saturation indices of minerals that might be reacting in the system. Saturation indices denote that most water is saturated with respect to quartz, calcite, dolomite, and goethite, and is near saturation with respect to aragonite, gypsum, and celestite.

The oxidation-reduction (redox) state of the water was estimated based on dissolved-gas concentrations. Water from wells along the inferred downgradient flow path had concentrations of dissolved oxygen and hydrogen sulfide that were small and near the detection limits (table 11). Concentration of these parameters varied between samples collected from individual wells and showed no distinct differences between wells completed in spoils or coal, making it difficult to accurately determine the redox state of the water. For purposes of equilibrium calculations, an Eh value of -0.01 volt was estimated for all samples from the downgradient wells and an Eh value of 0.2 volt was estimated from dissolved-oxygen concentrations for the upgradient wells.

Exhibit 28



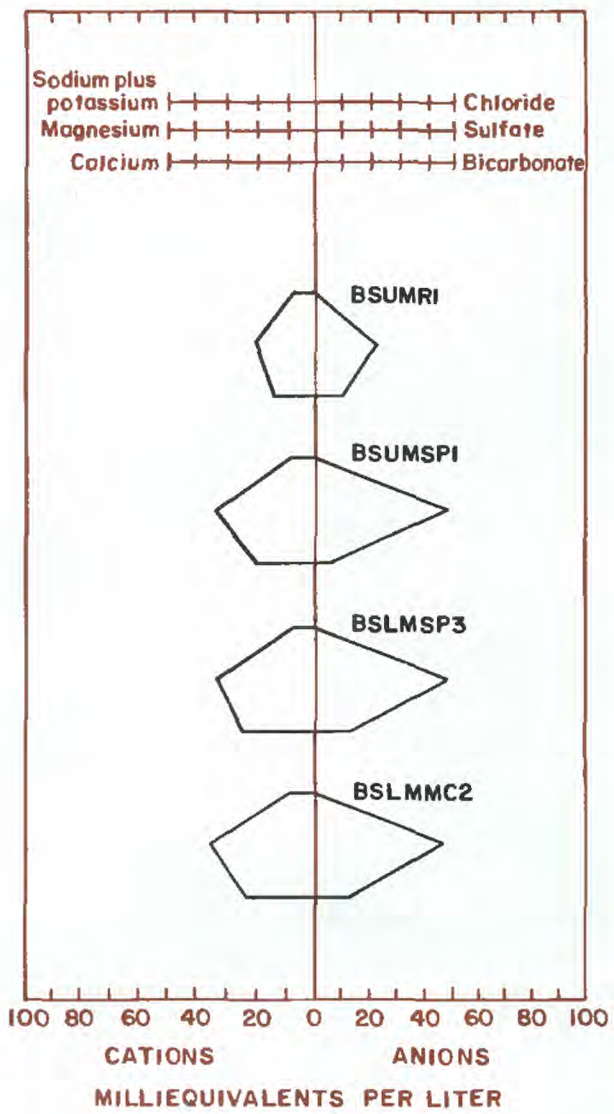


Figure 6. Trilinear and Stiff diagrams showing geochemical properties of ground water from the Big Sky Mine area, Montana.

Exhibit 28

Flow from Upgradient Coal Aquifer to Spoils Aquifer

The geochemical process of dedolomitization, the irreversible dissolution of gypsum at or near calcite-dolomite saturation, most likely occurred as water from the upgradient coal aquifer flowed into the spoils aquifer. Concentrations of calcium, magnesium, sodium, and sulfate increased and alkalinity decreased along the flow path from well BSUMR1 in the upgradient coal aquifer to wells BSUMSP1 and BSUMSP2 in the spoils aquifer (table 11). Water in the coal aquifer was saturated or nearly saturated with respect to calcite and dolomite and was undersaturated with respect to gypsum (table 14). Dissolution of gypsum added calcium to the water, which may have resulted in calcite precipitation, and caused the pH to decrease (Plummer and others, 1990, p. 1,987), owing to an increase in H^+ released from HCO_3^- during incorporation of CO_3^{2-} into the calcite. The decrease in pH and CO_3^{2-} probably caused the water to be undersaturated with dolomite, thereby increasing dissolution and increasing the concentration of dissolved magnesium. The amount of dolomite and gypsum dissolved normally would exceed the amount of calcite precipitated; therefore, the concentration of dissolved calcium normally would increase. As expected for the dedolomitization reaction (Plummer and others, 1990, p. 1,994, fig. 10), alkalinity decreased as sulfate increased. Calcite was more common in spoils samples from well BSUMSP1 than in the unmined overburden samples from well BSUMR1, whereas dolomite was more abundant in the overburden than in the spoils (table 5). This mineralization may have been due to precipitation of calcite and dissolution of dolomite within the spoils material as a result of dedolomitization. The increase in sodium concentration might have been the result of exchange of calcium ions for sodium ions on clay minerals or the dissolution of a sodium salt in the spoils material.

The dedolomitization reaction hypothesis was tested by constructing a mass-balance model to simulate the geochemical changes. The model is based on a set of probable reacting phases and the elemental concentrations corresponding to those phases for the initial and final waters. The phases selected were calcite, dolomite, gypsum, cation exchange, and carbon dioxide. Results of the simulated mass transfer, as calculated by the model NETPATH (Plummer and others, 1991), are given in table 15 and indicate the following geochemical processes: dolomite and gypsum dissolution with accompanying calcite precipitation, exchange of calcium ions for sodium ions, and transfer of carbon dioxide indicating an open system. In the overall dedolomitization reaction:

$$CaMg(CO_3)_2 + CaSO_4 \Rightarrow 2CaCO_3 + MgSO_4(aq), \quad (12)$$

where 2 moles of calcite are precipitated and 1 mole of dolomite is dissolved for every mole of $CaSO_4$ irreversibly added to solution, in a ground-water system at equilibrium with calcite, dolomite, and gypsum (Plummer and others, 1990, p. 2,010). The waters were saturated with calcite and dolomite but undersaturated with gypsum, indicating that mass transfer of gypsum might increase disproportionately to that of dolomite and calcite.

Flow from Spoils Aquifer to Downgradient Coal Aquifer

As water flowed from the spoils aquifer to the downgradient coal aquifer, the dissolved-solids concentration essentially was unchanged (fig. 5). Only small differences in concentrations of major ions were detected between the spoils wells (BSLMSP3 and BSLMSP1) and two of the coal wells (BSLMMC1 and BSLMMC2) (table 11). Concentrations of a few constituents were noticeably different only between the spoils wells and coal well BSLMMC3, as iron increased substantially, dissolved silica nearly doubled, and bicarbonate, manganese, and potassium decreased slightly. A possible explanation for the differences in concentrations was an additional source of recharge to well BSLMMC3, as water levels in well BSLMMC3 were slightly higher than those in well BSLMMC2.

Results of samples collected in October 1988 show a gradual decrease in concentrations of most trace elements along the inferred flow path. However, results from subsequent sampling did not substantiate this trend, possibly because of changes in laboratory or sampling procedures or physical changes in the ground-water system, such as slight changes in ground-water flow rate or direction. If the initial results were accurate, then the trace-element concentrations most likely decreased due to sorption of the dissolved elements onto the coal or onto clay minerals within the coal.

WEST DECKER MINE AREA

At the West Decker Mine study area, several dissolved constituents had large changes in concentration as water moved along an inferred flow path from a spoils aquifer to a downgradient unmined coal aquifer. The types

Exhibit 28

and quantities of changes, the possible causes and chemical reactions, and the mass transfer due to these geochemical changes are discussed in this section.

Geohydrologic Setting

The Decker Mine area consists of the East, North, and West Decker Mine areas (fig. 7). The West Decker Mine area was opened in 1972. The coal being mined is part of the Tongue River Member of the Paleocene Fort Union Formation. The main coal beds in descending stratigraphic order are the Anderson bed, the Dietz 1 bed, and the Dietz 2 bed. Within the West Decker Mine study area the Anderson and Dietz 1 are combined into one bed that generally is about 50 ft thick. This Anderson-Dietz 1 bed is separated from the 25-ft thick Dietz 2 bed by as much as 65 ft of interburden. The thickness of overburden above the Anderson-Dietz 1 bed varies within the mine area, ranging from tens of feet to about 100 ft. Also within the mine area is clinker which consists of shale, siltstone, and sandstone that has been fractured and baked by the burning of underlying coal beds (fig. 8).

The predominant lithologies in the overburden are siltstone, very fine-grained sandstone, some brown and gray to grayish-black shale, and several distinct layers of gray, calcareous siltstone (tables 3 and 4). These lithologic units generally were also identified in the spoils, which is composed of removed and replaced overburden.

The principal aquifers in the study area are clinker, coal beds, spoils, and alluvium. The clinker might be locally permeable as a result of fracturing and, thus, be a productive aquifer. The coal aquifer of principal interest is the Anderson-Dietz 1 coal bed. The spoils aquifer was created by placement of the removed overburden behind the advancing mine pit, creating a rubble zone at the base that might be at least partly confined by relatively impermeable clay in the overlying spoils. Alluvial aquifers in discharge areas generally are hydraulically connected to upgradient aquifers. The unmined shale and siltstone overburden is relatively impermeable and is not considered to be an aquifer. Davis (1984a, p. 19) reported hydraulic conductivities of the spoils aquifer ranging from 0.0033 to 8.4 ft/d, with a median of 1.8 ft/d determined from 6 aquifer tests, and hydraulic conductivities of the coal aquifer ranging from 0.46 to 29 ft/d, with a median of 2.2 ft/d determined from 16 aquifer tests.

Recharge to aquifers undisturbed by mining primarily is from infiltration of precipitation on clinker outcropping in regional recharge areas (fig. 8). Natural discharge from the unmined coal aquifers primarily is to the Tongue River Reservoir or clinker and alluvium along the valley of the Tongue River.

Ground-water inflow to the mine areas primarily is from adjoining clinker and coal beds. Infiltration of precipitation through the spoils probably is not a significant source of recharge. In many of the active mine areas, excavations are at a level lower than the Tongue River Reservoir at its normal stage of 3,412 ft. Because of the excavations, the natural gradient of the potentiometric surface might be reversed in local areas, especially near the reservoir, and water from the reservoir might be recharging the aquifers and discharging to the mine pits in those areas (fig. 8).

Water levels in spoils wells within about one-quarter mile of the Tongue River Reservoir apparently respond to seasonal fluctuations in the stage of the reservoir with water levels rising in summer in response to spring runoff refilling the reservoir. However, water levels in wells one-half mile or greater from the reservoir apparently do not respond to these seasonal reservoir fluctuations (data from Montana Bureau of Mines and Geology). Wells used during this study are at least one mile from the reservoir and water levels in these wells show no response to the seasonal changes in the reservoir stage.

Hydrographs of long-term water levels in the West Decker Mine area (fig. 9) indicate that when mining of the Anderson-Dietz 1 coal bed started in the early 1970's, water levels in that coal bed (well WR-01) (fig. 10) declined about 40 ft in 2 years. Water levels gradually declined in the Dietz 2 coal bed (well WR-07) (Van Voast and Reiten, 1988, sheet 2). Water levels in well WR-01 recovered partly during the late 1970's and early 1980's. When mining of the Dietz 2 coal in the southeast part of the mine area started in the early 1980's, water levels in that coal bed declined an additional 30 ft and water levels in the Anderson-Dietz 1 coal bed (well WR-01) declined gradually (fig. 9).

Figure 11 shows fluctuations of long-term water levels for a spoils well and two Anderson-Dietz 1 coal wells about one-quarter mile east and downgradient from the spoils well. Water levels in the spoils well, DS-6A, rose about 14 feet in 1976, and continued to rise another 10 feet in the next two years, most likely in response to initial saturation of the spoils aquifer. Water levels began to decline in 1981 and dropped about 20 feet in one year probably in response to mining of both the Anderson-Dietz 1 and the Dietz 2 coal southeast of the well. The hydrographs of the two coal wells WR-01 (104 feet deep) and WR-06 (135 feet deep), are similar to each other and show trends similar to the spoils-well hydrograph. The coal-well hydrographs indicate that water levels began to rise in 1977, about one year after the water-level rise in the upgradient spoils well, and began to decline in 1980, about 1-2 years before the water level declined in the spoils well. These water-level fluctuations may indicate the relative hydraulic

connection between the spoils aquifer and the coal aquifer. Water saturating the spoils aquifer in 1976 apparently then flowed into the coal, resaturating that aquifer within one year. Mining of the coal aquifers southeast of the wells resulted in water-level declines in the coal wells starting in 1980. Within 1-2 years water levels in the upgradient spoils wells began to decline. Assuming that water in the spoils aquifer recharged the coal aquifer and that the resaturation occurred within one year, then the water flowed at a rate of more than one foot per day, a relatively fast travel time.

The location of six wells drilled in the West Decker Mine area as part of this study is shown in figure 10. Three wells (WDFCL1, WDFD12, and WDFSP3) are near the active mine area boundary and the other three (WDESP1, WDESP2, AND WDED11) are in either the saturated spoils aquifer or the downgradient coal aquifer. Lithologies determined in drilling the wells are listed in table 3. Well WDFCL1, located near the boundary of active mining, is completed in about 30 ft of unmined Anderson-Dietz 1 coal. Well WDFD12, located within the mine disturbance area, also was completed in Anderson-Dietz 1 coal. Well WDFSP3, completed in the spoils, was downgradient of coal and clinker. Water levels in well WDFD12 recovered slowly after being pumped dry, and the hydraulic conductivity, although not measured, was assumed to be at the lower end of coal-aquifer values. Water levels in well WDFCL1 recovered relatively quickly upon cessation of pumping sustainable yields of over a gallon per minute, indicating a substantially larger hydraulic conductivity. Water levels in well WDFSP3 recovered very slowly after bailing small quantities of water, indicating a small hydraulic conductivity, assumed to be at the lower end of spoils-aquifer values.

Figure 10 illustrates a cross-sectional view of wells WDESP1, WDESP2, and WDED11. The wells were drilled through spoils material, overburden, or the Anderson-Dietz 1 coal bed, and a few feet into the underlying interburden. The approximate potentiometric surface of the water levels in the spoils aquifer and Anderson-Dietz 1 coal aquifer (fig. 10) indicates flow from the north toward the south-southeast. Dewatering effects of mining, the initial saturation of the spoils aquifers, and the consequent resaturation of coal aquifers have greatly changed the hydrologic processes at the West Decker Mine area. Even though water levels have dropped significantly in this

area since mining began in the early 1970's, the general configuration of the water table has not changed substantially. Prior to mining, water flowed from the recharge areas north and west of the mine area to discharge areas near the Tongue River Reservoir (fig. 7). The potentiometric surface in 1988 (fig. 10) is about 20 to 30 feet lower than the pre-mining potentiometric surface (fig. 7). The hydraulic gradient of the potentiometric surface shown in figure 10 is about 0.005, the change in head between the three wells shown in the cross-section is also about 0.005, whereas the pre-mining gradient in this area (fig. 7) is about 0.003 indicating that mining effects have steepened the gradient. Further information on the hydrology of the West Decker Mine area including a ground-water flow model is in Davis (1984a).

Water levels in wells shown in the hydrogeologic section (fig. 10) are higher in the spoils well and lower in the coal wells, indicating flow from the spoils into the coal. Although it is possible that wells WDESP1, WDESP2, and WDED11 might not be along a direct flow path, it is assumed for the purpose of this report that they are along a direct flow path. However, because of these uncertainties, this flow path will be referred to in this report as the inferred flow path.

Geochemistry

The major emphasis of the study of geochemistry at the West Decker Mine area was to determine the potential for geochemical changes as ground water flows from a spoils aquifer into an unmined coal aquifer. Results of analyses of solid-phase samples from spoils, unmined consolidated rock, and coal, and ground-water samples were essential to the determination of geochemical processes and water-rock interactions.

Results of Solid-Phase Analysis

The mineral content of the unmined consolidated rock (overburden and clinker) and spoils collected from drill-core samples is listed in tables 4, 5, and 6. The clinker sample, collected from well WDFCL1 at a depth of 50 ft, was a fine-grained clayey siltstone that primarily contained quartz, muscovite, feldspars, and trace amounts of iron (tables 4 and 5). Unmined overburden from well WDED11 included a slightly calcareous clayey siltstone with calcite and dolomite cement and trace amounts of gypsum, and a calcareous siltstone containing abundant calcite and dolomite and a trace of barite (tables 3 and 5).

The mineral content of mine spoils was determined by X-ray diffraction of 11 drill-core samples (tables 5 and 6). Quartz was the most abundant mineral in all samples. Carbonate minerals, particularly dolomite, and feldspars were common in most samples. Trace quantities of thenardite (a sodium-sulfate mineral), siderite, and celestite were detected in some samples. The clay content of the spoils included abundant kaolinite and smectite (table 6). This

Exhibit 28

was markedly different from the clay content at the Big Sky Mine area, where the expandable clays of the smectite (montmorillonite) group were much less common. The expandable clays typically have a much larger cation-exchange capacity (CEC) than other clays and, therefore, a greater effect on ground-water chemistry. A range of CEC for clay minerals, as reported by Carroll (1959, p. 754) in meq/100 g, are: kaolinite, 3-15; illite, 10-40; chlorite, 10-40; and smectite, 70-100.

The chemical concentrations of cations and trace elements were determined from nine drill-core samples of unmined overburden, mine spoils, and clinker from the West Decker Mine area (table 7). The predominant elements are aluminum, silica, iron, and potassium, probably associated with clay minerals, and calcium and magnesium, associated with the carbonate minerals. The median sodium concentration in samples from the West Decker Mine area is much larger than the median sodium concentration in samples from the Big Sky Mine area. The range of values for most major constituents, except calcium, is small, and no substantial difference is indicated between the chemistry of the unmined overburden and mine-spoils samples.

Concentrations of exchangeable cations were determined on four drill-core samples from spoils and unmined overburden from the West Decker Mine area. Calcium and sodium were the most prevalent exchangeable cations, with lesser amounts of magnesium and potassium (table 8). The median concentration of exchangeable sodium ions from the West Decker Mine area samples is about 900 µg/g, whereas the median concentration of sodium ions from the Big Sky Mine area samples is about 60 µg/g, which demonstrates the more sodic nature of the rock material in the West Decker Mine area.

Two coal samples from the upgradient well WDFCL1 and four coal samples from wells WDESP2 and WDED11 downgradient from the spoils aquifer were analyzed for concentrations of major and minor oxides and trace elements (table 9). Concentrations from all coal samples are similar. The median concentrations of selected constituents were compared to the mean concentrations from analyses of 410 coal samples from throughout the Powder River structural basin (table 10). Concentrations of sodium, strontium, and barium at the West Decker Mine area are larger than or near the maximum values detected from the 410 Powder River coal samples. Concentrations of silica, aluminum, manganese, zinc, and percent of ash at the West Decker Mine area are near or less than the minimum values detected in the Powder River coal samples.

Results of Ground-Water Analysis

Water samples were collected three times from wells WDESP1, WDESP2, and WDED11 along the inferred flow path from the spoils aquifer to the downgradient coal aquifer, and once from wells WDFCL1, WDFD12, and WDFSP3. Results of the analyses for major ions and trace elements are shown in table 11. Ground water in the area was a sodium bicarbonate type, with large variations in dissolved-solids concentration. The dissolved-solids concentration in water from well WDFCL1, completed in the coal aquifer upgradient of the active mine area, was 1,430 mg/L, which is similar to that reported by Davis (1984a, p. 34). The dissolved-solids concentration in water from coal aquifer wells within the active mine area (WDED11, WDESP2, and WDFD12) ranges from about 2,100 to 2,800 mg/L. Dissolved-solids concentrations in water from two wells completed in the spoils aquifer range from about 4,100 to 5,700 mg/L, compared to an average concentration of 2,500 mg/L reported by Davis (1984a, p. 35) for a larger number of wells. The concentration of 5,700 mg/L in water from well WDFSP3 is much larger than the average concentration and is probably one of the largest concentrations in water from the spoils aquifer. The water having 4,100 mg/L concentration, although larger than the 2,500 mg/L average concentration, probably can be assumed to be representative, as the chemical character of this water is virtually the same as other spoils water with smaller dissolved-solids concentrations.

Predominant cations and anions are depicted on diagrams (fig. 12) for samples collected during October 1988. The data on the trilinear diagram for all six wells indicate the overall similarity of the ground water in the area, the predominance of the sodium and bicarbonate ions, and the paucity of calcium, magnesium, and chloride ions. Data for water samples from four selected wells, plotted as Stiff diagrams (fig. 12), indicate differences in the ground-water quality between the coal and spoils aquifers. Water from the spoils aquifer (well WDESP1) had larger concentrations of sodium, bicarbonate, and sulfate ions than water from the upgradient coal aquifer (well WDFCL1), which potentially recharged the spoils aquifer. Concentrations of all ions, particularly sulfate, decreased between the spoils well WDESP1 and the downgradient coal wells WDESP2 and WDED11.

Water samples for laboratory determination of dissolved-gas concentrations were collected from five wells, with oxygen, carbon dioxide and methane being the gases of primary interest (table 12). Oxygen was detected at trace levels in all five wells. Concentrations of carbon dioxide decreased substantially, from 280 to 51 mg/L, along the inferred flow path from well WDESP1 to WDED11. Methane concentrations of less than 1 mg/L were detected in samples from wells WDFCL1, WDFD12, and WDESP1, whereas concentrations of 8.8 and 6.6 mg/L were detected in samples from wells WDESP2 and WDED11.

Exhibit 28

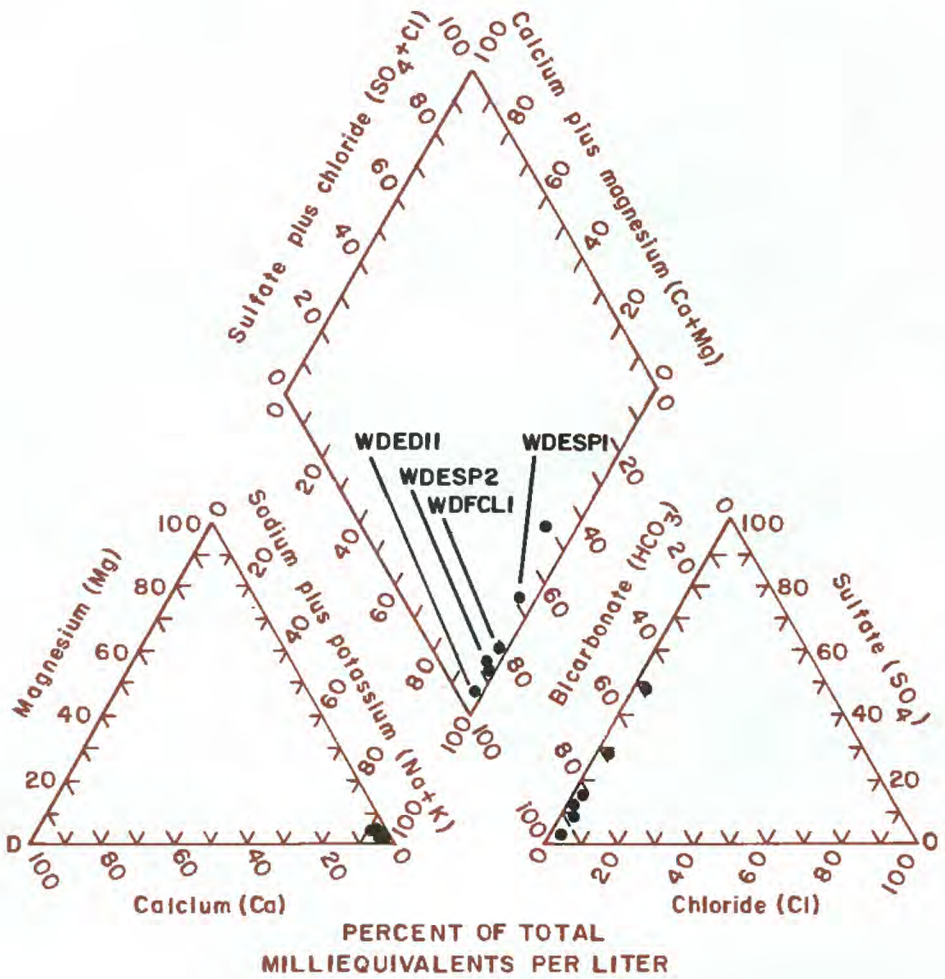

Figure 12. Trilinear and Stiff diagrams showing geochemical properties of ground water from the West Decker Mine area, Montana.

Exhibit 28

The tritium-activity values in water from wells WDESP1, WDESP2 and WDED11 were similar (10, 11, and 8 TU) (table 13). The values might indicate a similar source for the water. Although similar values may not necessarily substantiate other data to indicate that the wells were along a flow path, the values do most likely indicate that the water in the wells has relatively similar ages. Tritium-activity values in water from wells WDFCL1 and WDFD12 were larger than values in water from the other wells, possibly indicating a younger source of recharge water to these wells. Conversely, the tritium data might indicate that some water recharging the spoils aquifer, represented by well WDESP1, originated from an older source having small tritium values, possibly from the aquifer in the Dietz 2 coal bed by way of unplugged exploration drill holes (Van Voast and Reiten, 1988, p. 4).

Thermodynamic speciation calculations for water from the West Decker Mine area were made using the program WATEQF (Plummer and others, 1978) (table 16). Saturation indices listed are for minerals considered to be potentially reacting in the ground water. Saturation indices demonstrate that, in general, the water was saturated with respect to quartz, calcite, aragonite, and barite, near saturation with respect to dolomite, and undersaturated with respect to strontianite, gypsum, anhydrite, and celestite. The saturation indices for the iron minerals siderite, goethite, and amorphous FeS demonstrate that the water might have been either saturated or undersaturated with respect to the minerals, depending on the concentration of dissolved iron and the redox state of the water. Eh values were not measured but were calculated by the WATEQF model based on ion pairs. An Eh value of 0.18 volts calculated from the dissolved-oxygen concentration was used for saturation calculations for water from well WDESP1 (table 11). The Eh values for the other samples which contain dissolved sulfide and Fe^{2+} were calculated from the sulfur-ion concentrations, and ranged from -0.24 to -0.16 volts.

Geochemical Processes Along an Inferred Flow Path From Upgradient Coal Aquifer to Spoils Aquifer

The geochemical processes along an inferred flow path from an upgradient, unmined coal aquifer to a spoils aquifer were studied using solid-phase, ground-water, and hydrologic data. Dissolved-solids concentrations in water from the spoils aquifer were more than three times the concentrations in the assumed recharge water from the coal aquifer (table 11). In water from the coal aquifer within the mine area (well WDFD12), the dissolved-solids concentration was about 50 percent more than the concentration in water from the upgradient coal aquifer.

No direct evidence was available to determine the amount of water, if any, that might have been recharged from the upgradient coal aquifer represented by well WDFCL1 to the spoils aquifer represented by well WDFSP3. Although the potentiometric-surface data (fig. 11) indicate that water flowed from the coal aquifer toward the mine area, hydrologic barriers may have prevented some water from entering the spoils. Some recharge water to the upgradient coal aquifer might have been from the Tongue River Reservoir, because mine dewatering has lowered aquifer water levels below the level of the reservoir. Primary recharge sources prior to mining were aquifers northwest of the mine area (Davis, 1984a, fig. 7), which potentially continue to be major sources of recharge. Upward migration from deeper aquifers through exploratory drill holes (Van Voast and Reiten 1988, p. 19) was another possible source of recharge.

The water in well WDESP1, completed in spoils, is assumed to be most representative of water in the spoils aquifer. Although actual dissolved concentrations might be larger or smaller than median values for the spoils aquifer, the reactions necessary to create the spoils water from upgradient coal aquifer water are assumed to be similar.

The changes in water chemistry between the recharge water and water in the spoils aquifer most likely were the result of only a few processes. The large increases in dissolved sulfate and sodium concentrations were likely a result of an initial dissolution of gypsum followed by the exchange of calcium or magnesium ions for sodium ions on the smectite clays in the spoils aquifer. The increase in bicarbonate concentration was likely the result of dissolution of the carbonate minerals calcite or dolomite.

Results of solid-phase analyses show that calcite and dolomite generally were common to abundant in the spoils. Gypsum was detected at only trace levels; however, it might have been concentrated in zones that were not sampled or it might have been in quantities too small for detection. Pyrite, which was abundant near the top and bottom of the coal bed, probably was oxidized when exposed by mining, thereby increasing acidity and the concentration of dissolved sulfate ions. The acidity probably was buffered by dissolution of the carbonate minerals. The sulfate ions were either transported to the aquifer or precipitated as gypsum or possibly other sulfate minerals in the unsaturated zone, and then dissolved and transported to the aquifer by recharge water.

Changes in isotopic composition of the waters could not be attributed to a specific or evident process. Differences in isotopic composition of water from well WDFCL1 and water from wells WDFD12 and WDESP1 (table 13) might have been the result of dilution or dissolution rather than isotopic fractionation.

Exhibit 28

Mass-balance models were used to simulate possible geochemical changes that might occur as water from the coal aquifer recharged the downgradient spoils aquifer. Simulations were made for paths from the coal aquifer, represented by well WDFCL1, to the spoils aquifer, represented by wells WDFSP3 and WDESP1. The results of the simulation indicate that the major geochemical processes were the dissolution of gypsum, calcite, and some dolomite; the exchange of calcium ions for sodium ions; the consumption of carbon dioxide gas; and the dissolution of minor quantities of strontianite and halite (table 17). The results of the simulations generally were supported by the solid-phase and gas analysis. Calcite, dolomite, and gypsum were detected by X-ray diffraction techniques and substantial quantities of carbon dioxide in the water were confirmed by gas analysis (table 12).

Geochemical Processes Along an Inferred Flow Path from Spoils Aquifer to Downgradient Coal Aquifer

The concentrations of major dissolved ions, some dissolved trace elements, stable isotopes, and dissolved gases were substantially different in water from well WDESP1 in the spoils aquifer than in water from wells WDESP2 and WDED11 in the downgradient coal aquifer. Selected median dissolved-ion concentrations for samples from each well are given in table 18. The dissolved-solids concentration decreased by nearly one-half, from 4,170 to 2,140 mg/L, along the inferred flow path from well WDESP1 to well WDED11 (fig. 10). Large decreases in median concentrations of major dissolved ions include sulfate, from 1,100 to 64 mg/L; bicarbonate, from 3,080 to 2,390 mg/L; and sodium, from 1,500 to 890 mg/L. Changes in concentrations of other ions along the inferred flow path include calcium, magnesium, manganese, strontium, all of which decreased to less than 30 percent of initial values, and barium which increased about 3,000 percent from the initial value. Although the relative concentrations of major ions decrease substantially along this inferred flow path, the chemical character of the water remained a predominantly sodium bicarbonate type (fig. 12).

This study was conducted as a follow-up to the laboratory experiments conducted by Davis and Dodge (1986). As a means of comparison, selected median values from the report by Davis and Dodge (1986) are included in table 18. A comparison between water from spoils and coal shows similar changes in laboratory and onsite results for most of the selected constituents, including decreases in concentrations of calcium, magnesium, sodium, bicarbonate, dissolved solids, manganese, and strontium, and increases in barium concentrations. Sulfate changed relatively little in the laboratory experiments but decreased substantially under onsite conditions because the experiments did not simulate the reducing environment found onsite. Davis and Dodge (1986, p. 7) concluded that the reactions causing the changes observed in the laboratory experiments included adsorption or ion-exchange reactions involving sodium ions exchanging for calcium ions and the precipitation of calcite.

Saturation indices calculated for minerals that might be reacting along the inferred flow path are given in table 16. The saturation state of dolomite and possibly goethite changed from saturated to near saturated or unsaturated as water flowed from the spoils aquifer to the coal aquifer. The saturation state of quartz, calcite, and strontianite was virtually unchanged, whereas the saturation state of the sulfate minerals gypsum, anhydrite, and celestite decreased substantially. Results for the remaining selected minerals generally were mixed.

The large change in the $\delta^{34}S$ isotopic ratio in sulfate of -0.2 to 62.5 ‰ along the inferred flow path was due to enrichment of the heavier sulfur isotope, whereas the change in the $\delta^{13}C$ in carbon of -0.8 to -9.4 ‰ was due to enrichment of the lighter carbon isotope (table 13). The magnitude of these isotopic changes is significant in that the changes occurred along a relatively short inferred flow path. Concentrations of carbon dioxide gas decreased substantially along the inferred flow path, and concentrations of methane increased (table 12).

Analytical results of solid-phase samples collected from drill cores were used to help substantiate potential geochemical reaction processes. Calcite and dolomite were relatively common to abundant in the spoils; gypsum, pyrite, siderite, and barite were identified in trace amounts; and smectite and kaolinite were the prevalent clay minerals (tables 4, 5, 6). Relatively large concentrations of sodium (table 7) and exchangeable sodium (table 8) demonstrate the sodic nature of the rock material in the West Decker Mine area. The presence of iron-bearing minerals such as goethite, pyrite, and siderite indicates that iron was available for the precipitation of iron-sulfide minerals.

Potential Reaction Processes

The changes in ground-water chemistry that occurred as water flowed from the spoils aquifer to the coal aquifer were likely the result of at least several reaction processes. The largest changes were decreases in the concentration of sodium, sulfate, and bicarbonate ions, and increases in dissolved sulfide. Possible reaction processes were the exchange of sodium ions for calcium ions on the surface of organic matter, bacterial reduction

of sulfate which decreased sulfate concentrations and produced sulfide ions, removal of the produced sulfide ions by precipitation of sulfide minerals, and decreases in the concentration of bicarbonate by precipitation of carbonate minerals. For all these processes to proceed in the same system, specific hydrogeochemical reactions must have occurred.

Ion-Exchange and Adsorption Reactions

Ion-exchange and adsorption reactions within saturated coal might have been important processes resulting in the decrease in cations as water flowed from the spoils aquifer to the coal aquifer. Typically, calcium or magnesium ions exchange for sodium ions (equation 10). If the reaction is reversed, the concentration of sodium ions in solution decreases and the concentration of calcium or magnesium ions increases. The extent to which exchange occurs primarily depends on the cation-exchange capacity (CEC) of the solid and the ion concentrations in solution.

The CEC for specific clay minerals generally is well known (Carroll, 1959, p. 754). Although coal and other organic material potentially have a relatively large CEC, only sparse information is available. Data for lignite samples from the Tongue River Member of the Fort Union Formation at a mine area in North Dakota (Donald C. Thorstenson, U.S. Geological Survey, unpub. data, 1985) indicate that the CEC of the lignite averages about 70 meq/100g, which is similar to the value of 70-100 meq/100g for smectite, an expandable clay, as reported by Carroll (1959, p. 754).

Typically, divalent calcium or magnesium ions in solution will exchange preferentially for monovalent sodium ions. However, in somc solutions containing large sodium concentrations (Drever, 1982, p. 84, Davis and DeWiest, 1966, p. 91) and in solutions containing virtually no dissolved calcium or magnesium and relatively large concentrations of dissolved sodium (Palmer and Cherry, 1984, p. 49), the sodium ions in solution tend to be exchanged for calcium or magnesium ions. Monovalent sodium ions in solution are unlikely to displace divalent ions unless the sodium percentage, which is the percentage of total cations in milliequivalents made up by sodium, is considerably greater than 50 (Hem, 1985, p. 161). The sodium percentage for the water from wells in the West Decker Mine area is considerably greater than 50 and generally greater than 90.

The possibility of the exchange of sodium ions for calcium ions in coal has been addressed in previous studies. Davis and Dodge (1986, p. 6) hypothesized about this exchange on the basis of experiments. During an earlier study of sodium and associated elements in the Anderson-Dietz 1 coal bed near Decker, Mont., Hildebrand (1988, p. 218) reasoned that the coal contains significantly larger concentrations of sodium, strontium, and barium and significantly smaller concentrations of potassium, calcium, and magnesium than samples from the Powder River structural basin owing to ion exchange. That study concluded that a large sodium percentage in the ground water causes chemical disequilibrium, which in turn causes sodium cations to be adsorbed by the coal in preference to other dissolved cations. The other adsorbed cations, particularly potassium, calcium, and magnesium, are then exchanged for the adsorbed sodium ions, resulting in a gradual increase in the sodium content in the coal. Large concentrations of barium and strontium in the coal could also be a result of cation adsorption.

Sulfate Reduction

Another major geochemical change along the inferred flow path was the substantial decrease in the concentration of dissolved sulfate from about 1,100 to 64 mg/L (table 17) and the subsequent increase in the concentration of dissolved sulfide. The removal of most of the sulfate is assumed to be the result of bacterial reduction with oxidation of organic carbon as the energy source. Dockins and others (1980, p. 6) found relatively large numbers of the sulfate-reducing bacteria *Desulfovibrio desulfuricans* in 25 of 26 observation wells sampled in southeastern Montana, and reported sulfide concentrations of about 1 mg/L. The occurrence of the sulfide in water in these coal aquifers probably can be attributed to bacterial reduction of sulfate and not to the slow kinetics of abiotic sulfate reduction.

Two assumptions are made for sulfate reduction and associated reactions to occur--the organic carbon source utilized is the subbituminous coal (represented compositionally by CH_2O) and the Fe_2O_3 is present as a source for iron and FeS_2 is present as a sink for sulfur (Thorstenson and others, 1979, p. 1,493). Using these assumptions, sulfate reduction with iron-sulfide precipitation can be represented by the following irreversible reaction:

$$15CH_2O + 2Fe_2O_3 + 8SO_4^{2-} + H_2CO_3 \xrightarrow{\text{sulfate-reducing bacteria}} 4FeS_2 + 16HCO_3^- + 8H_2O\,. \qquad (13)$$

Exhibit 28

With the completion of sulfate reduction, decomposition of the organic matter might continue according to the reaction:

$$2CH_2O \Rightarrow CH_4 + CO_2 \,. \qquad (14)$$

On the basis of results of hypothetical geochemical models, Martin and others (1988, p. 91) indicate that an ideal situation for large decreases in dissolved-solids concentrations within a coal aquifer involves populations of sulfate-reducing bacteria, organic-carbon sources that can be utilized by the bacteria, and a source of iron that will facilitate removal of the produced sulfide by mineral precipitation. Because coal at the West Decker Mine area is subbituminous, and in some instances nearly lignitic, the source of organic carbon for the bacteria was assumed to be the coal itself, which likely contains an unlimited supply of aromatic carbon compounds available to the bacteria.

Both dissolved sulfate and methane were detected in water samples from the coal aquifer (tables 11, 12). This geochemical incongruity is potentially explained by the existence of microzones within the coal aquifer, where all dissolved sulfate has been removed by reduction and where methanogenesis predominates. Chapelle and others (1988, p. 170) suggest that such bacterial microenvironments produce a mosaic of redox conditions, resulting in apparent redox non-equilibrium conditions. Sulfate-reducing bacteria generally will outcompete the methanogens in the same system, primarily because both rely on the same fermentation products, including hydrogen, an intermediate product in the decomposition of organic matter. When sulfate concentrations are not limiting, the sulfate-reducing bacteria maintain hydrogen at a concentration so small that methane production from hydrogen is thermodynamically unfavorable (Loveley and Goodwin, 1988, p. 2,994). However, at minimal sulfate concentrations, the metabolism of the sulfate reducers is so limited that methanogens might be able to outcompete the sulfate reducers and prevent further sulfate reduction.

Precipitation of Sulfide and Carbonate Minerals

Potential products of the reaction processes are iron-sulfide and calcium-carbonate minerals. Plummer and others (1990, p. 1,994-1,998) report laboratory studies wherein reactions of sulfide gas with goethite ($HFeO_2$) at temperatures of 22 to 24 °C formed an iron-sulfide precipitate that was assumed to be either a form of very fine-grained pyrite or amorphous iron sulfide. If iron was available within the coal aquifer, either dissolved or as goethite, then the sulfide gas produced during sulfate reduction could have reacted with the iron and precipitated an iron-sulfide mineral. Therefore, in a system where sulfide concentrations are small, sulfate reduction might still occur at relatively fast rates because the sulfide is being precipitated. Results of petrographic analysis for this study (table 4) indicate the presence of iron oxides, chemical analyses of water (table 11) indicate relatively large concentrations of dissolved iron, and thermodynamic calculations (table 16) indicate that some water is supersaturated with respect to goethite. Therefore, sufficient iron was assumed to be available for the precipitation of iron-sulfide minerals. The form of the iron-sulfide minerals was not determined as part of this study.

Carbonate minerals, such as calcite or magnesian siderite, might have precipitated as a result of reaction processes. A relatively large decrease in bicarbonate concentration along the inferred flow path (table 11) was likely a result of carbonate-mineral precipitation. Even though concentrations of calcium decreased along the inferred flow path (table 11), speciation calculations (table 16) show that all waters were slightly oversaturated with respect to calcite. The degree of oversaturation required to precipitate calcite given the observed field conditions is unknown, but the calculated oversaturation was assumed to be sufficient for precipitation.

Results of Laboratory Experiment

A laboratory experiment was conducted to determine if the decrease in dissolved-sodium concentrations along the flow path could be the result of preferential exchange of sodium ions in solution for calcium and magnesium ions in the coal. The experiment was conducted using coal samples from the West Decker Mine area collected during the drilling of observation wells, and concentrated solutions of sodium sulfate (Na_2SO_4). The experiment was conducted using samples of coal collected from the saturated and unsaturated zones. Samples from each zone were used to determine the effect of soluble minerals in samples from each zone on the experiment results.

Four of five crushed coal samples were initially mixed with deionized wash water for 48 hours to determine the quantity of soluble minerals within the coal. The mixing water was then decanted, filtered through a 0.45-µm filter, and analyzed for major ions. The coal was air-dried for 48 hours. The fifth coal sample, used as a control, was not mixed with deionized water. The five coal samples were then mixed using a 1:1.5 weight ratio with a Na_2SO_4 solution in 500-mL bottles. Two concentrations of Na_2SO_4 solution, 0.05 and 0.1 M, were used. The bottles, filled completely to eliminate oxygen, were shaken periodically for 48 hours. The mixtures settled, and the

Exhibit 28

coal and solutions were separated by decanting and filtering through a 0.45-μm filter. The filtered samples and the Na_2SO_4 solutions were analyzed for major ions.

Results of analyses of post-mixing wash water indicated substantial differences in the concentrations of the major constituents between mixtures using coal from the unsaturated zone and mixtures using coal from the saturated zone. The dissolved-solids concentration in the wash water from the unsaturated-zone mixtures was about twice that of the wash water sample from the saturated-zone mixtures (table 19). In addition, the wash water from the unsaturated-zone mixture was a sodium sulfate type, whereas the wash water from the saturated-zone mixture was a sodium bicarbonate type. These results might indicate that as water levels declined, soluble sodium-sulfate or sodium-carbonate minerals were precipitated above the water table.

When the sodium-sulfate solutions were added to the coal samples, analyses of the post-mixing solutions showed a general decrease in sodium concentrations and a large increase in the concentrations of calcium and magnesium ions. Sodium ions from the 0.05 M Na_2SO_4 solution apparently were exchanged for about 150 mg/L of calcium ions and about 60 mg/L of magnesium ions (table 19). Sodium ions from the 0.1 M Na_2SO_4 solution apparently were exchanged for about 340 mg/L of calcium ions and about 130 mg/L of magnesium ions, or approximately twice the amount exchanged from the 0.05 M Na_2SO_4 solution.

The results of the experiment indicate that sodium ions in solution can be preferentially exchanged on coal for calcium and magnesium ions. A large concentration of sodium ions in solution, especially when compared to small concentrations of calcium and magnesium ions, might control the direction of the exchange reaction (equation 10) and the quantity of exchange. The large concentration of sodium ions in the spoils water relative to the concentration of calcium and magnesium ions (table 11) indicates that the conditions for exchange of sodium ions for calcium or magnesium ions existed in the study area.

Mass-Balance Reaction Models

An objective of the geochemical modeling was to identify reactions or processes that resulted in the initial quality of ground water and caused chemical changes to occur along inferred flow paths. Ideally, the modeling would determine the quantities and types of minerals reacting in the system, either precipitating or dissolving, and would calculate speciation and isotopic effects as the reactions progressed. Geochemical mass-balance models were constructed to calculate the mass transfer of phases between water in the spoils aquifer and water in the downgradient coal aquifer. Possible reactant or product phases are listed in table 20.

The wells along the inferred flow path were sampled three times from October 1988 to May 1990. However, mass-balance calculations are presented only for the October 1988 samples, for which dissolved-gas analyses and full isotope analyses were available. Sulfur-isotope analyses for sulfate and sulfide in water collected in May 1989 from well WDESP2 were used in calculations. Mass-balance calculations were made using water-quality data for four wells (table 21).

Plausible Phases

Eight plausible reactant or product phases were considered for mass-balance reaction modeling (table 20). Organic matter was assumed to represent a carbon source and was included as a probable energy source and electron donor for bacterial reduction of sulfate. Sources of available iron species, such as goethite, are assumed to be present in sufficient quantities for the precipitation of pyrite or other iron-sulfide mineral forms such as amorphous FeS. Dissolved sulfide was included as a product of sulfate reduction because of the presence of sulfate-reducing bacteria. Carbon dioxide was included as a product of the oxidation of the organic matter. Calcite and magnesian siderite were included as plausible sinks for the removal of bicarbonate. Cation exchange of sodium ions for calcium or magnesium ions was included as a plausible phase for removing sodium ions from solution and for providing calcium and magnesium ions necessary to precipitate calcite, magnesian siderite, or other carbonate minerals.

Oxidation-reduction reactions are considered plausible along the inferred flow path, including sulfate reduction and the oxidation of organic matter and ferric hydroxide. The redox state (RS) shown in table 21 is a method of keeping track of electron transfer for redox reactions. The redox state is defined as follows:

Exhibit 28

$$RS = \sum_{i=1}^{I} m_i v_i \qquad (15)$$

where

I = the number of species in solution,
m_i = the molality of the i'th species in solution, and
v_i = the operational valance of the species.

Further description of operational valance and redox state is addressed by Plummer and others (1990, p. 1,991).

Isotopic Ratios

Stable-isotope data for dissolved carbon, sulfate, and sulfide were used in conjunction with other water-quality data to construct geochemical-reaction models for the inferred flow path from the spoils aquifer to the downgradient coal aquifer. Isotopic data were included in reaction modeling because they might provide an independent constraint without adding an additional phase. The sulfur- and carbon-isotope data were treated as Rayleigh distillation and not as dilution or isotope mass balance. Rayleigh distillation is a process where products in a chemical or physical reaction differ isotopically from the reactants and are isolated from the system after formation. Rayleigh distillation reactions were used to calculate the isotopic composition of the final solutions. The calculations were an independent check, because the correct reaction model would be among those predicting the observed isotope composition. The equation used for this report is described by Busby and others (1991, p. 43) and was adapted for Rayleigh distillation of the sulfur-isotope composition of dissolved sulfate from the equations developed by Wigley and others (1978, 1979).

To model fractionation and evolution of isotopes along the inferred flow path, isotopic values of initial sources and final products or isotopic sinks are needed. The value for a dissolved source, such as sulfate, can be determined from an aqueous sample. However, determining values for a solid source, such as an amorphous or microcrystalline precipitate, can be considerably more difficult. Some data are available in the literature for isotopic ratios of various sources and sinks.

Carbon

Dissolved carbon in ground water primarily is derived from carbonate sediments, soil organic matter, the decay of other organic material, and in some instances, atmospheric CO_2. The $\delta^{13}C$ of the dissolved carbon can vary widely depending on the source of the carbon. Values of $\delta^{13}C$ for coal range from -24 to -30 ‰ for samples collected from the Powder River structural basin, including the West Decker Mine area (Holmes, 1988, p. 211). Other values of $\delta^{13}C$ for coal include -28 $\pm$ 4‰ for sedimentary organic carbon (Rightmire and Hanshaw 1973, p. 959). The $\delta^{13}C$ of -0.8 ‰ in the initial water, well WDESP1 (table 13), was likely derived from dissolved carbonate or CO_2. The $\delta^{13}C$ of the dissolved carbon changed substantially along the inferred flow path to -8.8 and -9.4 ‰--potentially a result of bacterial fractionation of the carbon in the subbituminous coal.

The concentration of dissolved organic carbon (DOC) in water in the coal aquifers probably was significant. DOC samples were not collected during this study; however, concentrations in about 40 DOC and total organic carbon (TOC) samples collected by Lee (1979) from wells completed in the Tongue River Member of the Fort Union Formation ranged from 0.1 to 83 mg/L and had a median value of about 5 mg/L. This median value was assumed to be representative of DOC in the coal aquifer at the West Decker Mine area, and the $\delta^{13}C$ of the DOC was assumed to be the same as the $\delta^{13}C$ of the coal from which it presumably was derived.

Sulfur

The difference between the $\delta^{34}S$ values of the sulfide and sulfate ($^{34}\Delta$) determined in one sample was calculated by the equation:

Exhibit 28

$$^{34}\Delta = \delta^{34}S_{H_2S} - \delta^{34}S_{SO_4}. \quad (16)$$

The $^{34}\Delta$ used for this study, as calculated from the values at well WDESP2 (table 13), was -41.2 ‰ at a temperature of 17 °C. The equilibrium value for $^{34}\Delta$ for this system is not known; however, various studies indicate an approximate value of about -65 ‰ (Back and others, 1983, p. 1,422). The value of -41.2 ‰ most likely represents non-equilibrium conditions controlled by microorganisms or, in other words, a kinetic fractionation mediated by bacterial action.

Plummer and others (1991, p. 19) present an equation:

$$\delta^{34}S_{H_2S} = \delta^{34}S_{SO_4} - 54 + 0.40t, \quad (17)$$

to calculate $^{34}\Delta$ based on linear function of temperature (t in °C). Using the temperature of 17 °C in equation 17, the calculated $^{34}\Delta$ would be -47.2 ‰ which is in general agreement with the $^{34}\Delta$ determined for this study (-41.2 ‰). The value of -41.2 ‰ was therefore assumed to be the sulfur-isotope fractionation value representative of water from wells in the West Decker Mine area.

Water from 15 wells completed in alluvial, coal, shale, sandstone, and spoils aquifers in southeastern Montana was analyzed for $\delta^{34}S$ values for sulfide and sulfate (Dockins and others, 1980, p. 6). Values of $\delta^{34}S$ for sulfides ranged from -38.50 to 6.68 ‰ and averaged -23.80 ‰, whereas values for sulfate ranged from -0.20 to 45.17 ‰ and averaged 7.96 ‰. The $^{34}\Delta$ for these samples ranged from -9.54 to -48.13 ‰ and averaged -32.31 ‰.

Requirements for Preparing Mass-Transfer Models

The $\delta^{13}C$ value of organic matter (CH_2O) used in the models varied between -20 and -32 ‰, but generally ranged from about -28 to -30 ‰. Although this range is slightly isotopically lighter than the -25 ‰ that is commonly referenced, it does fall within the range of values reported by Rightmire and Hanshaw (1973, p. 959) and Holmes (1988, p. 211).

The initial $\delta^{34}S_{SO_4}$ was assumed to be equivalent to the value from well WDESP1 of -0.2 ‰. No additional input of $\delta^{34}S$ from other sources such as gypsum, anhydrite, or pyrite was likely because dissolved-sulfate concentrations decreased along the inferred flow path. The $^{34}\Delta$ fractionation of -41.2 ‰ was assumed to be the fractionation value along the inferred flow path; therefore, the $\delta^{34}S_{H_2S}$ used for samples from wells WDESP1 and WDED11 was calculated by subtracting the fractionation value from the values of $\delta^{34}S_{SO_4}$.

Amorphous iron sulfide (FeS) was included as a product because of the presence of H_2S, and goethite ($HFeO_2$) was included as a reactant. A laboratory study (Price and Shieh, 1979) indicated reactions of H_2S with goethite precipitated fine-grained pyrite, and the pyrite had only a slightly different $\delta^{34}S$ than that of the H_2S source, indicating little fractionation occurred between H_2S and the precipitated pyrite. Therefore, for the purpose of the mass-transfer model, the $\delta^{34}S$ of precipitated amorphous iron sulfide was assumed to be equal to that of dissolved H_2S.

Sulfate reduction was assumed to have occurred at relatively fast rates. Even though dissolved H_2S was detected in relatively minor quantities, the H_2S might have either degassed or precipitated as an iron-sulfide mineral in the presence of goethite. At least two products for the reduced sulfate were therefore considered in the model: H_2S gas, and precipitation of an iron-sulfide mineral in conjunction with the dissolution of an iron mineral such as goethite.

Another likely product was siderite, an iron-carbonate mineral detected in solid-phase samples from the West Decker Mine area (table 5). Siderite apparently is rarely found as pure $FeCO_3$ and the substitution of Fe^{2+} by other metallic ions such as magnesium (Mg) and manganese (Mn) is common (Deer and others, 1966, p. 487). Siderite might contain Mg in substitution for Fe to a complete solid solution as magnesite ($MgCO_3$). For the purpose of this mass-transfer model, magnesian siderite was assumed to precipitate at atmospheric temperatures and pressures with a composition of $Fe_{0.7}Mg_{0.3}CO_3$.

Exhibit 28

Ion exchange probably was an important reaction along the inferred flow path, as evidenced by results from the laboratory experiments and by the decrease in dissolved sodium ions. Ion exchange was calculated primarily for sodium ions exchanging for calcium ions, and to a lesser extent, for sodium ions exchanging for magnesium ions.

Traces of methane (CH_4) were detected in dissolved-gas analyses (table 12). Although methane was not considered to significantly affect the overall geochemical results, it may have affected the calculated value of $\delta^{13}C$, and therefore was included in the geochemical modeling. Methane production was assumed to occur either in microzones where sulfate had been removed, or after sulfate reduction had virtually eliminated dissolved sulfate from the entire system. The $\delta^{13}C$ of methane was assumed to have a value of 50 ‰ less than the measured $\delta^{13}C$ in water from each well (Plummer and others, 1990, p. 1,999).

The supply of water from some wells was not adequate to accurately measure all parameters in a closed flow cell, including onsite measurement of some pH values. In such instances, the pH values were calculated using concentrations of alkalinity and CO_2 gas (table 12) (Pearson and others, 1978). A substantial difference between the onsite and calculated values was detected only for the sample collected from well WDED11 in October 1988. The onsite value of 7.2 was corrected to a calculated value of 7.8 for use in thermodynamic calculations (table 21).

Mass-Transfer Results

The results of mass-transfer calculations for calcite, magnesian siderite, organic matter, goethite, iron sulfide, H_2S gas, CO_2 gas, and ion exchange, in millimoles per kilogram of water, are listed in table 22. The calculated and observed $\delta^{13}C$ and $\delta^{34}S$ values, and the assumed isotopic composition of organic matter and sulfur-isotope fractionation values, are also listed in table 22. The mass-transfer results are listed for four combinations of wells along the inferred flow path. Path 1 has water from spoils well WDESP1 as the initial water and water from coal well WDED11 as the final water, path 2 has water from spoils well WDESP1 as the initial water and water from coal well WDESP2 as the final water, and path 3 has water from coal well WDESP2 as the initial water and water from coal well WDED11 as the final water. In addition, transfer was calculated along a fourth path, which included initial water from spoils well WDESP1 and mixing of water from an underlying coal bed and coal well WDED11 as the final water. When the results from paths 2 and 3 are added together, the sum generally should equal the results from path 1, excluding the isotopic ratios.

The computed mass transfer from the initial water to the final water (table 22) represents net millimoles of each phase entering (positive sign) or leaving (negative sign) a kilogram of water. For example, water from spoils well WDESP1 moving along path 2 to coal well WDESP2 (table 22) might evolve according to the following net reaction:

$$\text{Water from well WDESP1} \overbrace{+\ 17.5\ CH_2O + 5.64\ HFeO_2 + 10.0\ CaMgX}^{\text{phases entering solution}} \Rightarrow$$

$$\text{Water from well WDESP2}\ \underbrace{+\ 9.09\ CaCO_3 + 8.06\ Fe_{0.7}Mg_{0.3}CO_3\ + 8.38\ H_2S + 11.8\ CO_2\ + 10.0\ Na_2X}_{\text{phases leaving solution}} \qquad (18)$$

The principal calculated mass transfers (table 22) were the oxidation of organic matter, the corresponding production of CO_2 gas, the exchange of sodium ions in solution for calcium and magnesium ions, and the corresponding precipitation of calcite and magnesian siderite. Two separate plausible reactions were calculated for the sulfur "sink": production of H_2S gas, and the dissolution of goethite with the corresponding precipitation of iron sulfide. Most likely, the sulfur "sink" was a combination of H_2S production, which was detected, and precipitation of iron sulfide.

Most of the mass transfer was calculated to occur between spoils well WDESP1 and coal well WDESP2 (path 2, table 22), where water from the spoils aquifer flows into the coal aquifer, and where sulfate reduction and exchange of sodium ions for calcium or magnesium ions is initiated. Calculated mass transfer along the path from coal well WDESP2 to coal well WDED11 indicate the same processes; however, the magnitude of the mass transfer was less than between wells WDESP1 and WDESP2. The results considered to be most representative of the inferred flow path are those calculated for the entire path from spoils well WDESP1 to coal well WDED11, path 1 in table 22.

Exhibit 28

To use the isotopic data as an additional modeling constraint, the mass-transfer results and the Rayleigh distillation equations of Wigley and others (1978, 1979) were included in the geochemical model NETPATH (Plummer and others, 1991) to predict observed values of $\delta^{13}C$ and $\delta^{34}S$ at the downgradient wells (table 22). An example of these detailed calculations is given in the NETPATH manual (Plummer and others, 1991).

Comparison of the calculated and observed $\delta^{13}C$ values helps in determining whether the predicted reactions might represent plausible reactions. The calculated and observed results for $\delta^{13}C$ along path 1 (table 22) were similar and based on representative isotopic values for the reacting and product phases. The results indicate that the isotopically light carbon of the subbituminous coal (-29.5 and -28 ‰) was likely utilized as an energy source by the sulfate-reducing bacteria. The utilization of the carbon caused the $\delta^{13}C$ in the water to become increasingly light along the path from a $\delta^{13}C$ value of -0.8 ‰ in the initial water to a value of -9.4 ‰ in the final water. The input values of $\delta^{13}C$ (-29.5 and 28 ‰) for both sets of mass-transfer calculations for path 1 are within an acceptable range of values. However, for the separate halves of the path (paths 2 and 3), the $\delta^{13}C$ values needed for the calculated values to approximate the observed values were unrealistically heavy, -21 ‰, or light, -31 ‰ (table 22).

Additional carbon inputs were dissolved organic carbon (DOC) and methane (CH_4). Both DOC and CH_4 were assumed to contribute carbon as an energy source for sulfate reduction. However, concentrations of both were relatively small compared to the quantity of carbon from organic matter necessary for the reactions to occur as postulated and therefore were not included in the mass-transfer calculations.

Mass-transfer results indicate that a large quantity of organic matter was oxidized and a correspondingly large quantity of CO_2 gas was outgassed. Although the quantity of CO_2 gas calculated to be outgassing was large, the quantity might not be unreasonable. The aquifer was relatively shallow and contained highly fractured coal, the overburden had been removed or replaced by spoils, and test holes which could vent CO_2 gas had been drilled throughout the area. In addition, relatively large concentrations of CO_2 gas were observed in samples collected in the West Decker Mine area (table 12).

Sulfur-isotope results were used to provide an additional constraint in the mass-transfer modeling. Sulfur-isotope values ($\delta^{34}S$) changed from -0.2 ‰ in water from spoils well WDESP1 to 33.2 ‰ in water from coal well WDESP2, to 62.5 ‰ in water from coal well WDED11. For the October 1988 samples, the dissolved-sulfate concentration decreased from 1,100 mg/L in water from WDEPS1, to 250 mg/L in water from WDESP2, to 51 mg/L in water from WDED11. This change was postulated to be the result of bacterially mediated sulfate reduction and not necessarily the result of another process such as dilution. Thermodynamically, the reduction of sulfate in the presence of reduced carbon (subbituminous coal) should proceed to the virtual disappearance of sulfate throughout the aquifer.

The magnitude of sulfate reduction observed is not unlikely when compared to other studies. Laboratory experiments performed by Fritz and others (1989, p. 103) induced sulfate reduction by *Desulfovibrio desulfuricans* bacteria in anaerobic water with a known initial sulfate concentration. Results indicated that the loss of dissolved sulfate during reduction was paralleled by increasing $\delta^{34}S$ values in the remaining sulfate (fig. 13). Experiments conducted for 211 to 228 days showed the largest isotope enrichment, whereas an experiment conducted for 50 days showed less isotope enrichment. The dissolved-sulfate concentration and isotope data from wells WDESP1, WDESP2 and WDED11 plotted on figure 13 show a similar pattern of decreasing sulfate and increasing enrichment of $\delta^{34}S$, indicating the loss in sulfate likely was due to sulfate reduction. The data from the experiments by Fritz and others (1989) including initial and final sulfate concentrations and $\delta^{34}S$ values closely match the data from the three wells. The time for the sulfate-reduction reaction for the experiments, 50 to 228 days, probably is similar to the time needed to produce the sulfate-reduction results observed in the three wells. These data would appear to provide further support for the assumption that wells WDESP1, WDESP2, and WDED11 are along a flow path.

Results of initial mass-transfer modeling using observed data and assumed values for input resulted in calculated $\delta^{13}C$ values closely approximating the observed $\delta^{13}C$ values. However, these same input data, including a $^{34}\Delta$ of -41.2 ‰, resulted in calculated $\delta^{34}S$ values that were about twice the observed $\delta^{34}S$ values. For the calculated values to approximate the observed values for the entire inferred flow path, a $^{34}\Delta$ factor of about -20 ‰, or about one-half the observed value, was needed. Additional model hypotheses were made in an attempt to have both carbon and sulfur isotope constraints result in calculated values that approximated observed values.

One hypothesis was adding a source for mixing water along the inferred flow path, causing the decrease in sulfate to be a result of both dilution and reduction. A potential source of mixing water is upward leakage from the underlying Dietz 2 (Dz2) coal bed. Upward leakage of water from the Dz2 coal bed into the Anderson-Dietz 1 (A-Dz1) coal bed is conceivable either through abandoned test holes or by diffuse seepage when water levels in the Dz2

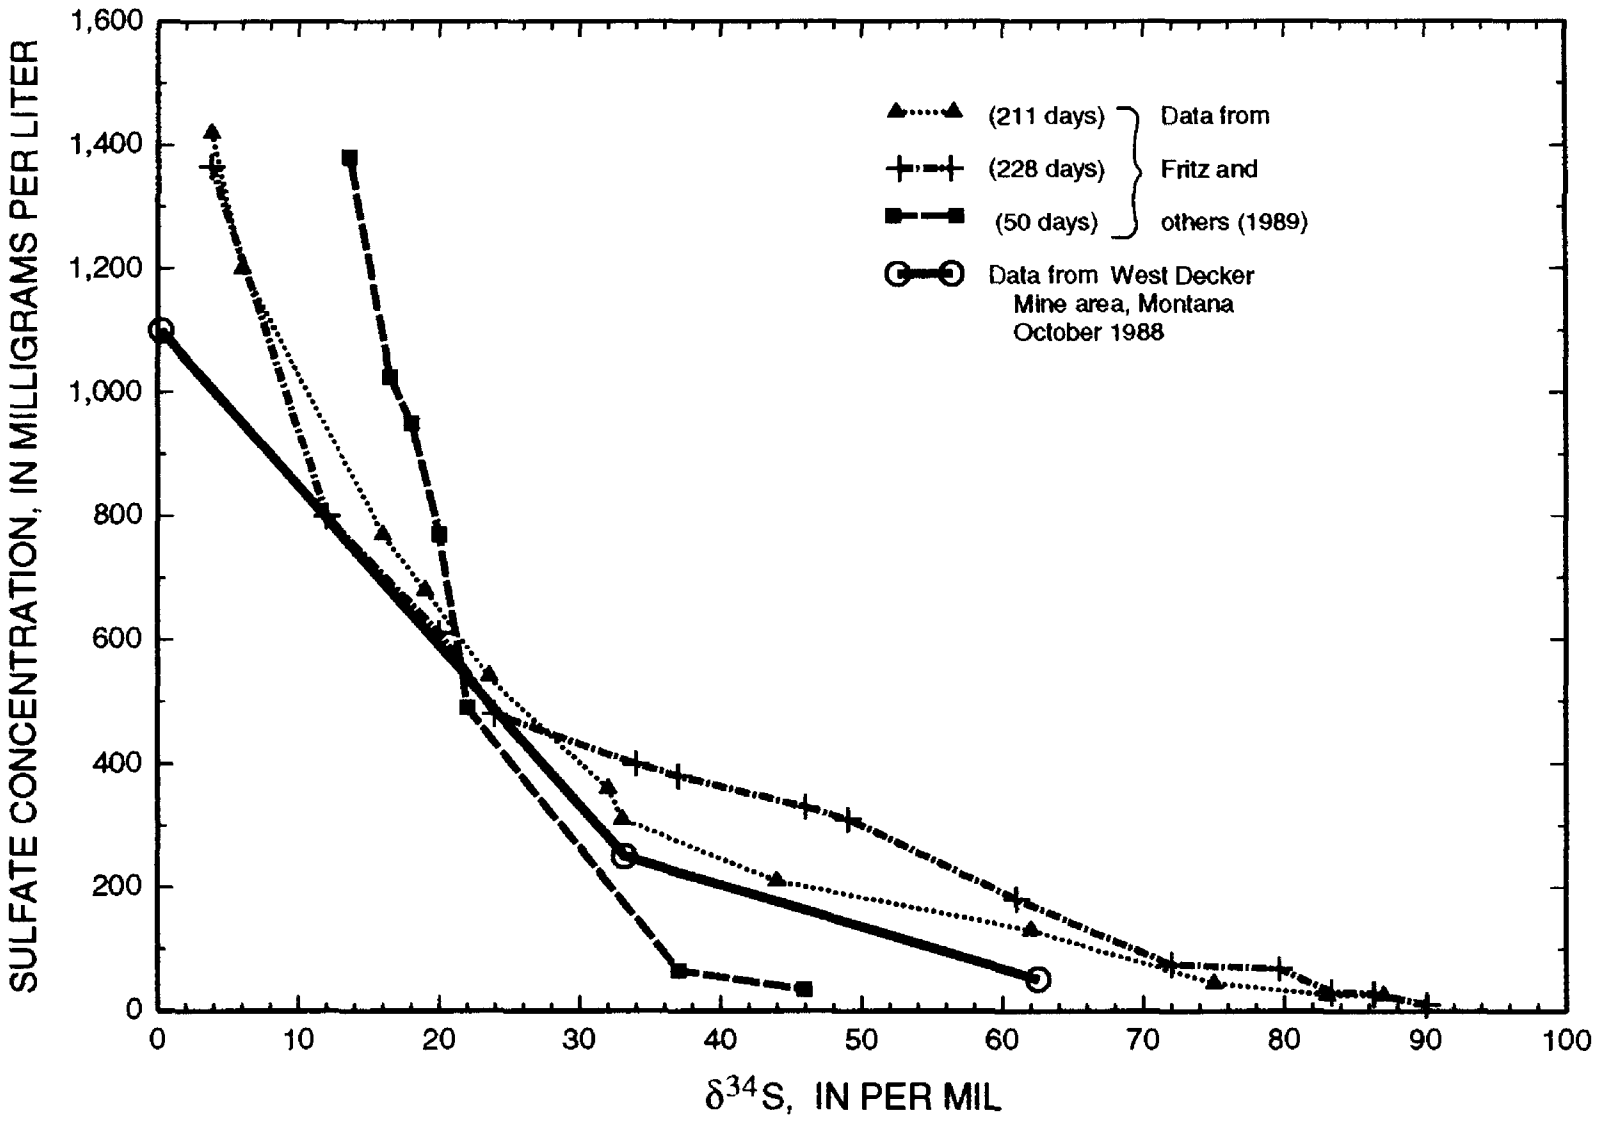

Figure 13. Relation of sulfate concentration in water to $\delta^{34}S$ values in residual sulfate after bacterial sulfate reduction.

coal bed were above the bottom of the A-Dz1 coal bed, and may have occurred during the late 1970's and early 1980's (Van Voast and Hedges, 1975, p. 14). Data from a ground-water flow model (Davis, 1984a) indicate the potential for a small quantity of premining vertical flow from the Dz2 to the A-Dz1 coal beds. Premining water-quality data from well WR-07 (tables 1 and 21) were considered to be representative of mixing water from the Dz2 coal bed. Isotopic values of $\delta^{13}C$ and $\delta^{34}S$ for the mixing water were assumed to be the same as the values from coal well WDED11, which contained the water with the smallest ion concentrations.

Mass-transfer model simulations were made with a range of mixing proportions, from about 10 percent Dz2 water and 90 percent spoils water to about 40 percent Dz2 water and 60 percent spoils water. Results from a model with 20 percent Dz2 water and 80 percent spoils water are given in table 22. When the results of path 4 are compared to path 1, a substantial decrease in the mass transfer of all reactant and product phases is indicated. In order for calculated values of $\delta^{13}C$ to match observed values, the addition of mixing water required changing the assumed $\delta^{13}C$ isotopic composition of the organic matter from -28 ‰ to -31 ‰, which is perhaps unrealistically light. Mixing the low-sulfate Dz2 water with the spoils water resulted in a slight change in the sulfur-isotope fractionation input factor from about -20 ‰ to about -23 ‰, which is still not close to the observed factor of -41.2 ‰. When a larger percentage of Dz2 water was used in the mixing models, the sulfur-isotope fractionation value that resulted was more negative, but the assumed $\delta^{13}C$ input value needed to be lighter and therefore even more unrealistic. Therefore, using mixing of waters in the mass-transfer models did not help solve problems related to the sulfur-isotope constraints.

Another possible explanation of the problem with the sulfur system is that water along the inferred flow path was not in chemical equilibrium. This explanation might mean that the sulfur concentration in the initial well, eventually reduced to the concentration in the final well, might have been considerably smaller than the observed 1,100 mg/L. However, results from mass-transfer models, wherein the sulfate concentration in the initial well was decreased from 1,100 to 500 mg/L or less, showed only a slight change in the sulfur-isotope fractionation factor and large discrepancies in the carbon-isotope results.

Exhibit 28

Mass-transfer models with isotopic constraints gave inconclusive results, especially with regard to the sulfur system. Observed and input data for the carbon-isotope system appear to be realistic; however, assumptions made about the sulfur system apparently are incomplete. If the sulfur-isotope fractionation factor were approximately -20 ‰ rather than -41.2 ‰, the model results would approximate observed results. Data in the literature support sulfur-isotope fractionation factors ranging from 0 to -65 ‰, and where the reaction is fast, kinetic fractionation is relatively small. However, no explanation is apparent as to why the observed difference between $\delta^{34}S$ of sulfide and sulfate was -41.2 ‰.

The most significant parameter in modeling error and inconsistency was $^{34}\Delta$, the sulfur-isotope fractionation factor, which was measured at only one of three wells along the flow path. In addition, unknowns about the $\delta^{13}C$ of the coal and the form of sulfide precipitate contributed to potential errors. Some parts of the modeling results, including the product and reactant phases, the proportions of the quantities transferred, and the carbon-isotope system, probably represent a reasonable solution to the geochemical processes that occurred along the inferred flow path. However, an almost unlimited number of small variations in isotopic composition, product phases, or minor changes in some analytical data due to uncertainties would also result in calculated values of $\delta^{13}C$ in close agreement with the observed values. Therefore, the calculated results are nonunique and semiquantitative. Possible reasons why the sulfur system could not be adequately modeled with observed data include that the water did not flow directly from the spoils aquifer to the coal aquifer without other influence, the water was not evolutionary, or additional isotopic data are needed to resolve the problem.

Verification of Results

Important phases in the mass-balance results were precipitation within the coal matrix of iron-sulfide minerals and the carbonate minerals, calcite and magnesian siderite. The quantity of either precipitate was likely very small in comparison to the mass of the coal matrix and therefore was difficult to confirm. The thermodynamic conditions and relatively short time frame probably equate to amorphous or microcrystalline mineral formation, making it unlikely that the quantities and size of precipitated iron-sulfide or carbonate minerals were large enough to be identified by standard techniques.

Minerals within fractures in the coal were extracted where possible, and analyzed by X-ray diffraction. Clay minerals were detected most frequently, including large quantities of almost pure crystalline kaolinite. In addition, significant quantities of pyrite, barite, and fibrous gypsum, apparently formed by the oxidation of microcrystalline pyrite, were found on the surface of the coal. In general, X-ray diffraction was not suitable for detecting the microscopic minerals expected to precipitate, primarily because of the lack of a method to extract the minerals from within the structure of the coal.

Scanning electron microscopy (SEM) also was used to quantify minerals precipitated within the coal. Thin sections prepared from coal having visible fracturing and from small fragments of coal affixed to slides were coated with a conducting layer of either carbon or gold for SEM analysis. Energy dispersive spectroscopy (EDS) was used to identify elements of non-organic material within the coal samples. Amorphous or microcrystalline minerals precipitated as a result of geochemical changes would likely be found in relatively porous areas of the coal such as fractures, cleats, or vugs. Therefore, SEM and EDS primarily were used to search cemented microscopic fractures for carbonate and iron-sulfide minerals. The SEM and EDS were used in an attempt to verify the existence of these minerals and not necessarily to quantify them.

A photomicrograph from SEM of a fracture in coal collected from well WDESP1 at a depth of 123 ft is shown in figure 14a and an enlargement of a section of that fracture is shown in figure 14b. The SEM was used with backscatter, which accentuates areas with heavy minerals such as iron sulfide. The lighter area around the fracture (fig. 14b) might be iron sulfide as the EDS graph for that area (fig. 14c) indicates a predominance of iron and sulfur. The physical structure of the material within the lighter area (fig. 14b) does not appear to be significantly different from the surrounding organic material, possibly indicating that the iron sulfide identified using EDS does not have a definite crystal structure but is instead amorphous. Similar SEM photomicrographs and EDS graphs indicating non-crystalline iron-sulfide were obtained for several other samples containing cemented fractures.

Carbonate-mineral precipitation was a major part of simulated water-quality changes along the inferred flow path. However, examples of precipitated calcite were difficult to locate and identify positively. If calcite did precipitate within the coal aquifer, the crystal form and association with organic or non-organic material would be unknown. Numerous samples observed using SEM and EDS contained crystals that were primarily calcium; however, these crystals were relatively large (5 to 20 µm) and not always within the structure of the coal. Other samples had non-organic material identified as predominantly silicon and calcium at various ratios, possibly indicating calcite associated with quartz. Examples of minerals containing both calcium and sulfur were fairly

Exhibit 28

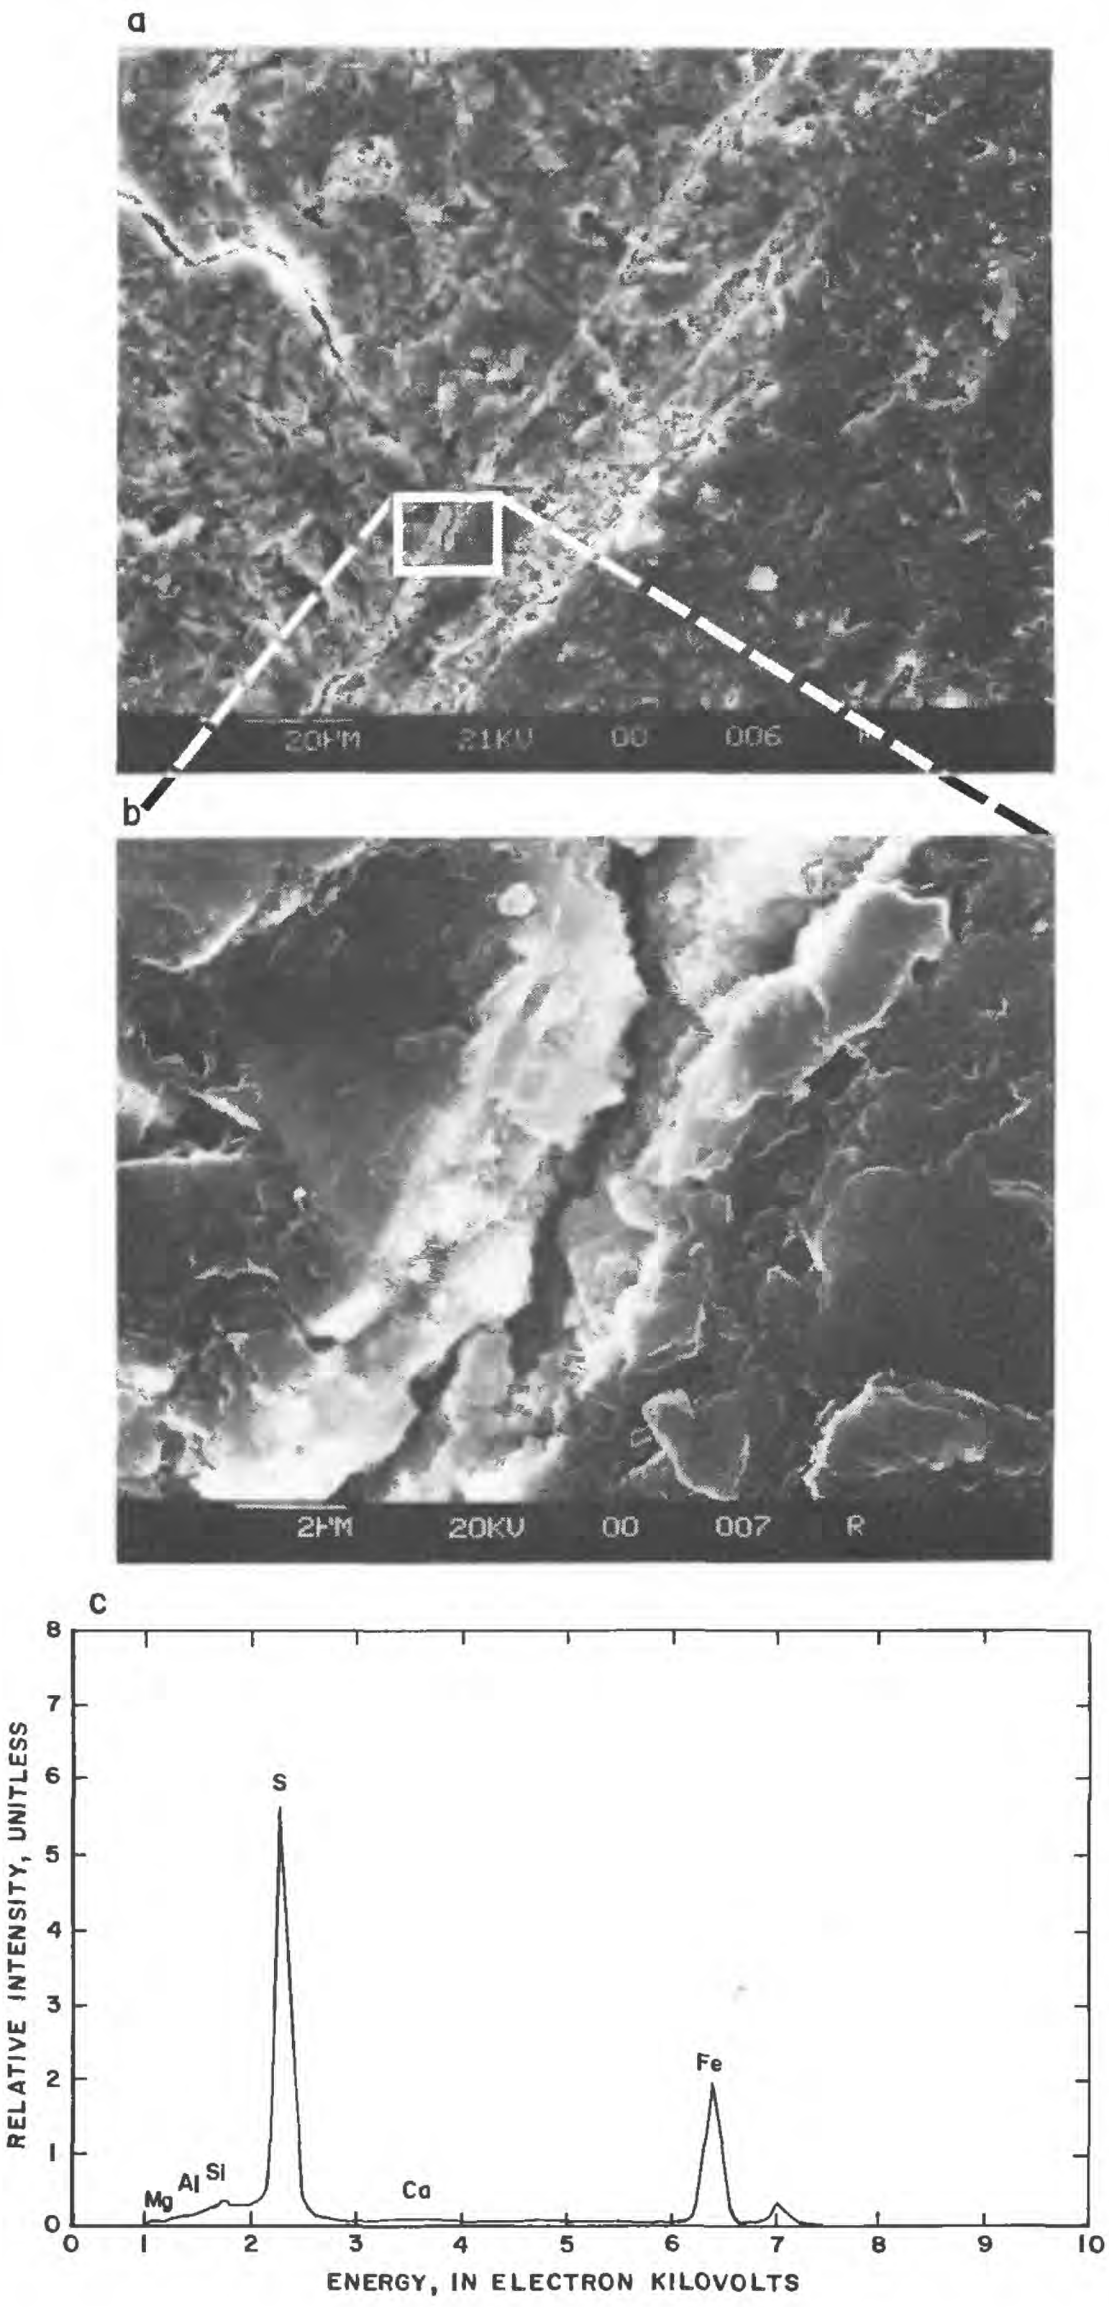

Figure 14. Photomicrographs (a,b) and graph showing elemental composition (c) of apparent amorphous iron-sulfide precipitate from a coal sample collected from the West Decker Mine area, Montana.

Exhibit 28

common, generally indicating gypsum; however, several samples contained ratios of calcium to sulfur substantially larger than the ratio expected for gypsum.

Several predominantly organic areas indicated by a large nondescript "hump" on the EDS graphs had substantial calcium associated with the organic material. Figure 15 shows an EDS graph of an area, about 2- to 4-µm in length, lining a small vug within the coal matrix of a sample collected from a depth of 123 ft in well WDED11. The figure shows that calcium and silicon are the predominant discernible ions within an organic matrix. In the center of a photomicrograph of another sample collected from well WDED11 at a depth of 123 ft is a 1-µm crystal (fig. 16). The crystal is most likely calcite; however, whether it was a primary or a secondary precipitate is unknown. Even though no definitive proof of secondary calcite precipitation as a result of mass transfer was found, there is substantial evidence from SEM and EDS of calcium within the coal that conceivably could be calcite.

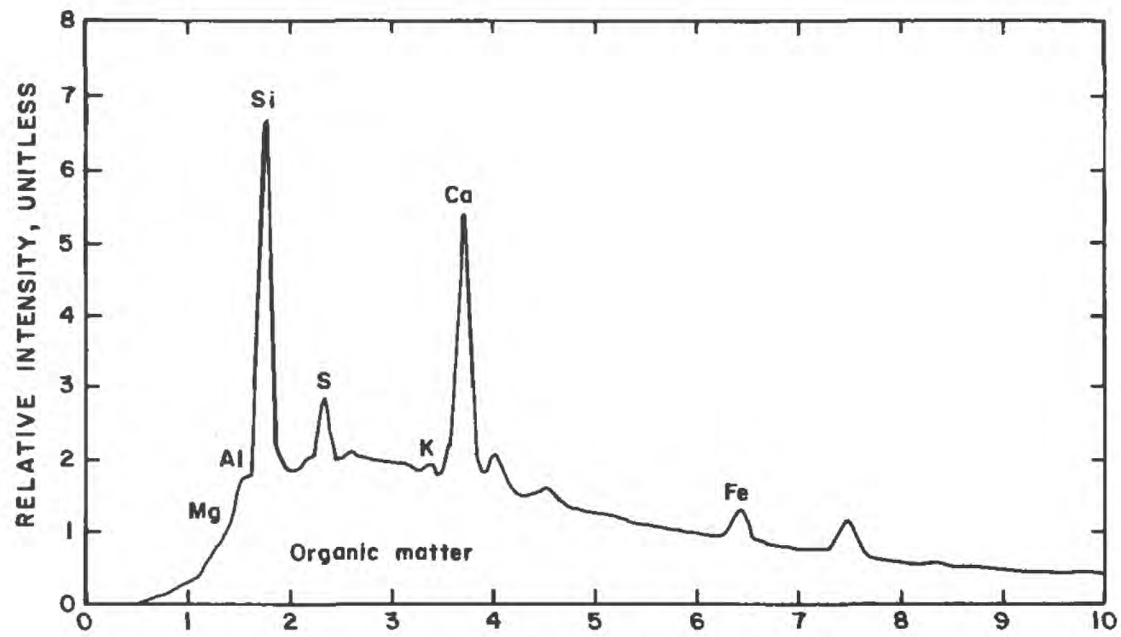

Figure 15. Elemental composition of apparent calcite crystal from a coal sample collected from the West Decker Mine area, Montana.

Processes Causing Geochemical Changes at the West Decker Mine Area

Processes postulated to cause geochemical changes in water as it moves along a potential flow path from the recharge area, to a spoils aquifer, and then to a downgradient coal aquifer at the West Decker Mine area are as follows:

1. Recharge Area
   - Entry of carbon dioxide into the system either by production in the soil or from the atmosphere.
   - Dissolution of carbonate minerals, primarily calcite and dolomite, resulting in an increase in the concentration of calcium, magnesium, and bicarbonate ions in solution.
   - Oxidation of pyrite, resulting in an increase in acidity and the concentration of sulfate ions in solution.
   - Precipitation of gypsum, or other salts, by evapotranspiration, resulting in an accumulation of sulfate minerals in the near-surface unsaturated zone.
2. Spoils Aquifer
   - Dissolution of gypsum, other salts, calcite, and dolomite resulting in a large increase in the concentration of dissolved solids.

Exhibit 28

- Cation exchange on clays in the spoils. Calcium and magnesium ions from dissolved gypsum and carbonate minerals exchange for sodium ions on clays, resulting in sodium bicarbonate or sodium sulfate type water. Exchange allows additional dissolution of gypsum and carbonate minerals.

3. Downgradient Coal Aquifer
   - Reverse cation exchange within the coal--exchange of sodium ions in solution for calcium and magnesium ions--which decreases sodium ion concentration and increases calcium and magnesium ion concentrations in solution.
   - Sulfate reduction by *Desulfovibrio desulfuricans* bacteria, with the production of H_2S and CO_2 gas and the use of coal as an energy source by the bacteria, resulting in large decreases in dissolved-sulfate concentrations.
   - Precipitation of calcium and iron-magnesium carbonate resulting in a decrease in bicarbonate concentration, and precipitation of iron sulfide as a sink for the sulfide produced by sulfate reduction.

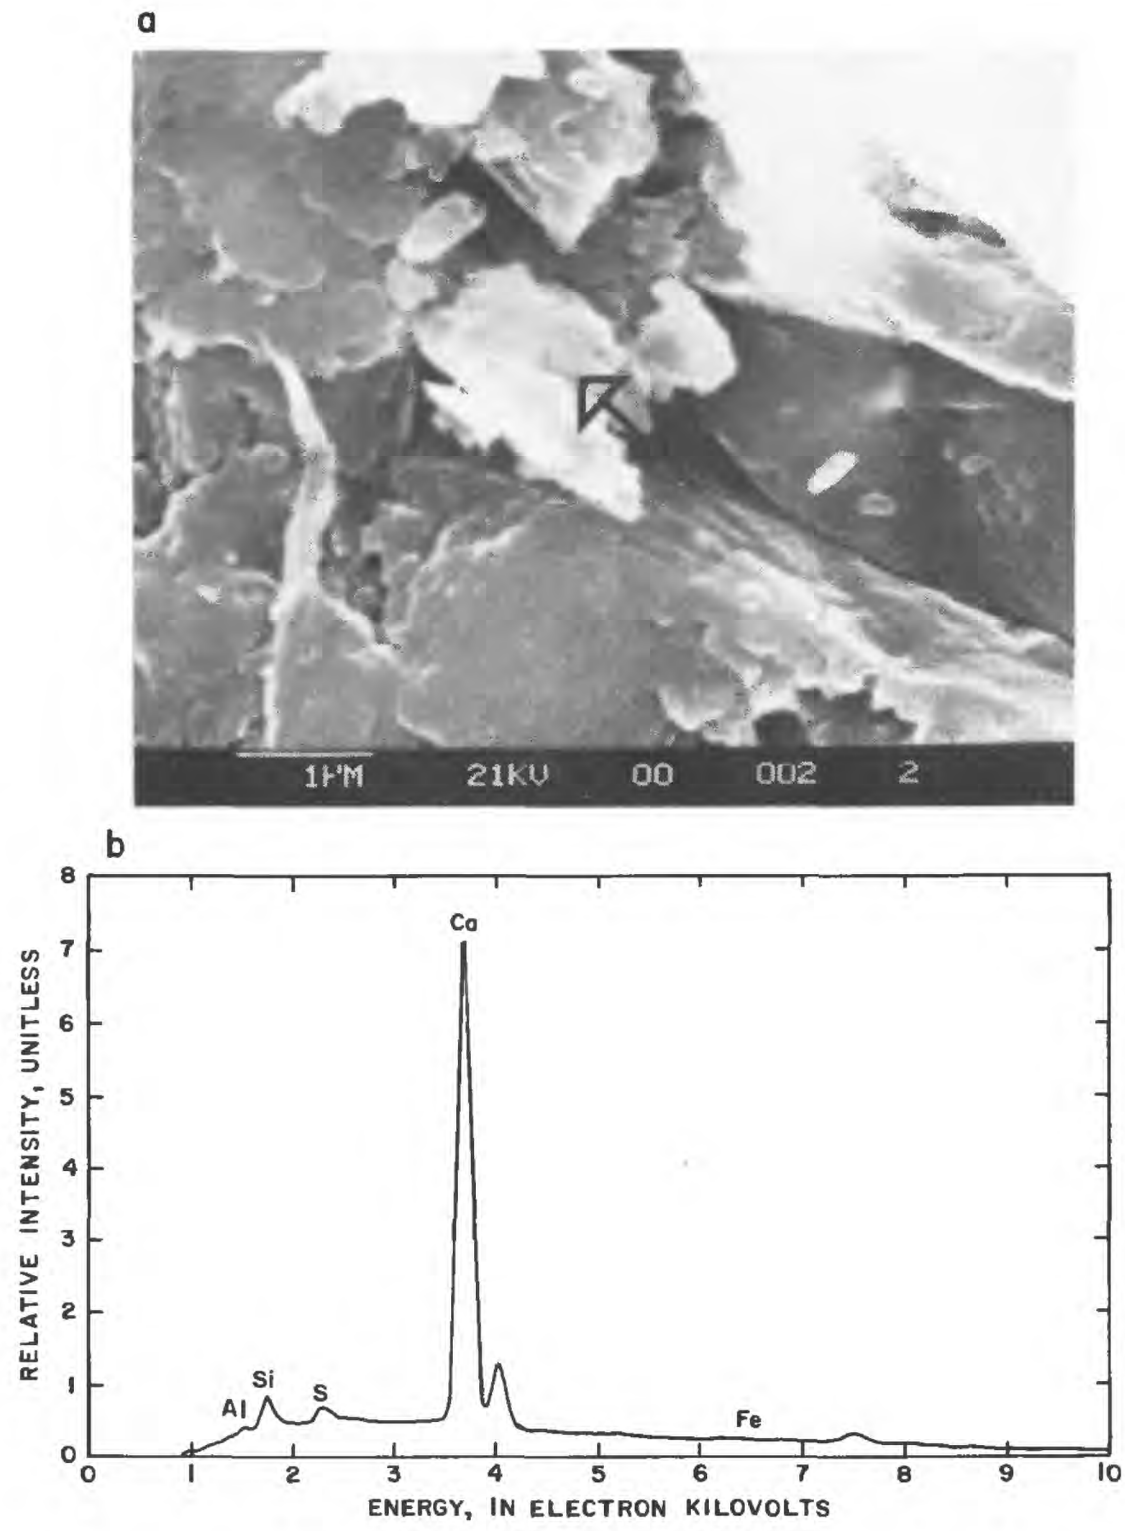

Figure 16. Photomicrograph (a) and graph showing elemental composition (b) of apparent calcite crystal from a coal sample collected from the West Decker Mine area, Montana. Arrow points to crystal.

Exhibit 28

The geochemical processes postulated to occur in the West Decker Mine area are the results of detailed sample collection and analysis. Even though the processes enumerated are thought to be those most likely occurring, they are considered nonunique and might not be the only feasible processes. Questions about the sulfate system and the $^{34}\Delta$ factor, the rate of sulfate reduction, the presence of sulfate and methane in the same water, the $\delta^{13}C$ of the coal, the large quantity of CO_2 apparently produced, the verifiable existence of secondary calcite and amorphous iron-sulfide precipitates in the coal, and other questions need to be resolved before the geochemical processes occurring in the system are fully understood.

IMPLICATIONS OF THE STUDY

Changes in ground-water chemistry along several inferred flow paths in two surface-coal mine areas of southeastern Montana were analyzed during this study. The two areas studied, the Big Sky and West Decker Mine areas, have distinct differences in mineralogy and ground-water geochemistry, and some differences in ground-water flow processes. Results indicate substantial increases in dissolved-solids concentrations as water flowed from an upgradient, offsite coal aquifer to a spoils aquifer. The general processes along the inferred flow paths from coal to spoils were similar at both areas and predominantly were the result of simple dissolution of soluble minerals such as gypsum, cation exchange within the spoils material, and potentially precipitation of carbonate minerals.

Changes in ground-water geochemistry also can occur when water flows from a spoils aquifer to a downgradient coal aquifer. Results differ substantially between the two study areas. At the Big Sky Mine area, only minor changes in dissolved-solids concentrations occurred along this path, whereas at the West Decker Mine area, large decreases in the concentration of several dissolved ions occurred along the inferred flow path. It is not fully understood why geochemical processes resulted in changes at the West Decker Mine area but not at the Big Sky Mine area. Probable reasons include differences in the mineralogy of the spoils material, age of the reclamation, differences in redox conditions, and bacterial reduction of sulfate.

Water at the Big Sky Mine area primarily was a calcium-magnesium sulfate type, whereas water at the West Decker Mine area was a sodium bicarbonate type, reflecting the mineralogy of the spoils material and coal in each area. Gypsum, calcite, and dolomite in the spoils and unmined material at the Big Sky Mine area were controlling factors on the geochemistry. At the West Decker Mine area, the sodic nature of the spoils material affected cation exchange processes, and thereby increased dissolved-sodium concentrations in the water in the spoils.

The primary processes involved in the decrease in dissolved-solids concentrations at the West Decker Mine area were: reverse cation exchange within the coal, bacterial reduction of sulfate and the consequent production of H_2S and CO_2 gas, and precipitation of carbonate or iron-sulfide minerals. These processes might not have occurred at the Big Sky Mine area for several reasons. Concentrations of dissolved sodium greatly exceeded those of calcium at the West Decker Mine area (table 11) allowing reverse cation exchange within the coal. At the Big Sky Mine area, however, concentrations of dissolved calcium were substantially larger than those of sodium, which negated the possibility of reverse exchange.

At the Big Sky Mine area, sulfate reduction was not a major geochemical process within the coal aquifer, even though dissolved-sulfate concentrations were large (table 11). Dissolved oxygen and sulfide concentrations varied, even between samples at the same well (table 11), indicating that oxidizing and reducing conditions might have alternately existed in the coal aquifer, thereby decreasing the opportunity for sulfate reduction. In addition, it is unknown if a viable population of sulfate-reducing bacteria existed in the coal aquifer at the Big Sky Mine area.

The results of this study include probable geochemical processes responsible for major decreases in concentrations of several dissolved ions as water flowed from a spoils aquifer into an unmined coal aquifer at the West Decker Mine area. The processes indicated by this study are assumed to include all major processes, although additional processes might occur. The saturated coal bed, where the major decreases occurred, was about 10 ft thick and 50 ft in length. The results of this study indicate that, under certain conditions, concentrations of certain dissolved ions in spoils water will decrease if allowed to flow into a layer of coal. Some of the geochemical conditions that would most likely result in large decreases in dissolved-solids concentrations are:

1. An indigenous population of sulfate-reducing bacteria.

2. Organic carbon that can be utilized as an energy source by the sulfate-reducing bacteria.

3. A source of iron that can assist in the removal of sulfide by precipitation of iron-sulfide minerals.

Exhibit 28

4. The capacity of the coal, or other organic-carbon source, to exchange sodium ions for calcium or magnesium ions in order to reduce concentrations of dissolved sodium ions and facilitate carbonate-mineral precipitation.

SUMMARY

A potential hydrologic effect of surface mining of coal in southeastern Montana is a change in the quality of ground water. Dissolved-solids concentrations in water in spoils aquifers generally are larger than concentrations in the coal aquifers they replaced; however, laboratory experiments have indicated that the concentrations might decrease if ground water flows from a spoils aquifer to a coal aquifer. This study was conducted to determine if the decreases indicated in laboratory results occur onsite and, if so, which geochemical processes caused the decreases. The Big Sky and West Decker Mine areas were chosen for study as both contain coal of the Tongue River Member of the Paleocene Fort Union Formation but have differences in mineralogy, ground-water quality, and flow processes.

Solid-phase drill-core samples of spoil, unmined overburden, and coal and ground-water samples were collected from 16 observation wells at the two mine areas. Observation wells were installed along inferred flow paths to obtain samples for quantifying possible geochemical changes as ground water flowed from an upgradient coal aquifer to a spoils aquifer, and from a spoils aquifer to a downgradient coal aquifer. Selected solid-phase samples were analyzed for elemental concentrations, exchangeable cations, and mineral constituents. Water samples were analyzed for major and trace constituents, selected isotopes, and dissolved gases. Equilibrium relations and mass-balance calculations were determined for water samples using geochemical models.

In the Big Sky Mine area changes in ground-water chemistry varied according to the inferred path studied. Along a path from the upgradient coal aquifer to the spoils aquifer, dissolved-solids concentrations increased from about 2,200 to 3,800 mg/L. These changes probably were a result of dedolomitization caused by the irreversible dissolution of gypsum at or near calcite-dolomite saturation. In contrast, along a path from the spoils aquifer to the downgradient coal aquifer, dissolved-solids concentrations were unchanged and concentrations of most dissolved ions were relatively small and probably not solely related to geochemical processes.

In the West Decker Mine area dissolved-solids concentrations increased substantially as water from an upgradient coal aquifer potentially flowed into a spoils aquifer. Increases in the concentration of dissolved sulfate and sodium most likely were the result of dissolution of gypsum followed by exchange of calcium or magnesium ions in solution for sodium ions on the smectite clays in the spoils aquifer. An increase in bicarbonate concentration was likely due to dissolution of calcite or dolomite.

Along an inferred flow path from a spoils aquifer to a downgradient coal aquifer at the West Decker Mine area dissolved-solids concentrations apparently decreased from about 4,100 to 2,100 mg/L. Apparent decreases in selected constituent concentrations included: sodium, from 1,500 mg/L to less than 900 mg/L; bicarbonate, from about 3,000 mg/L to less than 2,400 mg/L; and sulfate, from 1,100 mg/L to less than 100 mg/L. Data for solid-phase and aqueous geochemical characteristics, including types of reactive minerals, isotopic ratios, and dissolved-gas concentrations, were used to develop geochemical models to analyze changes in water chemistry. Geochemical processes postulated to result in the decrease in dissolved-solids concentration along this inferred flow path include: bacterial reduction of sulfate utilizing the organic matter in coal as an energy source; reverse cation exchange with sodium ions in solution exchanging for calcium and magnesium ions within the coal; and precipitation of carbonate and iron-sulfide minerals. Results of geochemical modeling were substantiated by solid-phase analysis and by applying Rayleigh distillation equations to the fractionation of carbon isotopes as an additional mass-balance constraint. Geochemical-modeling results using sulfur-isotope data as an additional constraint were inconclusive, implying that assumptions may have been incorrect or additional data were required. Even though these geochemical processes are thought to be the most likely to occur, they are considered nonunique and might not be the only feasible processes. In addition to sulfur-isotope data, questions about the rate of sulfate reduction, the isotopic composition of the coal, the large quantity of CO_2 produced, the existence of secondary carbonates and amorphous iron-sulfide minerals in the coal, and other potential questions need to be resolved before the actual geochemical processes occurring in the system are fully understood.

On the basis of results from this study, it can be assumed that concentrations of some dissolved ions in spoils water will decrease if allowed to flow to a coal bed under certain geochemical conditions. Some of the geochemical conditions most likely to result in large decreases in dissolved-solids concentration include a population of sulfate-reducing bacteria, organic carbon suitable for use by sulfate-reducing bacteria as an energy source, a source of iron to facilitate the precipitation of iron-sulfide minerals, and the capacity of the coal to exchange sodium ions in solution for calcium or magnesium ions.

Table 2. Summary of revised thermodynamic data

[Data from Nordstrom and others (1990) except where noted. Abbreviation: ΔH_r°, enthalpy of reaction; log K, equilibrium constant; Kcal/mol, kilocalorie per mole. Symbol: --, no data]

Mineral	Reaction	ΔH_r° (kcal/mol)	log K
Quartz	$SiO_2 + 2H_2O = H_4SiO_4$	5.99	-3.980
Calcite	$CaCO_3 = Ca^{3+} + CO_3^{2-}$	-2.297	-8.480
Aragonite	$CaCO_3 = Ca^{2+} + CO_3^{2-}$	-2.589	-8.336
Dolomite[1]	$CaMg(CO_3)_2 = Ca^{2+} + Mg^{2+} + 2CO_3^{2-}$	-9.436	-17.09
Strontionite	$SrCO_2 = Sr^{2+} + CO_3^{2-}$	-.40	-9.271
Siderite[2]	$FeCO_3 = Fe^{2+} + CO_3^{2-}$	--	-10.89
Gypsum	$CaSO_4 2H_2O = Ca^{2+} + SO_4^{2-} + 2H_2O$	-.109	-4.58
Anhydrite	$CaSO_4 = Ca^{2+} + SO_4^{2-}$	-1.71	-4.36
Celestite	$SrSO_4 = Sr^{2+} + SO_4^{2-}$	-1.037	-6.63
Barite	$BaSO_4 = Ba^{2+} + SO_4^{2-}$	6.35	-9.97
Goethite	$HFeO_2 + 3H^+ = Fe^{3+} + 2H_2O$	--	-1.0
FeS(ppt)[3]	$FeS = Fe^{2+} + S^{2-}$	--	[4]-3.915

[1]Thermodynamic data are for ordered dolomite.

[2]Thermodynamic data are for crystalline siderite.

[3]Amorphous iron-sulfide precipitate.

[4]Data from Plummer and others (1978).

Exhibit 28

Table 3. Logs of observation wells from the Big Sky and West Decker Mine areas, Montana

[Thickness penetrated is in feet. Bottom of depth interval is in feet below land surface]

Lithology	Thickness penetrated	Bottom of depth interval
Big Sky Mine area		
Observation well BSUMR1; drilled September 22, 1988		
Fill, topsoil	5	5
Mine spoils, gray, sandy	30	35
Mine spoils, sandy, clinker, calcareous	15	50
Mine spoils, grayish-green, sandy	17	67
Siltstone, gray	2	69
Sandstone, gray, very fine grained, calcareous	2	71
Sandstone; wet	12	83
Coal (Rosebud); water	21	104
Shale, gray; dry	1	105
Observation well BSUMSP1; drilled September 21, 1988		
Fill, topsoil, clinker, shale	5	5
Mine spoils, sandy; moist	5	10
Mine spoils, sandy, contains gravel, calcareous	12	22
Mine spoils, sand, clinker, coal; moist	38	60
Mine spoils, sand; wet	34	94
Shale	1	95
Observation well BSUMSP2; drilled September 21, 1988		
Mine spoils, sandy; moist	20	20
Mine spoils, sand, clinker, coal; moist	65	85
Mine spoils, sand; wet	12	97
Shale	1	98
Observation well BSLMSP3; drilled September 21, 1988		
Mine spoils, coal	10	10
Mine spoils, sand	10	20
Mine spoils, sandy, dark	5	25
Mine spoils, coal; wet	13	38
Mine spoils, siltstone, sandy, coal; water	12	50
Sandstone (sub-McKay)	.5	50.5
Observation well BSLMSP1; drilled September 13, 1988		
Mine spoils, clinker, coal	5	5
Mine spoils, sandy, calcareous	19	24
Mine spoils, sandy	8	32
Mine spoils; water	10	42
Mine spoils, coal, shale; water	7	49
Sandstone (sub-McKay)	2	51

Exhibit 28

Table 3. Logs of observation wells from the Big Sky and West Decker Mine areas, Montana (Continued)

Lithology	Thickness penetrated	Bottom of depth interval
Big Sky Mine area--Continued		
Observation well BSLMMC1; drilled September 13, 1988		
Mine spoils, yellowish-brown	10	10
Mine spoils, sand	5	15
Mine spoils, sand, rocks, brown	9	24
Mine spoils, sand, coal, clinker	8	32
Mine spoils, siltstone, sandy	3.5	35.5
Coal (McKay)	8.5	44
Sandstone (sub-McKay)	.5	44.5
Observation well BSLMMC2; drilled September 14, 1988		
Mine spoils	23	23
Siltstone, gray	6	29
Coal (McKay)	10	39
Sandstone (sub-McKay)	1.5	40.5
Observation well BSLMMC3; drilled September 14, 1988		
Mine spoils	5	5
Mine spoils, clinker	5	10
Mine spoils, calcareous	5	15
Siltstone, calcareous	3	18
Siltstone, grayish-green, calcareous	5	23
Siltstone, yellowish-brown, sandy	2	25
Organic, dark, non-coal	2.5	27.5
Coal (McKay)	9	36.5
Sandstone (sub-McKay)	.5	37
Observation well BSLMSM1; drilled September 14, 1988		
Fill, clinker	8	8
Shale, light-brown	5	13
Siltstone and sandstone, hard, red	2	15
Siltstone, sandy	15	30
Sandstone	7.5	37.5
Siltstone, gray, slightly calcareous (sub-McKay)	12.5	50
Siltstone, gray, some sand (sub-McKay)	5	55
Sand, gray (sub-McKay); water	7	62
Observation well BSLMMC5; drilled September 20, 1988		
Fill, clinker	5	5
Shale	14	19
Sandstone and siltstone, red; moist	1	20
Siltstone, gray	2	22

Exhibit 28

Table 3. Logs of observation wells from the Big Sky and West Decker Mine areas, Montana (Continued)

Lithology	Thickness penetrated	Bottom of depth interval
West Decker Mine area		
Observation well WDFCL1; drilled September 12, 1988		
Fill, shale and siltstone, calcareous	5	5
Mine spoils, clinker	4	9
Mine spoils, brown shale, calcareous	3	12
Mine spoils, coal and sand	24	36
Mine spoils, sand and clinker	1	37
Mine spoils, sand	2	39
Mine spoils, coal	2	41
Mine spoils, sand and coal	6	47
Clinker	13	60
Clinker, sandy; moist	7	67
Coal (Anderson-Dietz 1)	18	85
Coal (Anderson-Dietz 1), contains some pyrite; wet	10	95
Shale; dry	1	96
Observation well WDFSP3; drilled September 11, 1988		
Mine spoils	30	30
Mine spoils, gray siltstone, calcareous	5	35
Mine spoils, gray shale	17	52
Mine spoils, gray siltstone, calcareous	1	53
Mine spoils, coal and clinker	2	55
Mine spoils, gray shale	3	58
Mine spoils, contains some clinker	7	65
Mine spoils, gray shale	5	70
Mine spoils, coal, and siltstone, calcareous	4	74
Mine spoils, brown shale, clinker, and coal	6	80
Mine spoils, gray shale	4	84
Mine spoils; contains some coal	8	92
Shale	2	94
Observation well WDFD12; drilled September 10, 1988		
Mine spoils	25	25
Mine spoils; wet	2	27
Mine spoils, gray, calcareous; contains coal; dry	3	30
Mine spoils, brownish-gray	11	41
Mine spoils, siltstone, calcareous	8	49
Shale	5	54
Coal (Anderson-Dietz 1)	43	97
Coal (Anderson-Dietz 1); wet	10	107
Shale	1	108

Exhibit 28

Table 3. Logs of observation wells from the Big Sky and West Decker Mine areas, Montana (Continued)

Lithology	Thickness penetrated	Bottom of depth interval
West Decker Mine area--Continued		
Observation well WDESP1; drilled September 8, 1988		
Mine spoils	6	6
Mine spoils, calcareous	2	8
Mine spoils	5	13
Mine spoils, calcareous	2	15
Mine spoils, rocks, coal, calcareous	35	50
Mine spoils, coal	5	55
Mine spoils, gray siltstone, calcareous	10	65
Mine spoils, dark shale	18	83
Mine spoils, brown shale, calcareous	19	102
Mine spoils, gray siltstone, calcareous	2	104
Mine spoils, brown, soft	12	116
Mine spoils, rock	3	119
Mine spoils, gray, fine-grained	13	132
Mine spoils; water	7	139
Mine spoils, coal	3	142
Shale; dry	2	144
Observation well WDESP2; drilled September 10, 1988		
Mine spoils, fine-grained, slightly calcareous	45	45
Mine spoils; contains some coal	19	64
Mine spoils, powdery, contains some coal	31	95
Mine spoils; soft, coal	7	102
Coal (Anderson-Dietz 1)	32	134
Coal (Anderson-Dietz 1), pyrite	1	135
Shale	.5	135.5
Observation well WDED11; drilled September 9, 1988		
Mine spoils	11	11
Siltstone, yellowish-brown, slightly calcareous	7	18
Siltstone, gray, calcareous	3	21
Siltstone, brown	6	27
Shale, grayish-black	10	37
Siltstone, gray, calcareous	2	39
Shale, grayish-black	4	43
Siltstone, gray, calcareous	2	45
Shale, gray	17	62
Siltstone, gray, calcareous	2	64
Shale, gray	16	80
Coal (Anderson-Dietz 1)	50	130
Coal (Anderson-Dietz 1); water	5	135
Shale, whitish-brown; dry	1	136

Exhibit 28

Table 4. Petrographic analyses of selected core samples from mine spoils and unmined consolidated rock from the Big Sky and West Decker Mine areas, Montana

[Depth of sample: in feet below land surface. Symbol: --, no data]

Observation well no.	Depth of sample (feet)	General lithology	Major identifiable mineral (5 percent or more of total)	Minor identifiable mineral (less than 5 percent of total)
		Big Sky Mine area		
BSUMR1	68	Siltstone, clayey, coarse-grained.	Clay, dolomitic cement, quartz, fine-grained lithics, feldspar.	Muscovite, biotite, coalified debris.
BSUMR1	71	Sandstone, clayey, calcareous, very fine grained.	Quartz, dolomitic cement, fine-grained lithics, clay, biotite, feldspar.	Muscovite, glauconite, pyrite.
BSLMSP1	50	Sandstone, clayey, kaolinitic, very fine grained.	Fine-grained lithics, quartz, clay.	Feldspar, carbonates, biotite, muscovite, heavy minerals, glauconite.
BSLMMC2	28-29	Siltstone, clayey, calcareous, very fine grained.	Illite, carbonates, quartz/ feldspar, sericite, biotite.	--
BSLMMC3	21-23	Siltstone, clayey, calcareous, medium-grained.	Clay, carbonate cement, quartz/feldspar, muscovite.	Biotite.
BSLMSM1	13-15	Siltstone, and sandstone, containing iron,very fine grained.	Iron oxides, fine-grained lithics, quartz, carbonates.	Dolomite, feldspar, muscovite.
		West Decker Mine area		
WDFCL1	50-52	Siltstone, clayey, containing iron, fine-grained.	Quartz/feldspar, biotite, illite, carbonates, muscovite, hematite.	--
WDESP1	103	Siltstone, and sandstone, calcareous, fine-grained.	Dolomite, quartz/feldspar, chert, schist, fine-grained lithics.	Calcite, muscovite, biotite.
WDESP1	117-119	Siltstone, clayey, calcareous.	Illite, calcite, quartz/feldspar, organics.	Biotite, muscovite, framboidal pyrite.
WDED11	13	Siltstone, clayey, calcareous, fine-grained.	Illite, quartz/feldspar, muscovite, carbonates.	Manganese and iron oxides.

Exhibit 28

Table 5. Bulk mineralogy determined by X-ray diffraction analysis of samples of mine spoils and unmined consolidated rock from the Big Sky and West Decker Mine areas, Montana

[Depth of sample: in feet below land surface. Type of material: Ms, mine spoils; Um, unmined consolidated rock. Bulk mineralogy content: MA, most abundant, greater than 40 percent; A, abundant, 10-40 percent; C, common, 5-10 percent; M, minor, 1-5 percent; T, trace, less than 1 percent; ND, not detected. Other minerals: BA, barite; CE, celestite; GO, goethite; PY, pyrite; SD, siderite; SR, stronianite; TH, thenaderite. The detection limit using X-ray diffraction is about 1-2 weight percent. Symbols: --, no data; ?, probable detection]

General Rosebud Mine Modeling Options
Michael Nicklin thoughts (5/15/13)

It is my sense that there is confusion evolving with respect to Rosebud Mine modeling efforts in part because of the different pending permit application runs. I recommend that we restructure the modeling presentation as follows:

1. Define ***one*** Rosebud Mine Groundwater Model for existing permits. Establish it as the baseline groundwater model which will be used for assessing significance of pending permit applications *[note that this modeling effort is effectively completed]*. **This would stand alone as a single report.**

2. Conduct application specific simulations and evaluate this as part of a pending permit.

Options that can be used for application purposes include the following:

Option 1: ***Use the Rosebud Mine Groundwater Model to evaluate significance of a proposed permit. No other pending or proposed permits that have not been approved would be a component of this modeling effort.***

Example: The baseline Rosebud Mine model will consider B-East only for evaluation of the significance of B-East Permit changes.

Advantage: Focuses on the relative significance of a given permit application.

Disadvantage: May not be as helpful to DEQ for developing a CHIA.

Option 2: ***Use the Rosebud Mine Groundwater Model to evaluate significance of all proposed permits, including the permit under consideration.***

Example: For B-East Permit Application all future pending permit applications for B-East, B-Ext, Area A MR62, Area MR66 and Area F permit to be included.

Advantage: Establishes the relative significance of all proposed permit applications and would be helpful to DEQ for developing a CHIA.

Disadvantage: Cannot isolate relative significance of given permit application.

Exhibit 27

Option 3: ***Develop two application reports, each stand alone.***

One model report is permit specific evaluation, and permit specific PHC. Essentially Option 1.

Second model report provides a compilation of all existing and pending permits. This would not be a part of the given PHC. In effect, it would be a separate deliverable solely for the purpose of providing a "running tabulation" of all future pending permits which would assist DEQ in developing its CHIA.

ACKNOWLEDGEMENTS

I am grateful to Dr. George Roemhild of Montana State University for the verification or identification of some of the difficult taxonomic groups, to Richard Oswald of MSU for identification of the Chironomidae and Dr. D. G. Denning for Trichoptera. Collection and analysis of water samples was conducted by Northern Testing Laboratories.

INTRODUCTION

Strip mining of Fort Union coal in southeastern Montana, electrical generation in Colstrip, Montana, and the associated construction activity and population growth has placed greater demands on the water resources of the region. The construction of two additional electric generators and increased coal production has necessitated the evaluation of potential impact to the aquatic ecosystems, particularly to East Fork Armells Creek which flows through the mining areas and the town of Colstrip.

A description of the existing water quality and aquatic biota will serve as a baseline for the purpose of monitoring possible future changes in the aquatic ecosystem. Water quality may be affected by changes in land use, by disturbance of groundwater aquifers, by construction activities associated with combustion facilities and population growth, and increased water use and treatment. Streamflow may be altered by mining, changes in land use and water consumption which will also affect water chemistry. The composition and distribution of benthic communities in Armells Creek may respond to long-term changes in water volume or quality.

This study was initiated in the spring of 1977, in order to examine the existing conditions of the East Fork of Armells Creek. Study objectives were to (1) describe existing water quality in the stream; (2) inventory the present macroinvertebrate communities; and (3) describe baseline ecological characteristics of the creek prior to expanded mining operations.

Armells Creek has been sampled previously (ECON, Inc., 1977) for macroinvertebrates and water quality. Chemistry of Colstrip area waters has been described by Van Voast, et al (1977), Dollhopf, et al (1977 and 1978), U. S. Geological Survey (1976, 1977 and 1978), Montana Water Quality Bureau (1978), Montana Department of Natural Resources and Conservation (1974), and Westinghouse Electric Corporation (1973).

This study also addresses the water quality and biology of Turtle Pond and the EPA Depression which are located in a reclaimed area near Colstrip. Information gathered from these ponds and other impoundments in the Colstrip area can be used in future reclamation plans relative to the creation of water impoundments for the benefit of livestock and wildlife use. There is little published information on the characteristics of existing ponds in the Colstrip area. Vocke, et al (1978) described aquatic plants and water quality of several impoundments in the Colstrip area.

STUDY AREA

East Fork Armells Creek originates about 24 kilometers (15 miles) west of Colstrip, flows east through Colstrip, then north to join the west fork and finally to the Yellowstone River, 48 km. (30 miles) from Colstrip (Figure 1). The stream drains an area of about 252 km.^{2} at a point 10.8 km. north of Colstrip (Mel White, USGS, Helena, Montana, 1978, personal communication; Surface Water Records published by the USGS reflect a drainage area of 401 km^2, which is an error) and produces an average discharge of .012 m^3/sec. (.44 cfs) at a point immediately downstream from the mouth of Stocker Creek which is about 7 km. north of Colstrip (Van Voast et. al., 1977). Van Voast estimates the average runoff rate to be 0.2 cm. per year. He reports that less than a 10th of 1 percent of the area's average annual precipitation leaves as streamflow, most of which occurs during short duration floods. Most precipitation is lost through evaporation and transpiration.

Armells Creek flows through a shallow valley with gentle slopes and is bordered by pine-covered ridges and sandstone outcrops. Sagebrush-grassland is the major habitat type of the drainage bottoms. Woody riparian vegetation is either non-existent or sparse along the creek bottom. This is due primarily to the ephemeral nature of the stream and, perhaps in part to livestock use along the stream bank. The upper portion of the East Fork

Exhibit 25

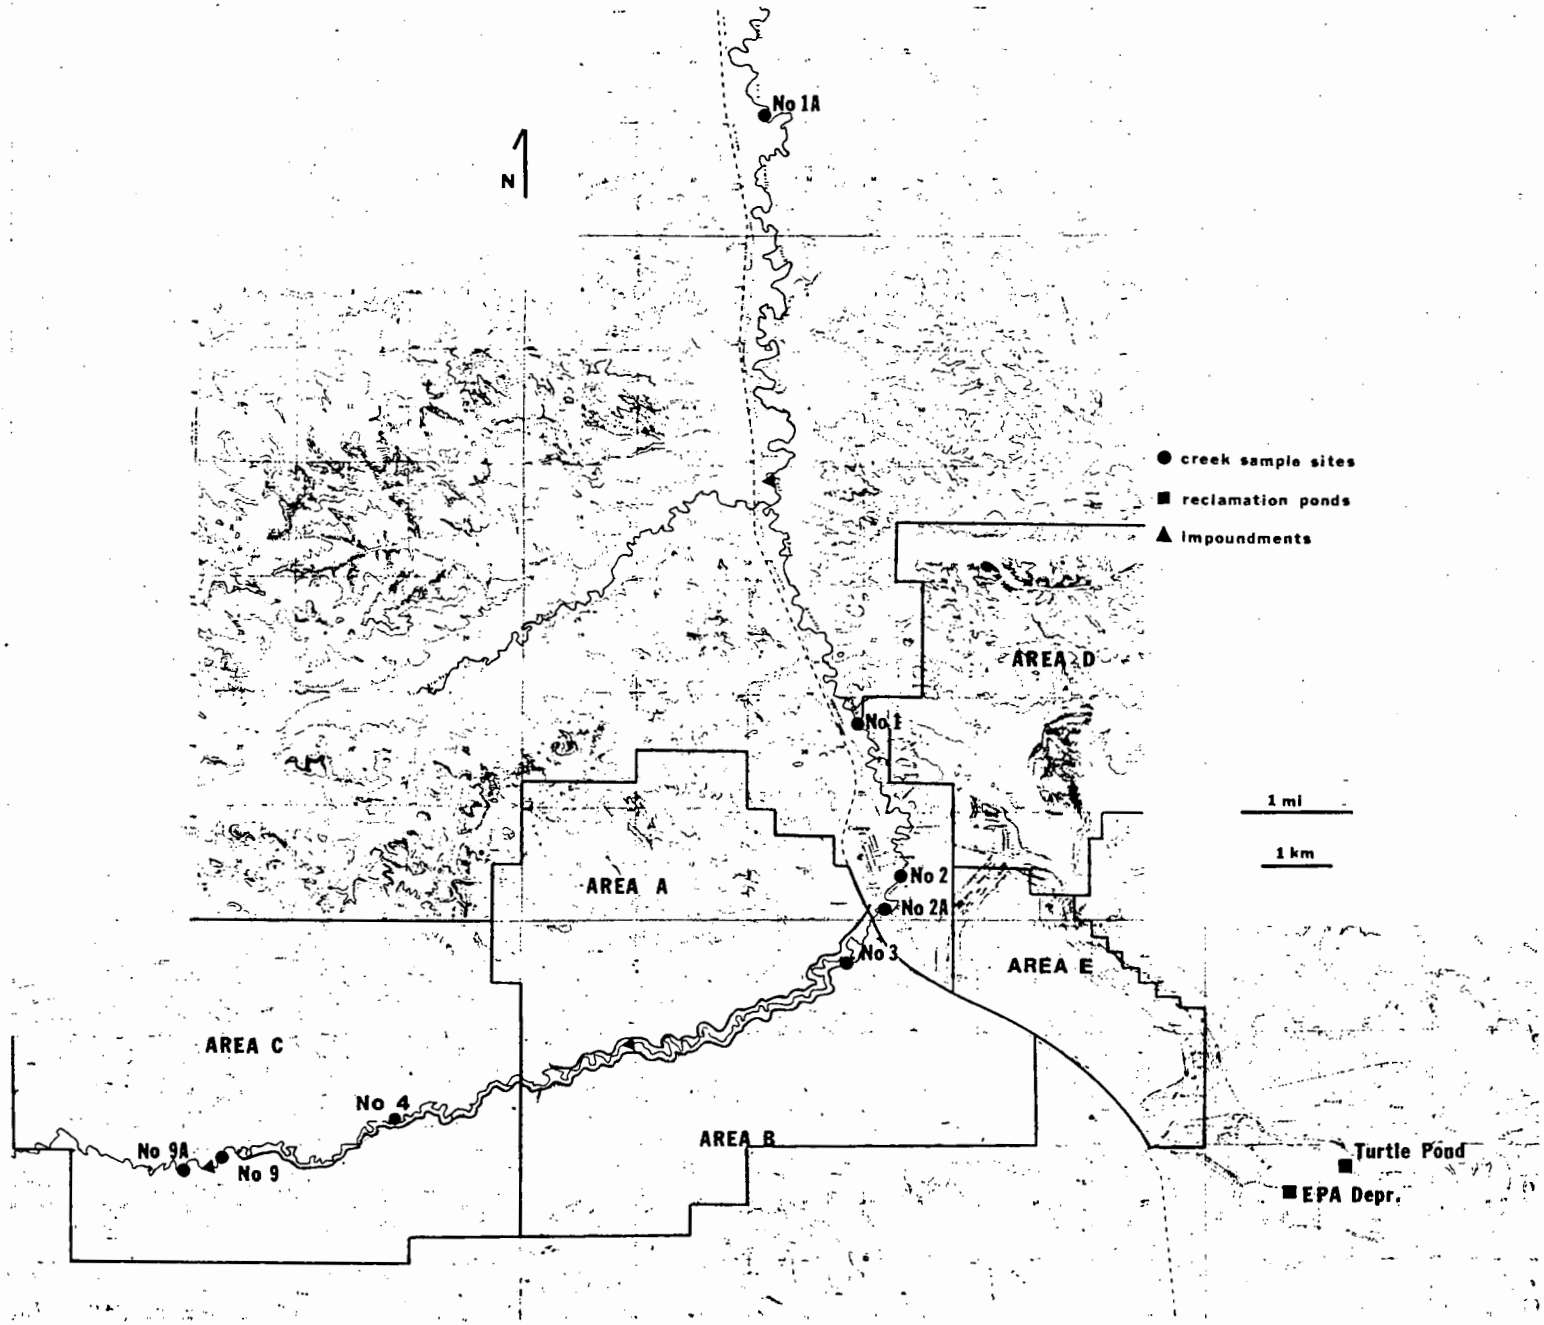

Figure 1. Study Area Map with Sampling Sites.

Exhibit 25

is dry throughout most of the year whereas below Colstrip, the stream contains some flow most of the time.

The stream bed consists of a mud substrate rich in partially decomposed organic materials. Deeper sediments are black and have the strong odor of hydrogen sulfide, produced under anaerobic conditions. The deep sediments are typical of low-gradient, meandering prairie streams. Surface runoff introduces sediments to the stream which settle to the bed because discharge is rarely sufficient to move the particles.

The major land uses of the area which have the potential to affect water quality are the strip mining of coal and agriculture, which consists primarily of livestock grazing, dryland crops and hayfields. Surface runoff from cultivated fields and concentrated livestock feeding areas can affect water resources. Surface erosion from disturbed mine areas is prevented through control measures. Strip mining will alter the characteristics of the groundwater aquifers which presently contribute to the high mineral concentrations in surface streams.

Water quality in East Fork Armells Creek changes considerably during the year in response to the influences of groundwater runoff from snowmelt or rainfall. The stream above Colstrip contains calcium-magnesium-sulfate-type water most of the time including periods of rainfall; however, the bicarbonate ion dominates during periods of runoff from snowmelt (Table 1).

Table 1. Mean Concentrations of Chemical Constituents from East Fork Armells Creek During Runoff from Snowmelt (Average of 3 Samples taken from 3/10-3/13/78) and Rainfall (Average of 2 Samples taken 5/19/78).
Source: Dollhopf unpublished and Dollhopf et al, 1978.

	Mean During Snowmelt	Mean During Rainfall
Specific Cond. (lab)	-150	1155
pH (Lab.)	8.1	8.5
Total Dissolved Solids (Calc.)	94	1041
Sodium Adsorption Ratio	0.21	1.05
Boron	-0.01	0.43
Alkalinity as $CaCO_3$	55	134
Bicarbonate as HCO_3	67	136
Carbonate as CO_3	0	6.8
Chloride	0.04	8.7
Sulfate as SO_4	36	693
Fluoride	0.06	0.26
Total Hardness as $CaCO_3$	59	679
Calcium	12	95
Magnesium	7	108
Sodium	4	63
Cadmium (Dissolved)	-0.005	-0.005
Copper (Dissolved)	0.091	0.016
Iron (Dissolved)	0.115	0.066
Lead (Dissolved)	-0.010	-0.010
Manganese (Dissolved)	0.013	0.083
Zinc (Dissolved)	0.008	0.013

Components are expressed in mg/l unless otherwise noted.

A minus sign indicates that less than the reported value was present in the sample.

Total dissolved solids were calculated at 94 mg/l in March of 1978 during a period of runoff from snowmelt (data concerning snow depth and stream discharge were not available). Morning and afternoon water samples, collected May 19, 1978, (Wayne Hedberg, Montana State University, personal communication, 1978) revealed an average total dissolved solids concentration of 1,041 mg/l during a period of heavy rainfall. Streamflow was not recorded; however, a total of 4.8 inches of rain fell during the period from May 17 through May 19 (unpublished climatological data recorded by Western Energy Company in Colstrip for the National Weather Service).

A chemical description provided in Table 2 typifies existing conditions in East Fork Armells Creek. Although these samples were taken from a site downstream from Colstrip, the water quality is not unlike that upstream from Colstrip except that below town the water is defined as sodium-sulfate type. Mean concentrations of chemical constituents in Table 2 are much higher than those shown in Table 1. This reflects the fact that relatively high flows occur for such brief periods that mean concentrations are characteristic of the usual low flow conditions.

In its natural state, Armells Creek has poor water quality. The drinking water standards of the U. S. Public Health Service are exceeded for total dissolved solids, sulfates, iron, cadmium and manganese. The Montana Department of Health and Environmental

Table 2. Chemical Analyses of Water Sampled from East Fork of Armells Creek, 10.8k m North of Colstrip (at Station No. 1A as used in this report). Source: USGS; 1976, 1977 and 1978.

Components expressed in mg/l unless otherwise noted.
A minus sign indicates that less than the reported value was present in the sample.

Sciences has proposed to downgrade the present classification for East Fork Armells Creek. Standards for the proposed classification would still be exceeded for total and fecal coliform, iron, cadmium, boron, and conductivity.

Exhibit 25

DESCRIPTION OF SAMPLING STATIONS

East Fork Armells Creek

Five sampling sites were established on the creek in April 1977. These locations are described in a previous report (Schwehr, 1978). Some changes in sampling locations were made prior to the 1978 field season. Figure 1 shows the locations of all sampling sites. Locations of these stations are described in Table 3.

Table 3. Creek and Pond Sampling Sites Near Colstrip

Armells #1A	T.3N R.41E Sec. 28 SW¼
Armells #1	T.2N R.41E Sec. 28 NE¼
Armells #2	T.2N R.41E Sec. 34 SW¼
Armells #2A	T.2N R.41E Sec. 34 SW¼
Armells #3	T.1N R.41E Sec. 4 NE¼
Armells #4	T.1N R.40E Sec. 11 SE¼
Armells #9	T.1N R.40E Sec. 15 NW¼
Armells #9A	T.1N R.40E Sec. 15 NW¼
Turtle Pond	T.1N R.42E Sec. 17 NW¼
EPA Depression	T.1N R.42E Sec. 18 NE¼

Station No. 9 is located immediately below a small impoundment on the creek. There has always been sufficient flow at this location to sample for water chemistry, however, flow is often too low to sample for invertebrates; therefore, an additional site was established immediately above the impoundment which is referred to as Station No. 9A. Either one or both of these

Exhibit 25

sites were sampled, depending on flow volume. This is one of the few locations on the creek upstream from Colstrip which has at least some flow through most of the year. These sites are upstream from Western Energy Company's mining areas A and B and are within the future mining area C. This portion of the stream has received heavy use by cattle which has resulted in localized widening of the stream channel and a loss of riparian vegetation.

Station No. 3 was abandoned because this site often had insufficient flow for an invertebrate sample. The site was located at a point above which streamflow seldom occurred. Standing or slow moving water is usually present below Station No. 3 and reflects the effects of groundwater recharge.

All riparian vegetation at Station No. 2 was removed in 1977. To avoid potential increases in sedimentation from this loss and from adjacent construction activity, Station No. 2 was terminated. A new site, Station No. 2A, was established prior to the 1978 field season. It is located approximately 0.8 km. upstream from Station No. 2 and 1.6 km. below No. 3. Streamflow is probably permanent at this site and is greater than that of No. 3, although flow velocities are sometimes negligible. Riparian species include rose and green ash.

Station No. 1 was relocated downstream approximately 300 meters to avoid construction of new sewage facilities and to

take advantage of better access. Riparian shrubs and trees are absent, although most streambanks are protected by tall grasses.

A new site, Station 1A, was established in 1978 and is located 10.8 km north of Colstrip. The U.S.G.S. has sampled water from this location since January of 1975. However, it may not be maintained permanently (P. W. McKinley, U.S.G.S., personal communication, 1978). Flows are permanent and riparian vegetation is well developed. The site is relatively undisturbed and was established to monitor the downstream effects of the total Colstrip project.

Ponds

Turtle Pond and the EPA Depression are both located in the Pit 6 reclamation area southeast of Colstrip (Fig. 1). Turtle Pond was created in 1958 at the conclusion of strip mining by Northern Pacific. Water depth at that time was approximately 5 meters. In the spring of 1968, Western Energy Company planted quaking aspen (Populus tremuloides) around the edge of the pond. Mining was resumed in 1968 at which time water was pumped out of the pond and the surface elevation dropped considerably. The area was regraded and revegetated in 1971 and 1972. During this period, fill material was placed into the pond particularly on the south end which raised the pond elevation (Richard Hodder, Montana Agricultural Experiment Station,

Exhibit 25

personal communication, 1979). Since the conclusion of reclamation, surface levels have not reached the treeline. At present, the pond depth fluctuates between 1½ to 3 meters. Turtle Pond receives most of its water supply from groundwater sources and is a permanent pond with a surface area of about one-half acre.

The EPA Depression was created in 1974 during the reclamation process. It is dependent entirely on surface runoff for its water supply. The Depression has a surface area of approximately two acres in the spring and a depth of about one-half meter. Evaporation in the summer months reduces the surface area considerably and in particularly dry years, the pond could be completely dry by late fall.

METHODS

Qualitative macroinvertebrate samples were collected in 1977 for the purpose of obtaining a species list and distribution information. These methods were described in a previous report (Schwehr, 1978). In 1978, a quantitative sampling device was used to provide relative abundance information, determine community diversity, and to supplement the existing data concerning species composition and distribution.

Five samples were taken at each site with an Ekman dredge which samples a 0.023 m^2 area of substrate. Flow velocities were generally low enough to permit sampling in lotic waters. Five samples were taken at each site on the creek when flows were adequate and from Turtle Pond in March, June, September and late November. Dredge samples were not taken from the EPA Depression in 1978. Each set of five samples was pooled to form one collection. Samples were then washed in a U. S. Standard No. 30 sieve, preserved in ethyl alcohol and returned to the laboratory.

Organisms were hand sorted from the samples, counted and identified to the genus or species level where possible using identification keys by Edmondson (1959), Edmunds, et al (1976), Johannsen (1977), Pennak (1953), Roemhild (1975, 1976), Usinger (1956), and Wiggins (1977). Difficult specimens were sent to

Exhibit 25

taxomonic experts for verification or identification. Some emergent adult insects were collected for species determinations, as were some organisms from miscellaneous collections.

Community structure was described through the use of a diversity function developed by Shannon and Weaver (1963). Although it was designed for the field of communications, the index has been employed extensively by ecologists in the following form:

$$\bar{d} = -\sum_{i=1}^{s} (N_i/N) \log_2 (N_i/N),$$

where $\bar{d}$ = mean diversity

s = number of taxa

N_i = number of individuals in the ith taxon

N = total number of individuals

The index combines two components, "species richness" and "eveness" to describe community composition (Tramer, 1969). Richness is simply the number of species in a sample. Eveness or "equitability" is a measure of the distribution of individuals among the taxa.

Heip and Engels (1974), in a comparative study of several indices, claimed that the Shannon index is the best method, statistically, for describing community diversity. Numerical indices are widely used, but some valid criticisms exist.

Exhibit 25

Dickman (1968) stated that $\bar{d}$ is unequally sensitive to relative abundances of the different levels in the trophic structure. Similarly, Hurlbert (1971) pointed out that diversity measures mask the potential ecological importance of less abundant species. This is probably true; however, that is not the intention in this application.

One characteristic of the diversity function which must be recognized is the fact that a collection containing few species and high evenness could have the same diversity as another collection with several species and low evenness (Pielou, 1977). The occurrence of this possibility may be noted in the results.

A diversity measure must also be independent of sample size (Wilhm, 1970a and Pielou, 1966). Independence is obtained by assuming that individuals are randomly distributed, equally likely to be captured, and when collections contain an equal number of samples. When distribution is not random, it is patchy, meaning that like organisms are concentrated. In this case, sample size should be increased until diversity of the pooled samples reaches an asymptote. Wilhm (1970a) sampled benthic communities of several habitats with an Ekman dredge and increased the number of samples to determine the diversity at the asymptote. For stream habitats, diversity values attained the asymptote after four or five samples.

Exhibit 25

In this report, the Shannon-Weaver index was used to detect changes in community diversity along the stream and to describe ecosystem quality as a function of community composition.

Water samples were collected and analyzed by Northern Testing Laboratories. Samples were taken quarterly at the same locations from which invertebrates were collected. Concentrations of various ions, nutrients and metals were determined.

RESULTS

Aquatic Macroinvertebrates

Armells Creek

A checklist of aquatic macroinvertebrates from East Fork Armells Creek is presented in Table 4. Insect species composition was greatest in the orders of Odonata, Diptera, Hemiptera and Coleoptera. Community composition and diversity are very similar to that of the upper portions of Sarpy Creek (Clancey, 1978) which has similar physical characteristics.

The results of stream collections taken in 1978 are presented in Table 5. Four samples were taken at Stations 1A, 1 and 2A, however, one sample from Station 2A was destroyed in shipment. Only one collection was made at Station 9 as flow was insufficient for bottom sampling throughout most of the year. The most abundant organisms were Hyalella and members of the family Chironomidae. Forty-eight different taxa were collected in 1978, 32 of which were found at Station No. 1. Twenty-four taxa were found at Station 1A and 19 at Station 2A. Fifteen species were present in the one collection taken from Station No. 9.

Quantitative comparisons between 1977 and 1978 invertebrate collections are not appropriate (see appendix A for 1977 data). Collections of 1977 were qualitative in nature and were intended to provide species composition and distribution information. Sample size and dates of collection are not comparable between the two years.

Organisms were sampled quantitatively in 1978 in order to determine more accurately the relative abundance of various species. Unfortunately, the lack of an equal number of samples from each site prevented a meaningful description of population changes along the creek.

Table 6 provides a summary of organism and species numbers as well as Shannon-Weaver diversity values for collections made in 1978. Diversity ($\bar{d}$) was generally highest in samples containing the greatest number of taxa; however, this was not always true. For example, fifteen taxa were collected at Station 1 in November, and $\bar{d}$ was only 1.73. This was due to the presence of 173 amphipods in the sample. Seven organisms in 5 taxa were collected at Station 1 in March, yielding a $\bar{d}$ = 2.13, which is attributed to high "evenness." There is no consistency or trends noted in diversity on a sample by sample basis, which indicates the occurrence of a patchy distribution, seasonal optimums, inadequate sample size and/or the inability to sample all microhabitats equally.

Exhibit 25

Perhaps more meaningful are the cumulative figures for the March and June samples (Table 6). The total number of taxa were similar at Stations 1A, 1 and 2A, but diversity was lowest at 2A and increased downstream.

The values of $\bar{d}$ are used as measures of ecosystem stability or quality. Wilhm (1970b) stated that $\bar{d}$ varies between 3 and 4 in clean-water streams and less than one in polluted streams. Diversity values for Armells Creek are in the mid-range. Invertebrate diversity for this creek is not only a function of water quality but also reflects the ecosystem instability caused by periods of no flow. Flows downstream from Colstrip are more permanent and result in more diverse aquatic communities.

Exhibit 25

Number of Taxa	20				20				18			
Shannon's d	2.67				2.49				1.78			

Exhibit 25

Organism distribution along the creek is presented in Table 7, which reflects the results of collections taken in 1977 and 1978. The results from closely related stations were combined in order to accommodate the change in stations used in 1977 and 1978. The total number of taxa found below Colstrip was only slightly higher than the number found in samples from stations immediately above Colstrip. Less than half as many taxa were found at Station 9 where only three samples were taken. There were 17 genera with a continuous distribution throughout the study section. Other groups may have broader distribution but were in such low numbers that they were not collected at all stations.

Ponds

A total of 36 taxa were collected from Turtle Pond during 1977 and 1978 (Table 8) from quantitative and qualitative samples. Species composition closely resembles that of the creek community.

Only three collections were taken from Turtle Pond in 1978 (Table 9). Ice cover was too thick during the winter to collect a sample. Winter deoxygenation and severe erosion in March from the adjacent road may have contributed to the low animal density; however, organism numbers were highest in the March collection.

Table 8 (Cont.)

- Gerridae
  - Gerris insperatus Drake and Hottes
  - G. comatus Drake and Hottes
- Corixidae
  - Sigara sp.
  - Cenocorixa sp.

Coleoptera
- Curculionidae
- Dytiscidae
  - Agabus sp.
- Haliplidae
  - Haliplus sp.
- Hydrophilidae
  - Hydrobius sp.
  - Berosus sp.

Malacostraca
- Amphipoda
  - Talitridae
    - Hyalella azteca (Saussure)

Arachnoidea
- Hydracarina

Gastropoda
- Basommatophora
  - Physidae
    - Physa sp.
  - Planoribidae
    - Promenetus sp.

Pelecypoda
- Heterodonta
  - Sphaeriidae

Hydracarina	6		
Amphipoda			
Hyalella		5	14
Mollusca			
Sphaeriidae		2	1
Planoribidae		1	
Physa	1		1

Exhibit 25

In 1977, five collections, each consisting of three Ekman dredge samples, were taken from Turtle Pond from April through September (see Appendix A). Shannon's diversity values averaged 2.42.

Diversity of 1978 samples declined from 2.97 in March to 2.04 in June and 1.95 in September, for an average $\bar{d}$ of 2.32. Although fewer individuals were collected in 1978, the number of taxa and diversity values were approximately the same for both years.

Cumulative $\bar{d}$ for 1977 samples was 3.18 and for 1978, $\bar{d}$ was 3.47. These values were significantly higher than those derived from creek samples. This indicates that impoundments in mined areas have the potential of high quality aquatic ecosystems.

The EPA Depression was not sampled on a regular basis in 1978. An incidental collection was taken in April, which revealed the presence of Tipula, a crane fly, Hydrobius, a water beetle, and three water bugs, Notonecta kirbyi, Sigara alternata and Cenocorixa utahensis.

Water Chemistry

Armells Creek

The results of water quality analyses are provided in Tables 10 through 13 for Stations 1A, 1, 2A and 9A/9 respectively. Concentrations of major ions were lowest in March (Tables 10, 11 & 12). Ionic concentrations increased in June

Exhibit 25

and September as surface runoff declined and effects of groundwater became more apparent. Concentrations declined again in late November in response to snowmelt.

Although Stations 9A and 9 are separated by a small stream impoundment, there was little difference in water chemistry between the two sites. Total anions and cations increased only slightly from March to June at Station 9A. A small increase in stream flow at Station 9 during November resulted in a slight decrease in total anions and cations. Concentrations of major constituents cannot be quantitatively correlated with streamflow because flows were not measured. References to changes in flow are based only on the relative change in the estimated width and depth of the channel.

Concentrations of many trace metals were below levels of accurate measurement and displayed no change by location or date. Concentrations of aluminum, iron and manganese varied inconsistently. The highest concentrations of total aluminum, 4.5 mg/l, occurred in March at Station 2A and 5.7 mg/l in November at Station 1. Total iron was highest at Station 2A in March with a concentration of 13.3 mg/l. A maximum of 0.6 mg/l dissolved iron occurred at Station 1A in September. Total manganese was greatest at Station 1A in September with a concentration of 2.02 mg/l followed by 1.96 mg/l at Station 9A in March.

Dissolved oxygen concentrations were lowest in September when water temperatures were highest. A low of 2.2 mg/l dissolved oxygen was observed at Station 1A. Only 3.8 mg/l dissolved oxygen was present at Station 2A at which time water temperature was 26.0 degrees. The stream was temporarily impounded at 2A due to road construction across the creek and macroinvertebrate life was virtually nonexistent. At the same time, dissolved oxygen at Station 1 was 12.2 mg/l with a temperature of 26.0 degrees. The low oxygen content at 2A was probably a result of input of unaerated groundwater to a pond-like environment. Oxygen levels at Station 1 remained high when water temperature was 26° because the flowing water enhanced the rate of oxygen solution into the water.

Information from the previous tables has been summarized in Table 14 which shows the mean concentrations of chemical constituents in all samples collected in 1978. The most significant observation in this table is the fact that the concentrations of total anions and total cations are lowest at Station 2A and increase both upstream and downstream. Streamflow is usually continuous from Station 2A through Stations 1 and 1A; therefore, the increase in chemical concentrations is real. Stations 9 and 9A are more than 15 kilometers upstream from site 2A and the majority of the intervening streambed is almost always dry; therefore, water quality at the upstream locations may neither resemble nor relate directly to conditions at Site 2A.

* Mean concentration of 4 samples.
Components expressed in mg/l unless otherwise noted.
A minus sign indicates that less than the reported value was present in the sample.

Continuous stream discharge data is not available for any locations on the East Fork; however, streamflow at Station 1A is probably consistently higher than that of Station 1 because several small drainages enter the creek between these two sites. Even though streamflow at Station 1A equals or exceeds that of Station 1 the concentrations of chemical constituents is significantly greater at the downstream location.

In general, average concentrations of major chemical constituents in stream water did not change from 1977 to 1978 (see appendix B for 1977 data). Major ions were less concentrated at Station 3 in 1977 and concentrations increased downstream, which duplicates the pattern noted in 1978. Concentrations of major elements from Stations 1, 2 and 3 in 1977 were similar to those observed at Stations 1 and 2A in 1978. Chemical concentrations at Stations 9/9A in 1978 generally exceeded levels at Station 9 in the previous year.

Ponds

The results of water analyses from Turtle Pond are presented in Table 15. Except for metals, the concentrations of most constituents increased steadily during the year. Surface runoff into the pond in the spring raised the surface elevation approximately one meter. As surface runoff declined and pond elevation dropped, concentrations increased in response to

Exhibit 25

effects of groundwater input. Parameters of interest in the March sample are the low pH, low dissolved oxygen, high acidity and high concentrations of iron and manganese. This combination of factors indicates the presence of anaerobic conditions in the pond. Surface ice was present from early December through mid March. At the time this sample was taken, little ice remained. The water sample was collected near the surface where dissolved oxygen was expected to be greatest. Unfortunately dissolved oxygen was not measured in deeper water. Wind action and surface runoff may have increased oxygen concentrations over levels that were present during the winter.

Concentrations of major constituents in 1978 were significantly less than concentrations from 1977 water samples (see Appendix B). For example, total dissolved solids ranged from 520 to 1,320 mg/l in 1978. In 1977, total dissolved solids varied from 1,692 to 2,994 mg/l. The differences may be due to changes in precipitation and runoff with respect to sampling dates.

Exhibit 25

DISCUSSION

The physical, chemical, and biological characteristics of the East Fork of Armells Creek are remarkably similar to those of Sarpy Creek (Clancey, 1978). Both streams are temporary and have substrates comprised of mud and organic debris. Similar macroinvertabrate communities exist in both ecosystems and are dominated by chironomids and amphipods.

The most abundant midge larvae were Chironomus, Micropsectra and Cricotopus. Of these genera, the first two are members of the subfamily Chironominae. The larvae of this group are primarily detritus feeders, many of which live in tubes constructed from the fine materials in the substrate (Bryce and Hobart, 1972). Percival and Whitehead, (1929) found that numbers of midge larvae increased as the amount of fine deposits and detritus increased.

Larvae of the subfamily Chironominae contain hemoglobin, hence the name "bloodworms". Walshe (1948) discovered that species of this group could survive without oxygen; however, the survival time varied with the species. The minimum oxygen levels survived by most species are unknown.

Larvae of the genus Cricotopus, subfamily Orthocladiinae, do not contain hemoglobin and are restricted to areas containing adequate

Exhibit 25

oxygen supplies. The organisms commonly live on the leaves and stems of aquatic plants and eat algae from plant surfaces (Bryce and Hobart, 1972).

The genera discussed above comprised about 31 percent of the total fauna from Armells Creek in 1978. Their abundance is related primarily to the combination of physical factors in the stream, namely the high amounts of detritus and fine materials in the substrate, dense growth of aquatic vegetation and low water velocity. When periods of low oxygen content occur, oxygen deficiency is most severe near the substrate where Chironomus and Micropsectra are present. These organisms will tolerate short term anaerobic conditions. Cricotopus larvae may survive periods of low oxygen because they are attached to aquatic vegetation above the substrate where oxygen concentrations are generally greater.

Another chironomid genera which deserves mention is Odontomesa of the subfamily Diamesinae. This group is typically found in mountain springs and is adapted to cold water (Bryce and Hobart, 1972). Seven larvae were found in June at station 2A. The presence of this organism was unexpected and cannot be explained.

Hyalella azteca comprised more than a third of the total number of individuals in the creek. This organism is commonly

found in shallow waters of small ponds and slow moving streams. Hyalella inhabits areas of dense aquatic vegetation and feeds on live plant material or on organic debris in the benthos (Cooper, 1965). Studies conducted by de March (1977) revealed that reproductive activity was initiated in the spring and terminated in the fall in response to photoperiod changes. Growth and reproductive activity was enhanced when water temperatures were between 20-26 degrees C. During midsummer the females may release young as often as every eight days. Numbers are highest in the summer and decline through the fall and winter months to a seasonal low in late spring. This pattern was evident in East Fork Armells Creek except at stations where oxygen levels were severely reduced in September. Pennak (1953) states that these amphipods require an abundance of dissolved oxygen; however, Sprague (1963) observed a mortality threshold of 0.7 mg/1 dissolved oxygen for Hyalella azteca. These animals are equipped with abdominal appendages called pleopods which are used for swimming and for circulating the water over their gills. These advantages should allow the amphipod to escape areas of low oxygen content and to increase the efficiency of their gills.

Of the mollusks found in Armells Creek, Physa and Lymnaea are the most abundant. Both are omnivorous (Pennak, 1953). Species determinations have not yet been made, however Physa is probably either gyrina or integra. Both species are typically found in substrate of silt and detritus (Harman 1972). Von Brand et al

(1950) demonstrated the Physa gyrina has a limited resistance to anaerobic conditions. Many snails are capable of escaping harsh conditions. Snails will hibernate in the mud to avoid freezing conditions in the winter and will aestivate in intermittent streams during dry periods (Pennak, 1953).

The invertebrate groups discussed above dominate the faunal community of East Fork Armells Creek. Their numbers are relatively high because they comprise the largest trophic level for macroinvertebrates in the creek. These organisms are primarily detritivores. Their food base, dead plant and animal material, is a major energy source for the ecosystem. In addition to an adequate food supply, organism abundance reflects the occurrence of environmental preferences, namely low water velocity, abundant aquatic vegetation and favorable water temperatures. Some of these species have also adapted to periods of anaerobic conditions or dry periods.

The remaining insect groups comprised a small percentage of the total number of organisms found in East Fork Armells Creek. Their low populations are primarily a result of unfavorable physical conditions in their environment or a reflection of position in the trophic structure.

Many species of Ephemeroptera are inhabitants of cool, clean, rapidly flowing streams. Caenis and Callibaetis are better adapted to slow moving streams and lakes and ponds. Caenis

nymphs are more tolerant of low oxygen levels than other mayflies (Hilsenhoff, 1975).

Members of the order Trichoptera are not common in Armells Creek because most caddisfly families are better adapted to cool running waters (Wiggins, 1977). Few larvae of Cheumatopsyche and Hydropsyche were collected in 1978 relative to the numbers found in 1977 because fewer summer collections were made in 1978. The larvae of these genera construct nets which filter food particles from flowing water. Nets are constructed to withstand a limited range of water velocities which varies with each species (Edington, 1965 and 1968). Increases or decreases in velocity will cause the net to collapse and force the animal to move to another location. Streamflow and water velocity in Armells Creek are subject to sudden changes in response to rainfall and snowmelt. As streamflow decreases in late summer, water velocities are often reduced to near zero. These conditions will not allow the successful establishment of large populations of netspinning caddisflies.

Several species of odonates were found in the creek since 1977. Warm, still or slow-moving water such as that of Armells Creek is often preferred by many species of dragonflies and damselflies. As predators, these insects are near the top of the food chain; therefore, their numbers are relatively low.

The majority of the insect groups discussed above have life cycles in which the immature larvae or nymphs are rather

long-lived, spending as much as a year or more in the water; therefore, collections of these individuals can be made throughout the year. The adults, however, are short-lived and survive for as little as a few hours, days, or weeks. Their adult life is spent as aerial insects.

The Hemiptera and Coleoptera are more common and varied in Armells Creek than indicated by the 1978 data. Most collections taken in 1977 were made during the summer months when most of the immature forms of bugs and beetles were present. The adults of these two orders normally survive the winter by hibernating or in an active state and will lay eggs in the spring. Both the young and the adults live in the water and most of the species are capable of swimming, unlike the insects discussed above. For these reasons more beetles and bugs were collected in 1977 when a kick net was used. Most water bugs and beetles also share the ability to obtain oxygen at the water's surface; therefore, they are not totally restricted from waters containing low concentrations of dissolved oxygen. Most of these insects in Armells Creek are predators with the exception of the family Corixidae. This family of bugs is herbivorous which explains the fact that they are more abundant in Armells Creek than other groups of bugs and beetles (Roemhild, 1976).

In addition to physical factors, the concentrations of chemical constituents in the water can also affect the occurrence, abundance and distribution of aquatic life in water bodies; however,

specific information is limited. The Environmental Protection Agency (1976) has established water quality criteria for several organic and inorganic parameters based on information obtained from an extensive literature review. Few of the criteria relate to freshwater aquatic life, particularly aquatic insects. Determination of toxic levels of specific elements for aquatic macroinvertebrates has been difficult because toxicity is often species specific and affected by water temperature, pH, hardness and duration of exposure. Some of the chemical parameters of Armells Creek occur in concentrations which sometimes exceed water quality standards or criteria. These elements and their possible causes and effects will be discussed in the following paragraphs.

Boron concentrations in Armells Creek varied from 2.3 to 3.3 mg/l in April, 1977. Since that time, concentrations were considerably less due to a change in analytical procedures (Jay Lyndes, Northern Testing Laboratories, personal communication). Boron levels in Armells Creek are similar to those of other streams in southeastern Montana (Knapton and McKinley, 1977). The EPA (1976) has established a criterion of 0.75 mg/l for boron for irrigation of sensitive crops such as citrus. Criteria for other uses were not recommended because the EPA believed that naturally occurring concentrations of boron would not adversely affect aquatic life.

A dissolved cadmium concentration of 0.005 mg/l was recorded for all water samples collected from the east fork. The criterion for cladocerans and salmonid fishes was set at 0.0012 mg/l cadmium in hard water (EPA, 1976). The cadmium criterion for less sensitive species is 0.012 mg/l. (Note: published literature which discusses criteria and toxicity levels of metals does not always express concentrations as dissolved or total recoverable. In such cases, it is assumed that the author is referring to dissolved concentrations. The same assumption will apply to this report.)

Beisinger and Christensen (1972) determined that a cadmium level of 0.005 mg/l was toxic to Daphnia magna, a cladoceran. An unidentified cladoceran occurs in Armells Creek. A sample taken in June 1977 contained about 1,000 of these organisms. Pickering and Gast (1972) found that 0.057 mg/l cadmium decreased the survival of fathead minnow (Pimephales promelas) embryos. This species is common in southeastern Montana, including Armells Creek.

Cadmium concentrations in waters of southeastern Montana including Armells Creek are often in excess of the criterion, 0.0012 mg/l (USGS, 1976, 1977, 1978). These levels are a natural characteristic of the region and adverse effects on biological communities have not been observed.

Other metals of importance in Armells Creek are iron and manganese. The recommended criterion for dissolved iron is 1.0

mg/l for protection of freshwater life (EPA, 1976). Concentrations of dissolved iron in streams of southeastern Montana, including Armells Creek, are generally well below this level (Knapton and McKinley, 1977). Manganese is rarely found at concentrations that exceed 1.0 mg/l which is below tolerance values reported for freshwater organisms; therefore, the EPA (1976) has not recommended a criterion for this metal.

Iron and manganese concentrations in Colstrip area soils are highest near the soil surface (Schafer et al, 1979). These metals may be leached from the soil during runoff which results in increased levels in surface waters. Most of the manganese is in the dissolved form. Little of the iron is dissolved because most of it becomes associated with suspended particles (Wetzel, 1975). Concentrations of total iron in Armells Creek increase as suspended sediments increase.

Nitrogen is present in aquatic ecosystems as organic or inorganic compounds. Inorganic forms such as ammonia, nitrates and nitrites can be toxic when present in high concentrations. Ammonia concentrations increase during decomposition of organic matter, particularly under conditions of low oxygen (Reid, 1961). Ammonia concentrations reported in this document include both the unionized portion, NH_3, and the ammonium ion, NH_4^+. The unionized form can be toxic to freshwater organisms; therefore, the EPA (1976) has established a criterion of 0.02 mg/l for freshwater aquatic life. The percent unionized NH_3 in

aqueous ammonia varies with temperature and pH. Using tables developed by Thurston et al (1977), the percent NH_3 was determined for ammonia values reported in this study, and none of the concentrations exceeded EPA criteria.

Nitrate nitrogen has increased at Station 1, since new sewage facilities became operational in late 1978. Nitrate N was 6.04 mg/l at Station 1 in November 1978 and decreased to 0.79 mg/l at Station 1A. The levels known to be toxic are much higher than levels in Armells Creek. The EPA (1976) did not recommend restrictive criteria for nitrates and nitrites for freshwater aquatic life because they believed that toxic levels would rarely occur.

Sulfates in surface and groundwaters of the coal regions of southeastern Montana are relatively high. A probable major source of sulfates is the decomposition of pyritic sulfur in the coal seams (Caruccio and Geidel, 1978). Decomposition of organic sulfur and reduction of sulfate under anaerobic conditions generates hydrogen sulfide. Hydrogen sulfide may react with iron to form insoluble iron sulfide (Wetzel, 1975). These reactions likely occur in Armells Creek, particularly near the sediments. The black sediments, characteristic of sulfides are present throughout the study section, especially in areas where groundwater enters the stream. Such areas usually have stagnant waters of low oxygen content. Anoxic conditions may occur during winter or summer, in the creek or in ponds of the area.

There was little difference in community composition of invertebrates of Armells Creek and Turtle Pond. This was not surprising because both ecosystems possess similar characteristics of groundwater influence, water chemistry and substrate. More important is the occurrence of minimal water velocities in the stream, a parameter which attracts invertebrate populations that are typical of a pond-like habitat.

Unlike portions of Armells Creek, particularly upstream from Colstrip, Turtle Pond is a permanent water body; therefore, ecosystem stability, diversity and number of species in the pond are greater than they are in the upper reaches of the stream. The creek immediately below Colstrip usually contains flow and its invertebrate community is similar in diversity to that of Turtle Pond.

Turtle Pond also provides a more stable environment for aquatic life than does the EPA depression. The extreme shallowness of the depression allows significant portions of the shoreline to alternate between wet and dry conditions in response to precipitation and evaporation. This feature prevents the successful establishment and growth of benthic organisms and plant life. The lack of groundwater removes the stabilizing influence on water chemistry. Water quality is subject to extreme fluctuations as water levels change.

Although Turtle Pond was not designed to create an environment capable of supporting aquatic life, the data presented in this

report demonstrate that the ability exists to provide aquatic ecosystems in reclaimed areas. It is evident that to support an aquatic community in an artificial pond, the pond must be supported by groundwater and surface drainage in order to provide a degree of stability in chemical and physical features. Turtle Pond is not ideal in this regard because it is not located along a significant drainage and is too small to minimize effects of precipitation events, evaporation and possible deoxgenation. Preferred sites for creating ponds or impoundments in reclaimed areas include the initial box cut or the final cut in small drainages with minimal depth to groundwater. Such ponds should have shallow depths near portions of the shoreline to allow access for watering livestock and wildlife and for establishment of emergent vegetation. Maximum water depth should range from a minimum of four or five meters to prevent excess vegetative production and minimize the potential for anoxic conditions to occur. Some allowance is also required for deposition of silts.

Subject: FW: AM 4 Area B-East

Mike, below is an e-mail that I sent Ed Coleman on July 21. Ed's reply is also below. We later got contacted by Chris Yde that he would like to meet with us and have the DEQ's Biology Expert at the meeting.

This meeting was on July 31 in Helena. Their Expert just described the way that he would recommend that we sample the stream. He also mentioned that he had been sampling other intermittent and ephemeral streams in Eastern Montana. They did not explain any scientific reason that we would be required to perform this sampling, other than that in the process of having a CHIA, they would be asked if this was performed.

We are planning on having a conference call with Penny Hunter next week and I would like to see if you can join us to have further discussions on this.

Daniel,

Let me run this email by some of our technical staff and either Chris or I will get back in touch with you. It may take a little while since we will most likely have to go outside the bureau to get the appropriate expertise. Thanks

To: Coleman, Ed
Cc: Yde, Chris; Peterson, Dicki
Subject: AM 4 Area B-East

Ed,

In an effort to address the Department's request for "conducting a current aquatic survey" in the AM 4 Area B-East deficiencies dated June3, 2014, WECo hired Penny Hunter with ARCADIS. As an expert in this field, Penny participated in our meeting in Billings with your Department on July 7, 2014 via conference call. After our meeting she email Dicki Peterson with the following:

> DEQ does have a provision for collecting biological data, but it is in the context of trying to evaluate beneficial use in ephemeral streams, and when it is "practical and appropriate". My understanding of

Exhibit 23
WECO 000599

the context of the discussion yesterday was on gathering information to understand impacts of the proposed discharge, not to evaluate beneficial use. Impacts to aquatic life would be addressed by the numerical standards established for the discharges, and those wouldn't be affected by the results of biological data collection.

On the phone, DEQ was discussing collecting the data to determine what the community assemblages were and a community diversity index. The aquatic survey data to date show, and this is emphasized in the literature, that developing any kind of quantitative index of diversity or specific community assemblage is difficult/impracticable in ephemeral and intermittent streams because of the high level of variability of the samples. The study in 1979 attempted to collect 4 samples at each site throughout the year, and in both intermittent and ephemeral stream sections, a reliable estimate of diversity could not be generated. This same issue would be expected if we were to repeat the exercise. Therefore, any new data collection would be at best qualitative in nature, and the usefulness of this information is not clear, since the findings would not impact the use designation or the numerical standards used for the streams.

Based on Penny Hunter's expertise in this field, WECo would like the Department to re-consider the request in the AM 4 deficiencies for "conducting a current aquatic survey". WECo agrees that it is not "practical or appropriate" to conduct aquatic survey that is meaningful in relation to the existing water use.

Please feel free to contact me if you would like to discuss this further.

Sincerely,

Daniel Munoz, PE

Subject: RE: Macroinvertebrate SOP
Date: Wednesday, July 09, 2014 3:57:55 PM
Attachments: WQPBWQM-001.pdf

The only MDEQ SOP that I was able to find related to macroninvertebrate sampling was an SOP for water quality assessment to identify "impaired" waters. See attached - section 3.6 on page 13 of 17 for assessment of aquatic life use. The SOP states,

DEQ usually assesses only aquatic life use support for ephemeral waterbodies and requires only physical/habitat data (minimum SCD score = 3).
However, DEQ recommends that chemistry/toxicity or biological data should be collected when it is practical and appropriate for evaluating aquatic life use support or the use support of other beneficial uses.

So, DEQ does have a provision for collecting biological data, but it is in the context of trying to evaluate beneficial use in ephemeral streams, and when it is "practical and appropriate". My understanding of the context of the discussion yesterday was on gathering information to understand impacts of the proposed discharge, not to evaluate beneficial use. Impacts to aquatic life would be addressed by the numerical standards established for the discharges, and those wouldn't be affected by the results of biological data collection.

On the phone, DEQ was discussing collecting the data to determine what the community assemblages were and a community diversity index. The aquatic survey data to date show, and this is emphasized in the literature, that developing any kind of quantitative index of diversity or specific community assemblage is difficult/impracticable in ephemeral and intermittent streams because of the high level of variability of the samples. The study in 1979 attempted to collect 4 samples at each site throughout the year, and in both intermittent and ephemeral stream sections, a reliable estimate of diversity could not be generated. Dicki,

Could you find out the exact document your consultant was referring to yesterday which indicated that macroinverebrate counts were not particularly useful for intermittent reaches? I want to make sure we are looking at the same thing. A copy of the document or the name of it & number of it would be most helpful.

Hi Penny -

I hope your vacation is going well...

WECo met with DEQ coal bureau and a gentlemen named Dave Feldman (DEQ aquatic expert) yesterday morning. The attached document is what he provided for sampling for invertebrates. DEQ is still insisting that we sample before the end of September... they are requesting a "reach wide approach" for ephemeral and intermittent reaches, at least one location possibly two. They do not want us to provide statistics only what is out there.

Do we have a leg to stand on if we refuse to conduct these studies? If we give in are we setting ourselves up for disaster on the other end?

Daniel would like to have a conference call with you and Dave (DEQ) and us on Tuesday afternoon. Does that work for you? I will be out of the office Monday but I can be reached through email or you can call me 406-749-0633.

Hello Dicki,

Exhibit 21

Unfortunately I will be out of the office on 7/31. I am actually going to be on vacation from 7/25 through 8/9, I hope that this is not too much of an inconvenience. I'll be away from phone and email during that time.

I could try and arrange another person to respond to the aquatic bug expert from here if you like. Give me a call this morning if you can and we can talk about that. Otherwise, I can respond when I get back.

Thank you-

Subject: RE: Macroinvertebrate SOP

Dicki,

The document you sent is designed for assessment of water quality for impairment decisions. This involves various assessment metrics and protocols that aren't going to be applicable to the Coal Program's needs with regards to macro sampling. The Coal Program wants only to quantify the extent and nature of the aquatic community along the stretch of EFAC bordered by mining. Aquatic use needs to only be assessed in reaches with water at the time of sampling (flowing or ponded).

We suggest you use the sampling procedures from the attached EMAP document in **Section 7.2** and the general considerations in **Section 1.1** from the WQPBWQM-009 document for guidelines on the time frame appropriate for sampling. The reason you have to look at two documents is that the reach-wide sampling procedures referenced by the WQPBWQM-009 document are more for ripple-dominated sites and they didn't include the alternate sampling technique in the document. The following information should be collected along with a macroinvertebrate survey

1) Habitat / reach description including photographs and location
2) Water quality samples at the point of macro sampling
3) Water temperature
4) Flow, if any

Metrics **do not** need to be run by the consultant on the data. Reporting of the taxa alone is sufficient.

Dicki,

It is easy for us to take any of the potential areas off the figure or take the entire figure out. Based on the definition of potential mining below, I think we should only show App 00184. As that is shown on Figure 3a, there is no need for Figure 3c.

That being said, we have no problem showing exactly what you think is best for Western Energy.

It is much more difficult to strip all of the Area F references and boundary from the main Rosebud Mine Groundwater Model Report which is meant to encompass the greater Rosebud Mine.

John

John –

My understanding of the Department's newly defined potential mining is "the proposed action for the area" – my interpretation for Area B… currently approved is the base and then App 00184 is the potential future mining. I don't know how difficult it is on your end, but at the very least B-Extension expansion would need to taken off. The Area A information was submitted as a minor and is under review (which you are aware).

When I talked to Michael this morning he didn't think leaving the line for Area F would be problematic. But I'm sure anything that involving B-Extension would be since they have not seen that information formally.

Hi Dicki,

Exhibit 19

Should I take this figure out of the B AM4 PHC to be consistent with your comments?

Thanks

John
